In early age, as the bones are elastic and partly cartilaginous, fractures occur less readily than in advanced life when they have become brittle and earthy. In children fractures frequently occur at the line of junction of the shaft with the epiphysis where ossification has not as yet become perfect. This separation of the epiphysis occurs chiefly at the lower ends of the humerus and femur, sometimes in the radius and other long bones. As age advances, the compact tissue of the shaft becomes denser and harder, but the cancellous structure of the extremities more dilated and looser; hence fracture of the neck of the femur is especially common in old people. In young persons the bone is usually broken transversely, but fractures taking place at a more advanced period of life are generally oblique, and often comminuted; in adults they also more commonly extend into joints than when occurring in early age. In children, more than one half the fractures

occurring in the upper limb are of the clavicle; and in the lower limb, fracture of the shaft of the femur by indirect violence is of extremely common occurrence.

Sex indirectly influences the liability to fracture, men being more frequently exposed to the causes of this injury than women. In women, the bones that are most commonly fractured are the clavicle, the radius, the tibia, and the neck of the femur; in men, the shafts of the long bones, the cranium, and the pelvis.

From statistical tables of fractures of the upper limb given by Flower, it appears that below five years of age the liability of the two sexes to fracture is equal. After five, the males steadily increase in liability up to middle life. After forty-five, the number of fractures of the upper limb in females exceeds that in males, in consequence of the extreme frequency of fracture of the lower end of the radius in women above middle life.

Side of the Body.—From the statistics of Gurlt, Middeldorpf, Lente and others, it would appear that fractures occur with about equal frequency on the two sides of the body.

Time of Year.—The popular supposition that the bones are more brittle in winter, and hence break more readily than at other seasons, is altogether a mistake; though fractures may be common at this period of the year, from falls being more frequent during frosty weather.

Spontaneous Fractures are those which happen without any very distinct cause, or under the influence of violence that would usually be insufficient to produce such an injury. They arise from various pathological conditions, amongst which the following are the chief. *Atrophy of bone* occurs naturally in old age, and is, as before stated, a powerful predisposing cause of fracture; but mere senile atrophy seldom reaches such a degree as to lead to spontaneous fracture. In the same way atrophy from want of use may render the bone brittle, so that a very small force may break it, as we occasionally see in attempted reduction of old dislocations. A much more important form of atrophy is that which accompanies certain forms of disease of the central nervous system, especially general paralysis of the insane. Bruns has collected the records of sixty cases of spontaneous fracture occurring in the insane, and amongst these were many instances of multiple fractures. In some of these cases the bones were found to be greatly atrophied, and in one they were easily cut with a knife. General paralysis is not unfrequently complicated by violent maniacal attacks, and in the necessary restraint at these times it has happened that one or more of the patient's bones have been broken although no undue force has been employed. These cases have more than once given rise to charges of cruelty or manslaughter against the keepers in lunatic asylums. Spontaneous fractures occurring in *locomotor ataxy* have been described by Charcot, Weir Mitchell and others. These, like the joint affections of this disease, appear usually to occur in the early stage, before the development of ataxic symptoms. *Mollities ossium* is, as will be seen when that disease is described, often associated with spontaneous fracture. *Rickets* is more often a cause of bending or partial fracture under considerable violence, but cannot be said to be a cause of true spontaneous fracture. *Scurvy* was said by the older writers to cause a general weakness of the bones, but later observations have not confirmed this. In children it is said to predispose to separation of the epiphyses. *Constitutional Syphilis* was formerly believed in some cases to cause a general

thus the chief displacement in a broken leg is caused by the muscles of the calf. When one set of muscles is attached to the upper fragment and their opponents to the lower, as in the case of fracture of the radius above the insertion of the pronator radii, then the broken ends may be widely separated. As a rule, more than one cause is concerned in producing the displacement, but in some cases, as in fractured patella and fractured olecranon, muscular contraction acts alone.

The amount and direction of the displacement is often determined by the nature of the fracture. In longitudinal fractures there is no displacement; in transverse fractures the fragments may lock into each other and the displacement may be very slight. In oblique fractures the fragments commonly "ride" one over the other.

The **Direction of the Displacement** is influenced by the direction of the fracture, the position of the limb and muscular action: it may be angular, transverse, longitudinal, or rotatory. In the *angular* displacement there is an abnormal curvature of the limb, and one or both ends of the broken bone may form a marked projection on the convex side of the curve. The concavity is usually on the side of the most powerful muscles. Thus in fracture of the middle of the femur, the angle projects on the anterior and outer side of the limb, the upper fragment being flexed, abducted, and rotated outwards by the psoas and iliacus and the external rotators, and the angle thus formed increased by the powerful flexors passing from the pelvis to the bones of the leg. Angular deformity is most common in oblique fractures.

The *transverse* or *lateral* displacement occurs when a bone is broken directly across. The fragments often hitch one against another, thus being, as it were, entangled together, and in this case there is often but very little deformity.

Longitudinal displacement is invariably shortening when the fracture occurs in the shaft of a long bone. It is due in most cases to muscular action, the broken ends of bone being brought together so as to overlap or "ride" over one another. In other cases, the shortening may be owing to the impaction of one fragment into the other. In some cases there is preternatural separation of the fragments, the weight of the limb tending to drag the lower one downwards, as in some rare fractures of the scapula, or muscular contraction drawing the upper one away from it, as in fracture of the patella.

The *rotatory* displacement may be owing to the contraction of particular sets of muscles, twisting the lower fragment on its axis as well as producing shortening of the limb. Thus the pronators in some fractures of the radius have a tendency to rotate the lower fragments inwards. In other cases the line of obliquity of the fracture may determine the rotatory displacement; and in the lower extremity the weight of the limb will always turn the lower fragment outwards, just as the leg of a dead body rolls on to its outer side.

2. **Preternatural Mobility in the Continuity** of a bone cannot exist without fracture; hence, its presence may always be looked upon as an unequivocal sign of broken bone. But fracture may exist without it when the fragments are impacted firmly one into the other.

3. Another sign of much value is the **Crepitus or Grating together of the Rough Surfaces of the Broken Bone**, which can be felt as well as heard on moving the limb. This can be elicited only when the fragments are movable and in contact. It is not, however, an invariable accompaniment of fracture; being absent when the fracture is firmly impacted or the fragments

are widely separated. It must not be confounded with the crepitation that occurs from other causes, as from emphysema. The effusion of serous fluid into the sheaths of the tendons gives rise to a peculiar crackling sensation, easily distinguished from the rough grating of a fracture. There is a species of false crepitus also experienced sometimes in injuries of joints, consisting of a snap or click rather than of true grating, which is sometimes mistaken by inexperienced practitioners for true crepitus of broken bone. The roughened surfaces of a joint in the later stages of chronic rheumatic arthritis, will, however, give rise to a grating which it is very difficult to distinguish from that of a broken bone. As a rule it is finer and more regular than the crepitus of a fracture.

In some cases in which the mobility cannot be clearly felt, the patient will complain of pain at the seat of fracture when an attempt is made to find it, or when a distant part of the bone is pressed on. This is often a very useful means of diagnosis in fractures of the fibula and ribs.

It will thus be seen that no one of these three signs alone is absolutely to be relied upon, and a combination of at least two of them is usually required to determine whether fracture exists. In ascertaining the existence of a fracture, the Surgeon should make the necessary manipulations with the utmost gentleness, but yet effectually, so that no uncertainty may be allowed to remain as to the seat and nature of the injury, more especially when it occurs in the vicinity of a joint. The increased mobility may be ascertained by fixing the upper fragment and rotating the lower portion of the limb; the crepitus by drawing down the lower fragment, so as to bring the rough surfaces into apposition, and then grasping the limb at the seat of fracture with one hand, and rotating it gently with the other. The displacement must be ascertained by measuring the limb carefully in the way that has been directed, and by comparing the injured with the sound side.

DIAGNOSIS.—The diagnosis of a *simple* fracture is usually made without difficulty by the co-existence of displacement, abnormal mobility, and crepitus. There are, however, two conditions that may render the detection of a simple fracture difficult. The first is, when only one of two or several contiguous bones is broken; the other, when the fragments are impacted.

When only one bone is broken in a situation where there are two or more, as in the leg, forearm, metacarpus or metatarsus, very close and careful manipulation of the injured bone may be required. The Surgeon must run his finger carefully over the most projecting ridge, feeling for slight inequality or swelling at one part, or perhaps he may elicit faint crepitus on freely and deeply moving the bone at the seat of suspected fracture: or, failing this, severe pain may be caused in the line of the bone by forcing its two extremities towards each other, or by applying force in such a way as to bend it.

In the case of *impaction* the diagnosis is even more difficult. Here no crepitus, and no preternatural mobility, can be found, and the Surgeon must be led to his diagnosis by the recognition of the characteristic displacement of the particular fracture, as, for instance, the deformity of the wrist in impacted fracture of the lower end of the radius.

The difficulties of diagnosis are necessarily most seriously increased if there be much extravasation of blood; or, when the fracture is through an articular end, if there should be much effusion into the neighbouring joint. In cases of doubt it is wiser to put up the limb as if there were a fracture, and to wait

FRACTURES.

the subsidence of the swelling before the diagnosis is finally made. It is better to put up an unbroken limb than to neglect to put it up if injured.

The existence of a fracture when *compound*, and more particularly if *comminuted*, is usually readily determined. Here, the great mobility, the confusion of fragments or splinters, and the easily produced crepitus will seldom allow the Surgeon to be in error. Should any doubt exist, the introduction of the finger into the wound will enable him to determine with certainty, not only the existence, but the condition and extent, of the fracture: on no account must a probe or metal instrument of any kind be used, or a simple fracture complicated with a wound may accidentally be made compound: *nor should the finger ever be introduced without first thoroughly purifying the hand with some efficient antiseptic solution.* Nevertheless, with all the assistance that may thus be afforded, the existence of a compound and comminuted fracture may be unsuspected for many days even after the most careful

examination. Of this important fact, which may have weighty medico-legal bearings, the following case is a good illustration. A young man was shot with a wooden ramrod through the left hand and shoulder, by the accidental explosion of his gun whilst he was loading it. The ramrod struck the humerus three inches below the shoulder-joint, on its fore part. It was splintered against the bone, the fragments passing on each side, and mostly escaping through two apertures posteriorly; some passing to the inner side between the large vessels and the bone, the others to the outer side between it and the deltoid. The patient was brought to the Hospital, where I saw him a few hours after the injury, and, enlarging the wounds, extracted a

Fig. 100. Comminuted Fracture of the Humerus without displacement.

Fig. 101. Fractured humerus, a dog on the limb, showing the external and internal pyramidal fracture.

number of splinters of the ramrod from around the bone. The limb was carefully examined, not only by me, but by several other Surgeons present, to determine whether the bone had been fractured, or the joint injured, but no sign of fracture was detected. The limb was laid on a pillow, and irrigation employed. Septic cellulitis set in, followed by extensive and deep suppuration in the limb. On examining this, with the view of giving a free exit to discharges, eight days after the accident, angular displacement and crepitus were for the first time found, and it became evident that the humerus was the seat of a comminuted fracture. The patient died of pyæmia; and at death the bone presented the appearance shown in Fig. 100, a long splinter having been detached in a longitudinal direction, and the shaft broken across at C. It appeared probable that the blow of the ramrod had fractured the bone longitudinally, detaching the large splinter, which had

enclose spaces containing the vessels and cellular elements, and so-called osteoid tissue is formed. In that part of the callus, on the other hand, which lies opposite the line of the fracture, true cartilage is formed; whilst in that portion which is intermediate between these two extremes a transitional tissue is produced, the cells of which resemble those of cartilage, but the matrix of which differs from that of cartilage in that it stains deeply with carmine. The formation of true cartilage invariably occurs in animals, but only under certain circumstances in the repair of fractures in man. This fact and the relation of the cartilage, when present, to the line of the fracture, suggest that its formation is in some way determined by want of rest.

Changes similar to those above described occur in the medullary canal, true cartilage being formed only at the immediate seat of fracture.

The complete ossification of the provisional callus.—The formation of new bone in the soft callus commences by the appearance of yellowish-white points or streaks, first seen in the part in contact with the bone at the point furthest removed from the seat of fracture. These points and streaks gradually increase till the callus becomes converted into soft spongy bone, containing wide cancellous spaces filled with red vascular medullary tissue. The ossification gradually spreads from above and below, towards the seat of fracture, till the process of conversion of the soft callus into bone is complete. The changes that occur within the medullary canal are of the same character. The new bone thus formed differs from normal compact tissue in being softer, more vascular and spongy. If a longitudinal section of the bone be made, it will be seen that the callus is covered by a thick vascular periosteum which can be stripped off without difficulty; it leaves the surface of the callus rough and spongy, with wide Haversian canals containing some red medullary tissue. The trabeculae of the callus are set at right angles, or nearly so, to the surface of the compact bone beneath, from which the callus can at first be separated without difficulty. If this be done, however, the surface of the compact bone is seen to be slightly more spongy than natural, the openings of the Haversian canals being enlarged.

Microscopic examination shews that when ossification occurs in that part of the callus which has undergone conversion into osteoid tissue, the process consists in the deposit of bone by osteoblasts, layer by layer, on the surfaces of the trabeculae of lime salts which have already been formed in the ground-substance. The spaces around the vessels are thus gradually narrowed until they assume the form of Haversian canals, whilst many of the osteoblasts become imbedded in the osseous tissue as bone-corpuscles. In that part of the callus in which true cartilage is developed, the process of ossification is preceded by the penetration of vessels into the cartilage from the periosteum and from the bone beneath, whilst the further changes observed are similar to those met with in the normal process of ossification in cartilage.

The ossification of the callus in the medullary canal proceeds in the same way.

The development and ossification of the intermediate or definitive callus proceed in the same way as in the formation of the provisional callus. The time at which it forms will depend greatly upon the perfection of the apposition, and the immobility attained by treatment. It is evident that no process of repair can take place between two surfaces of compact bone so long as they are grinding against each other at each movement of the limb. The

FRACTURES.

point of fracture, are more or less extensively lacerated; the periosteum is a rule completely torn through, and separated from the broken ends for a distance on one or both sides, leaving a ragged edge. In some cases the periosteum on one side may be intact, and it is said to have been found so even in complete fractures. As a rule it remains uninjured over a simple fracture. Blood will be found extravasated also in the medullary canal mixed with the fat.

The Period of Inflammation and Exudation.—The first changes observed after the injury are the ordinary signs of inflammation—hyperæmia, swelling, and abundant exudation. This affects the whole of the injured soft parts, so that by the third or fourth day the fracture will be found to be surrounded by a greyish-red, soft mass, not sharply defined, but infiltrating the neighbouring tissues; the torn ends of the muscles are pale in colour from the exudation between the fibres; the areolar tissue is no longer clearly recognizable, its spaces being filled by the coagulated inflammatory exudation; the outer layer of the periosteum is in like manner swollen and scarcely recognizable, and the inner layer is so soft and swollen as to be almost gelatinous; the whole membrane can be stripped from the bone with unusual ease for some distance from the seat of fracture. In the midst of the exudation, patches of unaltered blood-clot will still be seen, but a great part of the extravasation in the immediate neighbourhood of the fracture will have already been partly discoloured.

Microscopic examination at this stage shows the usual appearances of inflammation; the vessels are distended with blood, and all the spaces of the tissues are filled with wandering white corpuscles, either closely in contact with each other, or separated by a small quantity of homogeneous or fibrinous intercellular substance.

In the medulla the fat has disappeared from the immediate neighbourhood of the injury, and its place is taken by an exudation similar to that lying externally.

The growth of the soft provisional callus.—During this stage the excess of the inflammatory exudation and the remainder of the blood-clot in the neighbourhood of the injury are absorbed, and there is gradually developed round the ends of the broken bone a fusiform mass, holding them together with some degree of firmness. At first this is soft, almost jelly-like, and homogeneous in appearance, and the ends of the torn periosteum become lost in it. This soft provisional callus presents under the microscope the ordinary appearances of granulation tissue, but close to the bone many cells are found of larger size than the rest, and having one or more nuclei surrounded by a finely granular protoplasm. These *osteoblasts* are usually oval or spindle-shaped, or sometimes angular in form. They play, as we shall see, a most important part in the process of repair, and probably take their origin in the deeper layers of the swollen periosteum.

The callus next increases in density, and the superficial part undergoes the ordinary changes of the conversion of granulation tissue into fibrous tissue, thus forming the fibrous part of the new periosteum covering the callus. The changes which occur in the deeper parts of the provisional callus differ according to its situation. They are thus described by Bruns. In the part distant from the line of the fracture, lime salts are deposited in the form of trabeculae in the intercellular ground-substance. These trabeculae

found exactly opposite the seat of fracture, where there will necessarily be the greatest disturbance from movement.

Modification of Union of Simple Fracture.—The amount of callus formed in the union of a bone varies considerably. It is greater in children than in adults. In transverse fractures which are kept steadily in apposition, but little callus is formed; externally it may be scarcely perceptible, and internally it may be merely a thin tube not obliterating the medullary canal. It is greater in those bones and those parts of a bone which are thickly covered by soft parts, being formed as before stated not only from the periosteum and bone, but also from the surrounding tissues. The influence of the neighbouring soft parts in determining the formation of new bone is well marked in the tibia. In a fracture of this bone we find that, at the anterior and inner part, which is thinly covered, union takes place by the direct formation of intermediate callus; but at the posterior and outer side, where there is a thick envelopment of tissue, a large mass of provisional callus will often be found, filling up even the interosseous space. Occasionally we find that the inflammation set up around a fracture has extended to a neighbouring bone, and caused a formation of new bone upon it.

The formation of callus is also greatly influenced by the nature of the fracture. If the fracture be comminuted and the fragments displaced, there may be an abundant formation round the splintered fragments, welding them together. If there be great displacement, one end riding far over the other, the callus will be found chiefly between the two fragments, connecting them together by a bridge of bone. So also, in cases of great angular deformity, when the final process of partial absorption and moulding of the new bone has taken place, a larger amount is left in the angle, partly filling it up, and forming a sort of buttress to strengthen the bent bone. Lastly, the amount of callus is influenced very greatly by treatment; the more perfectly rest is maintained, the smaller will be the amount of callus formed.

Union of a separated Epiphysis takes place in the same way as union of a transverse fracture. It almost invariably causes complete ossification of the epiphysal cartilage and consequent arrest of growth from that end of the bone.

Clinical Course of a Simple Fracture.—The great majority of simple fractures of the larger bones are followed by slight febrile disturbance. This is very rarely sufficient to give rise to the general symptoms of fever, such as heat of skin, thirst, headache, &c.; in fact without the thermometer its existence could seldom be recognized. The temperature rarely exceeds 101° F., and in fact seldom reaches this point, unless there be considerable tension of the limb from extravasated blood. The nature and causes of the fever which accompanies simple fractures have already been discussed (see p. 306). The temperature usually becomes normal about the end of the first week, and from that time to the end of the case the patient suffers from no disturbance of health save such as may be caused by want of exercise if the fracture be situated in the lower limb.

TREATMENT OF FRACTURE.

In the treatment of an uncomplicated simple fracture, all that the Surgeon has to do is to place the fragments in proper position and to retain them there,

first change observed is an enlargement of the Haversian canals. This is effected by the growth of new cells within the canal. These, according to some pathologists, are migratory white corpuscles, but according to others, cells developed from the medullary tissue in the Haversian canals. Be this as it may, the bony wall of the canal is absorbed before the new cells. As soon as the opposing fragments are put at perfect rest the new cells sprout out from the canals on each side and fill the space. Ossification then proceeds in the new tissue thus formed, but without the previous formation of cartilage.

The *absorption of the provisional callus* forms the final stage of repair of a fracture. At first the porous callus becomes more compact, harder, and less vascular, and as the change takes place, it becomes more intimately connected with the old bone which it now closely resembles in structure. This hardening is most marked in the deeper layers in contact with the old bone, and as it takes place absorption goes on in the part next the periosteum, which at the same time becomes smooth and even. In the medullary canal the new bone becomes more and more cancellous in its structure, and finally there may be complete restoration of the medullary canal, though this is undoubtedly rare. The absorption of the callus is never complete, some thickening permanently remaining at the seat of fracture, however perfect the apposition and rest may have been. Any irregular points of bone, that may have been projecting after the union, become gradually absorbed and rounded off. These final processes are not completed for a year or more after the fracture has been united.

The microscope shows that the agents by which the absorption of the provisional callus is brought about are large multinucleated cells, known as *osteoclasts*, which apply themselves to the surface of the bone, and produce pits or hollows upon it known as "Howship's lacunae."

Thus, it will be seen that the process is analogous in every way to repair of a wound by the first intention. First there is the exudation resulting from the simple traumatic inflammation, the effect of the mechanical violence; this follows the development of a vascular tissue, composed of indifferent embryonic cells or granulation-tissue; this develops into the form of connective tissue natural to the part; and finally the obliteration of vessels and consolidation of the cicatricial tissue occur, as in the formation of a scar in the soft parts. One point with regard to the blood-clot should be remembered, as it might be of importance in medico-legal enquiries. Although it completely disappears from the immediate neighbourhood of the fracture at an early period, layers of dark coagulum may often be found beneath the superficial fascia for four weeks or more after the accident.

The process above described, although essentially the same in man, differs much in its details. It is slower, and the formation of callus is as a rule less abundant. If the fracture be well treated, it may in fact be almost wanting, union apparently taking place by the direct, or almost direct, formation of the definitive or intermediate callus. Histologically, the most important difference is that in man, as a rule, the formation of cartilage does not occur. It has, however, been met with in the union of bones in children, and it is always found in a uniting rib, but even here it is calcareous, the ground-substance being usually fibrous. Possibly the formation of cartilage in the rib may be due to the impossibility of fixing the injured bone, owing to the movements of respiration. In animals, the purest cartilage is

found exactly opposite the seat of fracture, where there will necessarily be the greatest disturbance from movement.

Modification of Union of Simple Fracture.—The amount of callus formed in the union of a bone varies considerably. It is greater in children than in adults. In transverse fractures which are kept steadily in apposition, but little callus is formed; externally it may be scarcely perceptible, and internally it may be merely a thin tube not obliterating the medullary canal. It is greater in those bones and those parts of a bone which are thickly covered by soft parts, being formed as before stated not only from the periosteum and bone, but also from the surrounding tissues. The influence of the neighbouring soft parts in determining the formation of new bone is well marked in the tibia. In a fracture of this bone we find that, at the anterior and inner part, which is thinly covered, union takes place by the direct formation of intermediate callus; but at the posterior and outer side, where there is a thick envelopment of tissue, a large mass of provisional callus will often be found, filling up even the interosseous space. Occasionally we find that the inflammation set up around a fracture has extended to a neighbouring bone, and caused a formation of new bone upon it.

The formation of callus is also greatly influenced by the nature of the fracture. If the fracture be comminuted and the fragments displaced, there may be an abundant formation round the splintered fragments, welding them together. If there be great displacement, one end riding far over the other, the callus will be found chiefly between the two fragments, connecting them together by a bridge of bone. So also, in cases of great angular deformity, when the final process of partial absorption and moulding of the new bone has taken place, a larger amount is left in the angle, partly filling it up, and forming a sort of buttress to strengthen the bent bone. Lastly, the amount of callus is influenced very greatly by treatment; the more perfectly rest is maintained, the smaller will be the amount of callus formed.

Union of a separated Epiphysis takes place in the same way as union of a transverse fracture. It almost invariably causes complete ossification of the epiphyseal cartilage and consequent arrest of growth from that end of the bone.

Clinical Course of a Simple Fracture.—The great majority of simple fractures of the larger bones are followed by slight febrile disturbance. This is very rarely sufficient to give rise to the general symptoms of fever, such as heat of skin, thirst, headache, &c.; in fact without the thermometer its existence could seldom be recognized. The temperature rarely exceeds 101° F., and in fact seldom reaches this point, unless there be considerable tension of the limb from extravasated blood. The nature and causes of the fever which accompanies simple fractures have already been discussed (see p. 306). The temperature usually becomes normal about the end of the first week, and from that time to the end of the case the patient suffers from no disturbance of health save such as may be caused by want of exercise if the fracture be situated in the lower limb.

TREATMENT OF FRACTURE.

In the treatment of an uncomplicated simple fracture, all that the Surgeon has to do is to place the fragments in proper position and to retain them there,

and to attend to the general health of the patient on ordinary principles. Nature unites the bone. In no way can the Surgeon accelerate the process or improve upon it, but by meddling treatment he may retard and disturb it.

Constitutional Treatment in Simple Fractures requires but a very few words of explanation. As a rule, the general habits of life should be interfered with as little as possible. In uncomplicated fractures of the upper extremities, more especially in the young, rest in bed is rarely necessary. The patient may be allowed to move about with the limb supported by proper apparatus. In fractures of the lower extremities, with few exceptions, confinement to bed during part of the treatment at least, is unavoidable. In these cases the diet may be reduced, and aperients will usually be required during the first week or ten days. After this the usual habits of life may be resumed.

In old persons the shock of the accident, the enforced confinement to bed and the sudden interruption of the ordinary habits of life, are apt to exercise an injurious and sometimes a fatal effect. In these cases there are two dangers to be feared, viz., hypostatic congestion of the lungs and the formation of bed-sores. Both are avoided by propping the patient up in bed, the use of water or air cushions, and change of posture as far as practicable. It is necessary to see that the bed is smooth and firm, without creases; that all crumls be swept away daily; and that scrupulous attention be paid to cleanliness after the use of the bed-pan. Good diet and a fair allowance of stimulants are needed in these cases. The early use of the starched or plaster-of-Paris bandage is of great service in enabling the patient to get up sooner than would otherwise be possible.

In all cases of simple fracture of the lower extremities, the sooner the patient is got up and about on crutches the better. Some patients speedily learn to use these instruments, others never get accustomed to their use. In the latter case, a wheel-chair should be substituted for them.

Surgical Treatment of Simple Fracture.—The object of the Surgeon is not only to obtain a sound and strong limb, but one that presents little or no deformity. In order to accomplish this, the broken ends of the bone must be brought into as perfect apposition as possible, and the recurrence of displacement must be prevented.

It frequently happens that a Surgeon is called to a case of fracture immediately after the accident before the patient has been moved, and without being informed of the nature of the case. It is then his duty to see that the moving of the patient is done as far as possible painlessly, and without increasing the injury to the soft parts by needless movement of the limb. For this purpose temporary splints may be applied outside the patient's clothes, and secured, in the absence of bandages, by pocket-handkerchiefs tied round the limb. A couple of walking-sticks or umbrellas, or the handle of a broom, may thus be applied to the thigh or leg; or a splint cut from the cover of a book to the arm. Newspapers folded several times till they form a mass of sufficient stiffness make excellent temporary splints.

If the patient has already been moved and is upon a bed, the limb must be placed in such a position as to give the greatest general relaxation of the muscles. Thus the lower limb must be flexed and placed on its outer side with a thin pillow under the knee. In fractures of the upper limb the arm should lie on a pillow by the side with the elbow flexed. The patient is made as comfortable as possible, while the necessary preparations are being

made for the treatment of the fracture. If the case be one of severe fracture of the upper extremity, or of any kind in the lower limb, the Surgeon must see that the bed, on which the patient may have to remain for some weeks, is properly prepared, by being made hard, flat, and firm, and, if possible, covered with a horse-hair mattress. He must then remove the patient's clothes, slipping them along the seams, so that they may be taken off with as little disturbance as possible to the injured part. He next proceeds to the examination of the limb, using all possible gentleness consistent with acquiring an exact knowledge of the fracture, after which, the limb should be again placed in a comfortable position, until any necessary apparatus has been prepared.

Reduction.—When all is ready, the reduction of the fracture, or the bringing the fragments into proper apposition, must be proceeded with. This should be done *at once*, not only lest any displacement that exists may continue permanently—the muscles, after a few days, becoming shortened, rigid, and unyielding, not allowing reduction to be effected without the employment of great force—but also with the view of preventing irritation and mischief to the limb, by the projection of the jagged ends of bone into the soft structures. A great deal of time is sometimes lost, and much unnecessary pain inflicted upon the patient, and great irritation set up in the limb, by the Surgeon leaving the fracture unreduced on a pillow for several days, and applying evaporating lotions to take down the swelling and avert the threatened inflammation, which are consequences of the non-reduction of the broken bone. The application of cold lotions, irrigation, &c., in compound or even in simple fractures, is decidedly injurious. It lowers the vitality of the part, retards union, and occasions œdema. By early reduction it may sometimes prevent a sharp fragment from perforating the skin, and thus rendering a simple fracture compound, or lacerating muscles and nerves, inducing perhaps traumatic delirium and certainly undue local inflammation and muscular spasm.

In reducing a fracture our principal difficulty is caused by the action of the muscles. This may usually be overcome by relaxing them by position, after which the fragments will, in most cases, naturally fall into place. In the reduction of ordinary fractures, no force is necessary if proper attention be paid to the relaxation of the muscles chiefly concerned in producing the deformity. In impacted fractures it is occasionally necessary to use force in order to disentangle the fragments, but this is the only form of fracture in which its employment is justifiable. In effecting the reduction, not only must the length of the limb be restored, but its natural curves must not be obliterated by making it too straight. Muscular action being the chief, and, in most cases, the only obstacle to reduction, it would seem most natural to overcome the difficulty by administering an anæsthetic, which would at the same time save the patient the severe pain usually attending the setting of a broken bone. It is a rule, however, in reducing a simple fracture, to avoid anæsthetics. We never can tell beforehand whether or not insensibility will be preceded by a violent fit of struggling, during which there would be the greatest possible danger of a simple fracture being made compound. If from any reason, such as the nervousness of the patient, or the difficulty in overcoming the muscular action by position, it becomes necessary to give an anæsthetic, there must be plenty of assistants at hand to restrain the patient if necessary. The limb

and to attend to the general health of the patient on ordinary principles. Nature unites the bone. In no way can the Surgeon accelerate the process or improve upon it, but by meddling treatment he may retard and disturb it.

Constitutional Treatment in Simple Fractures requires but a very few words of explanation. As a rule, the general habits of life should be interfered with as little as possible. In uncomplicated fractures of the upper extremities, more especially in the young, rest in bed is rarely necessary. The patient may be allowed to move about with the limb supported by proper apparatus. In fractures of the lower extremities, with few exceptions, confinement to bed during part of the treatment at least, is unavoidable. In these cases the diet may be reduced, and aperients will usually be required during the first week or ten days. After this the usual habits of life may be resumed.

In old persons the shock of the accident, the enforced confinement to bed, and the sudden interruption of the ordinary habits of life, are apt to exercise an injurious and sometimes a fatal effect. In these cases there are two dangers to be feared, viz., hypostatic congestion of the lungs and the formation of bed-sores. Both are avoided by propping the patient up in bed, the use of water or air cushions, and change of posture as far as practicable. It is necessary to see that the bed is smooth and firm, without creases; that all crumbs be swept away daily; and that scrupulous attention be paid to cleanliness after the use of the bed-pan. Good diet and a fair allowance of stimulants are needed in these cases. The early use of the starched or plaster-of-Paris bandage is of great service in enabling the patient to get up sooner than would otherwise be possible.

In all cases of simple fracture of the lower extremities, the sooner the patient is got up and about on crutches the better. Some patients speedily learn to use these instruments, others never get accustomed to their use. In the latter case, a wheel-chair should be substituted for them.

Surgical Treatment of Simple Fracture.—The object of the Surgeon is not only to obtain a sound and strong limb, but one that presents little or no deformity. In order to accomplish this, the broken ends of the bone must be brought into as perfect apposition as possible, and the recurrence of displacement must be prevented.

It frequently happens that a Surgeon is called to a case of fracture immediately after the accident before the patient has been moved, and without being informed of the nature of the case. It is then his duty to see that the moving of the patient is done as far as possible painlessly and without increasing the injury to the soft parts by needless movement of the limb. For this purpose temporary splints may be applied outside the patient's clothes, and secured, in the absence of bandages, by pocket-handkerchiefs tied round the limb. A couple of walking-sticks or umbrellas, or the handle of a broom, may thus be applied to the thigh or leg; or a splint cut from the cover of a book to the arm. Newspapers folded several times till they form a mass of sufficient stiffness make excellent temporary splints.

If the patient has already been moved and is upon a bed, the limb must be placed in such a position as to give the greatest general relaxation of the muscles. Thus the lower limb must be flexed and placed on its outer side with a thin pillow under the knee. In fractures of the upper limb the arm should lie on a pillow by the side with the elbow flexed. The patient is thus made as comfortable as possible, while the necessary preparations are being

made for the treatment of the fracture. If the case be one of severe fracture of the upper extremity, or of any kind in the lower limb, the Surgeon must see that the bed, on which the patient may have to remain for some weeks, is properly prepared, by being made hard, flat, and firm, and, if possible, covered with a horse-hair mattress. He must then remove the patient's clothes, ripping them along the seams, so that they may be taken off with as little disturbance as possible to the injured part. He next proceeds to the examination of the limb, using all possible gentleness consistent with acquiring an exact knowledge of the fracture, after which, the limb should be again placed in a comfortable position, until any necessary apparatus has been prepared.

Reduction.—When all is ready, the reduction of the fracture, or the bringing the fragments into proper apposition, must be proceeded with. This should be done *at once*, not only lest any displacement that exists may continue permanently—the muscles, after a few days, becoming shortened, rigid, and unyielding, not allowing reduction to be effected without the employment of great force—but also with the view of preventing irritation and mischief to the limb, by the projection of the jagged ends of bone into the soft structures. A great deal of time is sometimes lost, and much unnecessary pain inflicted upon the patient, and great irritation set up in the limb, by the Surgeon leaving the fracture unreduced on a pillow for several days, and applying evaporating lotions to take down the swelling and avert the threatened inflammation, which are consequences of the non-reduction of the broken bone. The application of cold lotions, irrigation, &c., in compound or even in simple fractures, is decidedly injurious. It lowers the vitality of the part, retards union, and occasions oedema. By early reduction we may sometimes prevent a sharp fragment from perforating the skin, and thus rendering a simple fracture compound, or lacerating muscles and nerves, inducing perhaps traumatic delirium and certainly undue local inflammation and muscular spasm.

In reducing a fracture our principal difficulty is caused by the action of the muscles. This may usually be overcome by relaxing them by position, after which the fragments will, in most cases, naturally fall into place. In the reduction of ordinary fractures, no force is necessary if proper attention be paid to the relaxation of the muscles chiefly concerned in producing the deformity. In impacted fractures it is occasionally necessary to use force in order to disentangle the fragments, but this is the only form of fracture in which its employment is justifiable. In effecting the reduction, not only must the length of the limb be restored, but its natural curves must not be obliterated by making it too straight. Muscular action being the chief, and, in most cases, the only obstacle to reduction, it would seem most natural to overcome the difficulty by administering an anaesthetic, which would at the same time save the patient the severe pain usually attending the setting of a broken bone. It is a rule, however, in reducing a simple fracture, to avoid anaesthetics. We never can tell beforehand whether or not insensibility will be preceded by a violent fit of struggling, during which there would be the greatest possible danger of a simple fracture being made compound. If from any reason, such as the nervousness of the patient, or the difficulty in overcoming the muscular action by position, it becomes necessary to give an anaesthetic, there must be plenty of assistants at hand to restrain the patient if necessary. The limb

must then be put in the best position possible, and firmly supported by splints rather tightly applied. When everything is ready the injured limb must be confided to the charge of one assistant only. If two attempt to hold a leg, one by the foot and the other by the knee, they may cause the very mischief it is intended to prevent.

Conway, of New York, has succeeded in preventing the severe pain of reduction by means of cocaine. In a case of fractured radius he injected hypodermically min. of a 4 per cent. sterilized solution of cocaine between the broken ends, and a few minutes later *mxiv.*, part deeply and part superficially. Immediately after the last injection he applied a tourniquet above the elbow. In five minutes the limb could be manipulated without pain. The anaesthesia lasted for half an hour while the tourniquet was on, but disappeared in fifteen minutes after its removal.

Prevention of Return of Displacement.—After reduction has been accomplished, means must be taken to prevent the return of the displacement. We have already seen that the three great causes of displacement in a fracture are, external violence, the weight of the limb, and the contraction of the muscles. In the upper limb the weight is supported during the treatment of the fracture when necessary by slings or bandages. In the lower limb the chief displacement due to the weight of the limb is rotation outwards; this is prevented by lateral splints. The displacements due to muscular action are far the most troublesome, and in many cases it is exceedingly difficult, for the first few days, to keep the ends of the bone in position, in consequence of spasmodic contractions of the muscles, or of restlessness of the patient. About this, however, the Surgeon need not be anxious, as no union takes place for the first week or ten days: at the end of that time the muscles will have lost their irritability, and the patient have become accustomed to his circumstances, so that with patience, and by varying the apparatus and the position of the limb from time to time, good apposition may be obtained.

The displacements due to muscular action are overcome chiefly in two ways which may be used together or separately—**relaxation and extension**. The principle of **relaxation**, first laid down by Pott, consists merely in placing the limb in such a position as to relax the chief disturbing muscles. There is no doubt it is of the greatest value in the treatment of the majority of broken bones. **Extension** consists in applying an apparatus by which the lower fragment is pulled in the direction opposite to that in which the muscles are displacing it. In order to apply it efficiently, counter-extension must be made upon some part of the body above the fracture. Extension is usually made by the Surgeon pulling forcibly on the lower fragment, the apparatus being used merely to retain the limb in the position in which he has placed it: in some cases, however, elastic extension is applied during the subsequent treatment by means of india-rubber. Considering the power of the muscles, it is evident that in many parts it would be impossible to apply sufficient force to overcome the displacement to which they give rise. It seems, however, that long-continued and steady extension gradually tires out the muscles until they yield to it. Extension should therefore be constant. It is most useful in longitudinal displacement, but it also aids the reduction of angular deformity. As types of the application of these two principles, the treatment of fracture of the thigh by the double inclined plane, and by the long splint, may be referred to.

A third method of overcoming muscular action has been suggested: **the division of the tendons** of some of the stronger muscles inserted into the lower fragment. This, however, can very seldom be necessary, and I have rarely seen any benefit result from it. Displacement due to the violence which caused the fracture is overcome at the time of reduction; any further displacement from external causes is prevented by the treatment about to be described.

The return of displacement is prevented, and the proper shape of the limb maintained, by means of *bandages, splints, and special apparatus* of various kinds. In applying these care should be taken not to exert any undue pressure on the limb. Pads and compresses of all kinds intended to force a displaced fragment into position should, if possible, be avoided: they do nothing that cannot be effected by proper position, and may occasion sloughing of the integuments over which they are applied.

The **Bandages** used in the application of splints should be the ordinary grey calico rollers, about two or three inches in width, and eight yards in length. Special care must be taken that the turns press evenly upon every part, and that the bandage be not applied too tightly. *No bandage should be applied under the splints*, more particularly at the flexures of joints, and care must be taken that the limb be not bent, or its position otherwise materially altered, *after* bandages have been applied. A bandage *under* the splint is not only useless, but dangerous, from the risk of strangulation. No bandage should be applied to the seat of fracture. The part below may sometimes advantageously be bandaged, in order to prevent œdema; thus, in fracture of the humerus, the forearm may be bandaged, but no turns of the roller should be brought above the elbow. This point of practice I consider most important, as the application of a bandage to the immediate seat of fracture causes not only great pain, but danger of gangrene. When once a fractured limb has been "put up," the less it is disturbed the better. No good can possibly come from meddling with it, but a great deal of pain must necessarily result to the patient. The Surgeon should always bear in mind that, in the treatment of a fractured bone, he can do nothing to promote its union, beyond placing it in a good position. Nature solders the bone together; and the less the Surgeon interferes the better. But it is requisite to examine the limb from time to time, and especially about the second or third week, when bony union is commencing, in order, if necessary, to correct displacement. In the earlier stages, supervision is necessary lest the bandage be too tight; and, if the patient complain of any pain or numbness, or if the extreme parts look blue and feel cold, the bandage must immediately be removed: for, though the apparatus may not have been applied tightly, swelling of the limb may come on from various causes, to such an extent as to produce strangulation and gangrene, as I have seen happen in at least three instances, in each of which the limb required amputation (Fig. 166). It is remarkable that the whole of a limb will fall into a state of gangrene in these circumstances with but little pain, and often with very slight constitutional disturbance, the parts having their sensibility deadened by the pressure. Before applying the apparatus in a case of fracture, and as often as it is taken off, it is a good plan to sponge the limb with warm soap and water, to prevent the itching that otherwise may be very troublesome.

Splints of various kinds are used in cases of fracture. Tin, wire, zinc, or

thin sheet-iron, wood, leather, "poroplastic felt," and guttapercha, are the materials usually employed. Gooch's splint, which is made of narrow strips of wood glued upon a sheet of coarse calico, is very useful in many cases, and narrow rods of soft iron surrounded by thick india-rubber tubing, or thick telegraph wire is often very convenient. For some kinds of fracture, special, and often very complicated apparatus, is very generally used; but the Surgeon should never confine himself to one material, or to one exclusive mode of treating these injuries, as in different cases special advantages may be obtained from different kinds of splints. In applying leather, guttapercha, paste-board and poroplastic splints, a pattern should first be made of paper, of the proper size and shape, by which the splint is cut out; the material must then be softened by being well soaked in hot water, or in the case of poroplastic splints by dry heat or steam, and moulded on to the part whilst soft; as soon as it has taken the proper shape, it should, if guttapercha be used, be hardened by being plunged into cold water; paste-board or leather must be allowed to dry on the limb, and poroplastic felt will harden as it cools. The edges may then be feathered, the corners rounded and the interior lined with wash-leather or lint. These splints have the advantage of great durability, cleanliness, and lightness.

When a flat splint is used, not moulded to the part, it should be wider than the limb so that the limb may lie on the splint, and not the splint upon the limb. Whether flat or moulded to the part it should securely fix the two joints connected with the fractured bone: if the thigh, the hip and knee; if the leg, the knee and ankle. The splints must be smoothly covered with pads, which should overlap the edges. It is impossible to keep the fragments perfectly immobile, and in close and accurate apposition, unless these very important points be attended to.

Special Apparatus should be employed as little as possible in the treatment of fractures. It is scarcely ever necessary in simple fractures, and is far more cumbersome and costly than the means above indicated, which are all that can be required. I have no hesitation in saying that a Surgeon of ordinary ingenuity and mechanical skill may be fully prepared to deal successfully with every fracture which he can be called upon to treat, by having at hand a smooth deal plank half an inch in thickness, and a sheet of guttapercha, undressed sole-leather, paste-board, "poroplastic material," perforated zinc, or thin sheet-iron, to cut into splints as required.

To the means above described, some kind of **rigid apparatus**, moulded to the limb, forms an invaluable addition. Although various plans for stiffening and fixing bandages in cases of fracture had previously been employed, it was not till about forty years ago that their full value became recognized, chiefly through the practice and writings of Baron Serrin. Since that time a variety of substances, such as gum and chalk, glue, paraffin, tripolite, and water-glass, have been recommended for the purpose of stiffening bandages, but the two which are practically most useful and have longest maintained their reputation, are the starched bandage and the plaster of Paris bandage. These represent two different types of fixed apparatus. The starched bandage is applied over a mass of cotton-wool, which is firmly compressed during the application of the apparatus, and thus exerts a gentle uniform elastic pressure, holding the fragments in position. The plaster of Paris bandage takes an actual cast of the

injured limb; it is not intended to exert any pressure—in fact if applied in such a way as to do so, it is a dangerous application.

The Starched Bandage.—The following is the mode of applying this apparatus which I have found to answer well. The whole limb is enveloped in a layer of cotton-wool, thickest along and over the osseous prominences; this, being elastic, accommodates itself to the subsequent diminution in size of the limb, and keeps up more equable pressure. Over the cotton-wool are laid splints of thick, coarse pasteboard properly shaped to fit the limb, and then softened in hot water. The pasteboard should be doubled and torn down, *not* cut, as in this way the edges are not left sharp. If great strength be not required, as in children, or in some fractures of the upper extremity, a few strips of brown paper, well starched, may be substituted for the pasteboard. A bandage saturated with thick starch is now firmly applied; and lastly, this is covered with another dry roller, the inner sides of the turns of which may be starched as it is laid on.

The bandages must be applied with sufficient force to compress the mass of cotton-wool surrounding the limb. There is no danger of constriction if enough wool be used. No bandage must on any account be applied beneath the pasteboard splints. Both the pasteboard splints and the starched bandage

Fig. 162.—Sentin's Pliers.

should always include the joints immediately above and below the fracture, so that complete immobility of the fragments may be secured. During the application of this apparatus, extension must be kept up by an assistant, so as to hold the fracture in position; and, until the starch is thoroughly dried—which usually takes from thirty to fifty hours—a wooden splint may, if necessary, be applied to the limb. The drying of the starch may be hastened by the application of hot bottles. After the bandages have become quite dry, the patient may be allowed to move about on crutches, taking care, of course, to keep the injured limb well slung up, and not to bear upon it, or to jar it against the ground (Fig. 164). In the course of about three or four days after its application, as the swelling caused by the fracture subsides, the apparatus will usually be found to have loosened somewhat. In these circumstances, it must be cut up with Sentin's pliers, such as are represented in Fig. 162, or French vine-dresser's scissors, which are perhaps more durable. This section must be made up the front of the limb, care being taken not to injure the skin in so doing. If the fracture be so far consolidated that the limb can be handled without fear of displacing the fragments, the splint may be completely removed, and its edges pared, about three-quarters of an inch being taken from each. The cotton-wool is then cleaned out from its inside, a fresh layer is wrapped round the limb, and the apparatus re-applied by means of an unstarched roller or tapes. If the fracture be too recent to allow of this, the edges must be pared without removing the splint from the limb,

and changing the cotton-wool must be deferred to a later period. If the fracture be compound, a trap may be cut in the apparatus opposite the seat of injury, through which the wound may be dressed (Fig. 163).

The advantages of the starched bandage in the treatment of fractures consist in its taking the shape of the limb accurately, and maintaining it by its solidity; in its being light, inexpensive, and easily applied, with materials that are always at hand. It secures complete immobility of the limb in the position in which it dries. The joints in the neighbourhood of the fractured bone are securely fixed, and the perfect adaptation of the apparatus to the inequalities of the limb prevents all movement. Thus it maintains accurately

Fig. 163.—Starched Bandage : Trap left for Dressing Wound.

Fig. 164.—Starched Bandage applied to Fractured Thigh.

not only the length but the normal curves of the limb. From its lightness it possesses the great advantage, in fractures of the lower extremity, of allowing the patient to move about upon crutches during nearly the whole of the treatment; thus preventing the tendency to those injurious consequences that often result from prolonged confinement to bed; and, by enabling the patient to keep up his health and strength by open air exercise, facilitating the consolidation of the fracture. In addition to this, the patient will often be able to carry on his business during treatment. By employing the starched bandage in the way just described, I scarcely ever find it necessary to keep patients in bed with simple fractures of the leg for more than from four to seven days, thus saving much of the tediousness and danger of the treatment.

In several hundreds of fractures of all kinds, I employed Seutin's plan soon after its introduction into this country, putting the limb up in the starched

apparatus *immediately* after the reduction of the fracture. I found the practice a safe one, even in fractures of the thigh; so much so, that at the Hospital I for some time rarely used any other plan of treatment. The moderate pressure of the bandages, aided probably by the great evaporation from so extensive and thick a mass of wet starch, seemed to take down the swelling most effectually. Thus the patient was often able to leave his bed about the third day after the injury, when the fracture was in the leg or ankle, and about the sixth when it was the thigh that was broken.

Further experience, however, showed that the fractures to be treated in this way require selection. A simple fracture of one bone of the leg or of both bones, without comminution or marked displacement, or great extravasation of blood, may safely be put up immediately in the starched bandage or any other rigid apparatus. In more severe cases it is better to wait till the end of the first week or the beginning of the second before applying the starched bandage. In fractured thighs also it is better to allow a certain degree of consolidation to take place, otherwise from the difficulty of completely fixing the hip-joint by means of a starched bandage some return of displacement may take place. The best time for its application in these cases is about the end of the second week. Care must be taken to enclose the foot in the splint, otherwise rotatory displacement outwards may occur. By this means I have obtained the most satisfactory results in cases of fractured thigh: patients having frequently been cured without any appreciable shortening, with the preservation of the natural curve of the bone, and without confinement to bed after the second week.

Plaster of Paris may be used in the treatment of fractures in any one of the four following ways:—

1. The *simple plaster bandage* is thus applied: A coarse muslin bandage is first prepared by rubbing some fresh plaster thoroughly into its meshes. The very best plaster must be used, and it must be quite fresh; if it has been exposed even for a few days in a damp place it will be practically useless. The bandage is then loosely rolled up, a little more plaster being sprinkled between its turns as this is done. The necessary number of bandages having been got ready, the limb must be prepared. This is done in various ways. Formerly at University College Hospital we used merely to grease the limb and apply the plaster directly to the skin. This had the disadvantage of being difficult to remove. The better plan is to apply a dry flannel bandage smoothly to the limb. The bandage must be made of elastic Welsh flannel and must not be drawn more tightly than is necessary to prevent creasing, otherwise it might cause constriction of the limb. A prepared plaster bandage is then placed, end upwards, in a basin of water deep enough to cover it completely. It is then taken out and squeezed to get rid of the excess of water and smoothly rolled over the flannel. *The bandage must on no account be pulled.* It is to be laid smoothly on the limb without making reverses. In order to avoid these, it may be cut whenever necessary. The muslin bandage, it must be remembered, is used merely as a convenient means of applying the plaster and to give toughness to it when it is set; a plaster bandage must on no account be used to exert pressure, or when it sets it may cause serious constriction of the limb. As the bandage is applied it must be rubbed with the hands to squeeze out any air that may have got between the turns, and if necessary, some plaster made into a cream with water may be rubbed in with the hand. If it be

thought necessary to strengthen the apparatus at any point, this may be done by laying on strips of the plaster bandage, which must be secured by a final circular turn; or strips of thin tin-plate, perforated zinc, or telegraph wire, may be applied between the layers of bandage. In an ordinary case about three layers of bandage will be required. Some Surgeons prefer to use cotton-wool instead of the flannel; this however necessitates pulling the bandage, which is never a safe proceeding with plaster. Moreover, cotton-wool after a few days becomes packed together inside the plaster case, which no longer fits accurately. If a mass of cotton-wool be made to surround the limb it is better to apply either the starched bandage and paste-board splints or the silicate of soda bandage, both of which can be cut up and removed and repacked without destroying the splint.

Good plaster hardens in the course of about eight minutes, and, as it dries, it forms a solid, hard, and light casing to the limb, affording excellent support to the fracture. The setting of the plaster may be retarded by the addition to it of solution of borax. Thus a solution of 1 part to 12 of the water used will retard the setting fifteen minutes; and 1 to 8 will retard it fifty minutes, and so on. The plaster bandage possesses the advantage over the starched apparatus of being lighter and less cumbersome, and especially of hardening very quickly, so that not only can the limb be easily held in position till the plaster is firm, but the patient can be immediately moved to any distance after the setting of the fracture.

The plaster of Paris bandage may be applied to any fracture after the swelling has subsided, and it may be put on immediately in all cases in which, from the nature of the injury, but little swelling is to be expected, such as fracture of the metatarsal or metacarpal bones, or fracture of one bone of the leg. If applied when the limb is swollen the splint soon becomes loose as the swelling subsides. After its application the exposed parts of the fingers or toes must be carefully watched, and if they should become blue or cold the apparatus must be at once removed.

2. Nendorfer is a strong advocate for the employment of the plaster of Paris bandage. He recommends that it should be applied immediately on this he lays great stress), in the following way. Compresses of linen, or of lint, are dipped in plaster of Paris of the consistence of a common poultice. These are then placed longitudinally on the limb, first on the upper, then on the under part. A few turns of a bandage keep them *in situ* till the plaster is set. To prevent the contiguous edges from adhering, they are slightly greased, or a strip of greased lint is put between them. Nendorfer sometimes places pieces of thin wood, like veneer, lined with cotton-wool, next the skin; over these the bandage, saturated with the plaster, is applied by circular turns in the usual way.

3. The method of applying the plaster apparatus, as practised in the Bavarian army during the Franco-German War, is as follows. Two pieces of flannel, twenty inches broad, are stitched together down the middle for a length equal to that of the leg; beyond this both are cut through in the same line for the length of the foot. The flannel is placed under the limb, so that the seam reaches from the ham to the heel. The sides of the inner piece are brought together over the leg, and fixed in front, and along the sole, by hare-lip patches at a right angle, so that they may be easily extracted afterwards), and thus a closely fitting stocking is formed. The sides of the inner piece are

then brought forwards and out, so that each may overlap the middle line of the leg and sole by three-quarters of an inch. The limb is then laid on one side : and while the outer piece of flannel is held back, a layer of plaster of Paris of the consistence of thick cream is spread evenly, to the thickness of half an inch, over the inner piece, and made to pass quite to the seam behind, and the line of junction of the sides of the inner piece in front. The outer piece is pressed over this before it sets, and should just reach the middle line in front and along the sole. When this has set, the limb is turned over, and the process is repeated on the other side. The pins may now be removed. The seam serves as a hinge ; and when the whole has set, the splint may be taken off, the edges of the plaster trimmed, and those of the inner piece of flannel cut so as to leave sufficient to turn over and stitch down on the outer piece. The splint is then readjusted and fixed by a bandage (Fig. 165).

4. Another mode of applying the plaster, which has been recommended by Croft, of St Thomas's Hospital, will be found very useful. Some common

Fig. 165.—Bavarian Plaster Splint.

house flannel or old blanket is cut into the form of lateral splints, and of such a size as almost to meet round the limb. Two of these must be cut for each side of the limb. The one which is to lie next the skin is then placed upon a table, with its inner side downwards ; the other is well soaked in plaster of Paris and water of the consistence of thick cream, and immediately applied to it. The two are then taken up together and placed upon the limb ; those for the opposite side having been prepared in the same way are quickly applied, and the whole surrounded by a muslin bandage. The limb is to be held in position while the plaster sets. When all is solid the muslin bandage can be cut down the front of the limb, and the apparatus taken off whenever it is desirable to examine the fracture.

In all cases in which the plaster bandage is used, there is danger of unsafe constriction of the limb after the setting of the plaster, either in consequence of the apparatus having been applied too tightly, or of the inner bandage, which has been directly applied, becoming tightened by the swelling of the limb within it. Hence great care must be taken for several days after the application of the apparatus, to watch the limb carefully, and if signs of constriction come on, such as pain, coldness, numbness, and œdema of the toes or fingers, it should be immediately cut up, re-adjusted or removed. No time should be lost in doing this, as the limb may have become gangrenous in patches, with little suffering to the patient or constitutional disturbance.

The Silicate of Soda or Water-glass Bandage is another very useful form of rigid apparatus. The materials required are a solution of silicate of

soda of the consistence of syrup, which can be purchased ready prepared and keeps well in a stoppered bottle, and some thin bandages. The bandages are to be thoroughly soaked by being drawn through a sufficient quantity of the solution in the bottom of a basin, and then rolled up again. A thick padding of cotton-wool is then put round the limb, and the silicate bandage applied directly upon it. No pasteboard splints are used, and about four or five layers of bandage will be required. It dries in from 12 to 24 hours, and makes a clean, firm, light case, which can be cut up and treated like a starched bandage.

In the treatment of ordinary simple fractures of the shafts of long bones, the following are the chief points that require attention :

1. To effect reduction at once, and with as little disturbance of the limb as possible.
2. Not to apply any calico roller to the part of the limb in which the fracture is situated, nor under the apparatus.
3. To line or pad the apparatus uniformly.
4. To include and fix in the apparatus the two joints connected with the injured bone.
5. To disturb the apparatus as seldom as possible.
6. To use starched pasteboard or plaster apparatus, when practicable, in preference to any more special form of appliance.

Accidents and Complications during Treatment are liable to occur, some of which are general and others special. Amongst the complications to which cases of fracture are liable, in common with all others, are tetanus and erysipelas, but these rarely follow simple fracture, and require no further notice here.

Traumatic Delirium, or Delirium Tremens, is by no means an uncommon complication, and is always serious. The general treatment has already been given (p. 309). Locally, as soon as the symptoms show themselves, the fracture must be firmly supported by splints or by a starched or plaster of Paris bandage. The injured limb must be slung from a cradle, and on no account tied to the bed. This, as a rule, fixes only the lower fragment, while the upper works about during the struggles of the patient, and may cause the most serious mischief.

Fat Embolism.—If the lungs of a patient who has died shortly after a severe accident crushing one or more bones be examined microscopically, after staining with osmic acid, a certain number of the capillaries, and perhaps some of the terminal arteries, may be found plugged with liquid fat. The appearances are very characteristic, the fat being stained black by the osmic acid ; and it is easy to recognise the plugs in tortuous capillaries surrounding the air-vesicles or in the small branching arterioles. If the remaining organs be examined, similar embolic plugs may be found in all parts of the body and in the nervous centres. In the kidney the loops of vessels in the Malpighian vessels are frequently found distended with fat. Experimental enquiry into the subject has led to the following conclusions. If liquid fat or oil be in any way set free amongst the tissues it may find its way into the circulation either by means of the lymphatics or by the veins. If injected into the healthy subcutaneous tissue it enters the circulation more slowly than from the pleura or peritoneum. Pressure favours the process ; thus, if the fat of the medulla of a long bone be broken down and a laminaria tent inserted, fat embolism is

speedily induced. In many surgical injuries we have the conditions necessary for fat embolism. In fractures crushing the medulla of a bone a large number of the fat-cells of the marrow are broken up and the liquid fat set free; and the same may happen in violent contusions of the subcutaneous tissue in fat subjects, and in contusion or laceration of a fatty liver. At the same time the pressure of extravasated blood and of inflammatory exudation favours the entrance of the fat into the circulation. Fat embolism has also been met with in acute inflammation of the marrow of a bone, and in diffuse gangrenous inflammation of the subcutaneous areolar tissue.

Fat embolism as a complication of simple fracture may occur within the first twenty-four hours, as the direct effect of the injury, or on the second or third day, or as the result of the inflammatory exudation pressing on the injured medulla or adipose tissue. The symptoms caused by it are somewhat doubtful. Riedel and Scriba state that the fat is eliminated by the kidneys, and will, in a very large proportion of fractures of long bones, be found microscopically in the urine about the third or fourth day. At a later period, from the tenth to the fourteenth day, it is often met with again, a fact which Scriba attributes to the dislodgment of the emboli from the lungs and other viscera and their elimination by the kidneys. A trace of albumen and some casts are sometimes met with at the same time. These appearances need not be accompanied by any constitutional symptoms. Should the quantity of fat which enters the circulation be very large, it is supposed to be capable of causing grave or even fatal symptoms, of which, according to Scriba, the following are the most characteristic: slight lowering of temperature, dyspnoea, occasionally slight hæmoptysis, and in extreme cases, fatal collapse, spasms or localized paralysis, ending in coma and death. Scriba is of opinion that whenever fat embolism proves fatal it is from obstruction to the vessels of the brain, and that the interference with the pulmonary circulation is never sufficient to cause death. That death does occur in some rare cases after simple fractures with some or all of the above-mentioned symptoms is certainly true, and that fat embolism can be found *post mortem* is equally certain; but that it is the cause of the symptoms is doubted by Cohnheim and many authorities, as experiments have shown that very large quantities of fat can be injected into the circulation of animals so as to cause most extensive embolism without being followed by death or even any serious symptoms.

In cases of septic inflammation following a compound fracture or a severe laceration of adipose tissue, the fat emboli may become impregnated with the septic poison, and thus set up inflammation wherever they lodge. The emboli from subcutaneous injuries are said occasionally to give rise to hæmorrhagic infarcts around the point at which they are arrested, and in some cases to cause œdema of the lung by extensive obstruction to the circulation; but being perfectly unirritating they never set up inflammation.

No treatment has yet been suggested for fat embolism.

In fractures of the lower extremity occurring in old people, there is a great tendency to **Hypostatic Pulmonary Congestion**, as a consequence of long confinement in the recumbent position; these fractures often prove fatal in this way. The use of the starched bandage, by enabling the patient to move about, is the most effectual preventive of these accidents.

The treatment of the more general accidents presents nothing that need

detain us here; but those that are more special and peculiar to fracture require consideration.

Crutch palsy of the hands and arms may occur as the result of compression of the brachial nerves against the pad of the crutch. The whole plexus, or only one of its component nerves, as the musculo-spiral or ulnar, may be affected. The remedy is obvious: it consists in the discontinuance of the use of the crutch, and if need be, the employment of electricity to the pained muscles.

Spasm of the Muscles of the Limb, owing to the irritation produced by the fragments, is often severe so long as the fracture is left unreduced; but usually ceases after reduction, and the maintenance of the fracture in proper position. If the spasm be dependent upon nervous causes, full doses of opium will not unfrequently afford relief. In some cases it is of a permanent character, producing considerable displacement of the fragments. In these circumstances, division of the tendons has been recommended: but this practice appears to be an unnecessarily severe one, and may certainly most commonly be avoided by attention to the other plans of treatment which have been suggested.

Edema of a broken limb may occur from several causes, viz., over-tight bandaging, dependent position, pressure of extravasated blood, venous thrombosis or inflammatory effusion. It is of no great moment in itself, but may be of consequence as indicative of approaching gangrene. Relief may usually be afforded by loosening the bandages, and elevating the limb.

The edema, which is often very persistent after the cure of the fracture, is best relieved by diligent friction, douching, bandaging, and attention to position.

Considerable Extravasation of Blood is frequently met with in cases of simple fracture, causing great swelling and tension. The blood is in most cases readily absorbed; and the Surgeon should never be tempted by any feeling of fluctuation to open it, as he would thereby convert the simple into a compound fracture. In some of the cases of extensive extravasation, the limb appears to relieve itself of the serous portion of the blood effused, by the formation of large bullæ or blebs, which may be punctured, or else allowed to burst and subside, without any material inconvenience. This extravasation very rarely, indeed, runs into abscess; if it do, it must of course be opened, and treated upon antiseptic principles. If deeply effused it may lead to gangrene, by the compression which it exercises on the vessels.

Splint sores are easily produced if an imperfectly padded splint be allowed to exert undue pressure upon a superficial bony point, such as the internal condyle of the humerus or either malleolus. Under these circumstances sloughing of the skin may be caused with remarkably little pain. This troublesome complication can usually be avoided by a careful arrangement of pads around any bony prominences covered by the splint; when once formed, the resulting sore must be treated on general principles.

Gangrene not directly due to injury of the main vessels of the limb occurring as a complication of simple fracture, is a most serious mischance, and one as to which it is difficult for the Surgeon to exonerate himself from blame. But he is not always in fault. It may arise from causes residing in the limb. It may be contributed to by the negligence of the patient in not drawing the Surgeon's attention to early symptoms, after having been duly

warned. Gangrene of the limb (Fig. 166) may occur after simple fracture as the result (1) of tight bandaging ; (2) of the swelling of the limb and compression of the vessels consequent upon extravasation of blood ; or (3) of inflammatory infiltration causing strangulation within a bandage that has been at first but lightly applied. *Gangrene is almost invariably the consequence of the pernicious practice of applying a bandage directly to the limb under the apparatus.* I have never known gangrene to occur after fracture except when this had been done, since it is much more likely to occur in those cases in which the fracture is treated by the unskilful application of an immovable apparatus, whether of starch, plaster of Paris, or other similar material, than when splints are used. Indeed, if the splints be well padded, and no bandage be put on under them, it is almost impossible that an amount of constriction can be exercised on the limb sufficient to interrupt the circulation through it. I believe that this accident would rarely, if ever, occur, if the Surgeon were to avoid the direct application of a bandage to the limb, however lightly, in fractures, more particularly in children. The danger of strangulation is

Fig. 166.—Gangrene of Forearm and Hand from Tight Bandaging.

especially great if, as happened in the case from which the accompanying cut (Fig. 166) is taken, the limb be bandaged whilst straight, and then flexed, as the bandage will then cut deeply at the flexure of the joint, and will certainly destroy the vitality of the part, if not of the whole limb. The pressure of an axillary pad, used in many fractures of the upper extremities, may also tend to the supervention of gangrene by interfering with the return of blood through the axillary vein. Hence in these cases the fingers should be examined daily. Even if no direct bandage have been applied, the apparatus should at once be removed, and the limb examined if any appearances of congestion, such as blueness, coldness, œdema, or vesication of the fingers or toes, show themselves, or even if the patient merely complains of slight uneasiness. If it be left on beyond this, gangrene will probably set in, slow strangulation going on under the bandages without much, if any, pain. Vesications of very large size will often occur, as a consequence of the raising of the cuticle by the transuded serum of extravasated blood. It is only when associated with coldness of the limb, a dusky purple hue, and a putrescent odour, that they are indicative of gangrene. An excellent plan of judging of the activity of the circulation in a fractured limb, after it has been put up, is to leave the ends of the fingers or toes uncovered by the bandage ; when, by pressing upon one of the nails, the freedom of the circulation may be ascertained by noting the rapidity

with which the blood returns under it. A question of great medico-legal importance occasionally arises in connection with gangrene of the limb after simple fracture. It is this—Is the gangrene owing to over-tight, and consequently negligent, bandaging by the Surgeon, or to passive strangulation by inflammatory swelling of the limb under bandages not originally too tightly applied? The diagnosis of the two conditions on which the answer is dependent is as follows: 1. When a bandage has originally been too tightly applied, the patient will suffer severely for several hours, the pain being felt immediately after the application of the apparatus. On loosening the bandage, the pain ceases. When removed, if gangrene have set in, the skin will be found pale where the roller has been applied—the limb being compressed and small at this part, and marked with imprints at the edges of the turns of the bandage—whilst it is greatly swollen and congested at the fingers or toes beyond the bandage; these parts being also cold, purple, and vesicated. 2. When the strangulation occurs from inflammatory swelling of the limb, the whole member is equally swollen: it is red and blue, hot in parts, cold and sphacelated in others. It never becomes uniformly gangrenous, but deep infiltrating abscess and localised sphacelus form.

Treatment.—When a bandage or apparatus appears to be exerting painful or dangerous pressure, it must at once be removed. Should the circulation of the limb have been interfered with, friction with oil in an upward direction should be employed.

If gangrene have unhappily already occurred, the treatment will depend on the cause, and on the condition of the limb. If it be the result of self-strangulation of the limb, by swelling under the bandage, and if the parts be found to be red, swollen, and infiltrated, free incisions should be made, and some efficient antiseptic dressing applied. If, notwithstanding this, suppuration follows, with deep infiltration of the cellular tissue, and sloughing of the skin and muscles, the choice lies between amputation and the preservation of a limb that will be withered, contracted, and useless.

If the gangrene be the result of direct strangulation by an over-tight bandage, as in Fig. 166, there is no resource left but amputation above the seat of constriction.

After a fracture has united, the limb will sometimes be found to be **shortened**. This may of course be due to unskilful management on the part of the Surgeon, to want of proper coaptation of the fragments, or to the patient being allowed to bear on the limb whilst the callus is still soft and pliable. But it may have existed before the accident, and be natural to the patient and in no way a consequence of the accident.

Inequality in the length of the corresponding limbs on opposite sides of the body, independently of any accident or disease, is not very unfrequently met with. It may exist to a considerable extent without the patient being aware of it. I have several times found the spinal curvature of young adults to be due to one lower extremity being from $\frac{1}{2}$ to $\frac{3}{4}$ of an inch shorter than the other, thus causing obliquity of the pelvis. It is usually the right limb that is the longer, but in some cases the left is not only longer but also larger. Of 512 boys examined by Morton, of Philadelphia, appreciable differences between the two limbs were found in 271 cases, from $\frac{1}{4}$ of an inch in 91, to as much as $1\frac{3}{4}$ inch in one. The bearing of these facts on the cause of shortening of limbs after the treatment of fractures, and the question of malpraxis, is evident.

The shortening of a limb in a growing child after fracture may also be due to its necessary confinement in splints, and to the inaction causing interference with its growth, or to implication of an epiphysial cartilage, and not to the fracture having been inaccurately adjusted.

COMPLICATED FRACTURES.—Fractures may be **complicated** with various important local conditions. Extravasation of blood into the limb, from a wound of some large vessel, may go on to so great an extent as to occasion strangulation of the tissues; if not checked by position and cold applications, it may give rise to gangrene, and demand amputation. In other cases, again, the soft parts in the vicinity of the fracture may be contused to such a degree that they rapidly run into slough, thus rendering it compound; or a wound may exist, not communicating with the broken bone, but requiring much modification of treatment, and special adaptation of apparatus.

One of the most serious complications is **Injury of the Main Artery** of the limb opposite the seat of fracture. This is, however, far less common than might be supposed. Excluding complete smashes of the limb, Bruns, with considerable labour, has collected 87 cases, 63 in simple and 24 in compound fractures. The accident is far more common in the lower than in the upper limb, 68 of the cases occurring in the former and 19 in the latter. Amongst the cases were 24 of injury of the popliteal artery, 21 of the anterior tibial, 13 of the posterior tibial, 9 of the brachial, 8 of the axillary, 4 of the femoral. Amongst the other arteries rarely injured are the subclavian in fracture of the clavicle, the sciatic in fracture of the pelvis, the peroneal and the nutritive artery of the tibia. In 68 cases the exact nature of the injury is mentioned. In 24 the artery was completely ruptured, in about half the cases by the same violence that caused the fracture; in 26 the artery was partially divided; in 7 it was contused and subsequently occluded by thrombosis; and in 11 it was compressed or nipped by the fragments. The symptoms will depend on the nature of the injury. **If the vessel is merely compressed or contused** there will be no extravasation of blood, and the nature of the injury is indicated by loss of pulsation in the branches beyond the injured point and coldness of the limb. **If the artery is completely torn across** it commonly soon ceases to bleed, being closed in the way already described (p. 407), but before this occurs a considerable amount of blood may have been poured out subcutaneously. The symptoms in such a case would be great distension of the limb, ceasing to increase after a short time, with absence of pulsation beyond the injured point. The chief danger in these cases is the supervention of gangrene, a termination more likely to follow when the fracture is the result of direct violence crushing the soft parts as well as the bone, than when the artery has been injured by the displaced fragments in a fracture by indirect violence, the surrounding tissues being but little contused. The *treatment* in these cases will depend on the nature of the injury. If the artery is merely compressed by a displaced fragment, reduction of the fracture may restore the circulation. If it is occluded, with little or no extravasation and but slight bruising of the soft parts, so as to justify a hope that the collateral vessels are not greatly injured or pressed upon, an attempt should be made to save the limb. It should be placed in the best possible position and warmly wrapped in cotton-wool. Splints and bandages must as far as possible be avoided, lest the collateral circulation be interfered with by their pressure. If there has been great extravasation of blood, the pressure of which would

evidently prevent the establishment of the collateral circulation, gangrene is inevitable, unless this can be relieved. If the fracture is from indirect violence, and the soft parts are but little contused, an attempt might be made to relieve the pressure by free incision and evacuation of the blood clot, if this can be done with efficient antiseptic precautions. If decomposition occurred the septic inflammation and swelling would almost inevitably so far interfere with the circulation as to cause gangrene, and necessitate amputation under very unfavourable circumstances. If, therefore, there is any doubt about preventing putrefaction, or if the soft parts are much bruised, as in a fracture by direct violence, or if after an attempt to save the limb gangrene has set in, amputation above the seat of injury is our only resource.

If the artery be only partially ruptured or be torn across and not closed, the hemorrhage will continue subcutaneously. In the great majority of cases this leads to the formation of a so-called diffused traumatic aneurism. The symptoms consist in the rapid formation of a uniform elastic tense swelling, in which there may be obscure pulsation, though this is often wanting. On laying the hand on the swelling a thrill may be perceptible. According to V. Wuhl, a bruit will be heard in all cases in which the artery is merely punctured or partially divided, but it is wanting when the vessel is completely torn across. There is cessation of pulsation in the artery with coldness and numbness of the limb beyond the injury. Some blood usually finds its way into the limb by the collateral vessels even if the main artery, as the femoral or brachial, be wounded, but the pressure of the extravasated blood hinders the venous return and the limb soon becomes of a dusky purple colour. There is always severe tensive pain, sometimes throbbing. If it be one of the tibial arteries that is wounded the swelling may cease to increase, the circulation in the arteries of the foot may return after a day or two, and the coldness and numbness may diminish, but such a result is rare. If it be the popliteal that is injured, no such amelioration will take place, but the arterial extravasation in the ham will increase, the circulation will become more and more impeded, and gangrene will result. Much less commonly the traumatic aneurism may develop slowly from eight days to a month after the accident and then it assumes the circumscribed form. In these cases the wound has probably been very small, or possibly the external coat may not have been torn at the time of the accident but has yielded subsequently.

In the **treatment** of subcutaneous arterial extravasation complicating fracture the Surgeon has three alternatives.

1. The case may be treated as one of open arterial wound, the tumour laid open, and the vessel ligatured at the seat of injury. The objections to this treatment are, that a large cavity is opened, which, if it suppurates, will give rise to the most serious constitutional disturbance, the fracture being rendered a compound one of the worst kind, complicated by the great extravasation of blood amongst the surrounding parts. Securing the artery is, moreover, under any circumstances extremely difficult, and even uncertain. In the present day the dangers of suppuration and sloughing following in the cavity may be greatly reduced, if not abolished, by the employment of some efficient mode of antiseptic treatment, and the exposure of the artery can be facilitated by the bloodless method of operating. If the means of treatment at the command of the Surgeon are such that he may hope effectually to prevent the injurious consequences of exposing the fracture to the air, there is no reason why he

should deviate from the acknowledged rule of Surgery, to tie the wounded vessel at the injured spot.

Amongst the cases tabulated by Bruns are the following treated by this method :—Axillary artery, 3 cases, 2 deaths ; brachial, 2 cases, 0 deaths ; femoral, 1 fatal case ; anterior tibial, 7 cases, 5 cured, 1 amputated, and 1 death ; and posterior tibial, 2 cases, 1 amputated and 1 died. In two of the cases of the anterior tibial the vessel could not be tied, and the wound was plugged successfully. In the successful axillary case the aneurism did not appear till the eighth day.

2. The circulation through the main artery may be arrested by compression or by ligature on the proximal side. Bruns records five cases in which compression was attempted. Of these three were successful. In one the artery wounded was supposed to be the circumflex at the shoulder ; in the two other cases the injured vessel was the anterior tibial ; but in both the aneurism was of small size and slow formation. Compression failed in a circumscribed aneurism of the brachial, and still more markedly in a large diffuse aneurism of the femoral artery. Proximal ligature is recorded in seven cases. In one the subclavian was tied for a diffuse axillary aneurism with a fatal result ; in one the axillary was tied for a circumscribed aneurism of the brachial ; in one the femoral was tied successfully for a popliteal aneurism, which appeared four days after the fracture, and in one for a diffuse popliteal aneurism, fatal from gangrene ; and in three cases, only one of which was really diffused, the femoral was successfully ligatured for aneurism of the posterior tibial.

3. Amputation may be performed. This severe measure need not be carried out at once. The Surgeon may wait a day or two and watch the progress of events. If he find that there is no sign of restoration of pulsation in the vessels beyond the injury, that the coldness and numbness of the limb continue to increase, and, in fact, that gangrene is impending, then the sooner he amputates the better for the patient's safety. If the artery have been tied, and gangrene result, the limb ought at once to be removed.

To sum up : It would seem from the evidence before us that if one of the larger vessels, such as the femoral, popliteal, axillary, or brachial, be wounded in a fracture, and a rapidly spreading extravasation form at once, the best chance for the patient lies in following the ordinary treatment of subcutaneous arterial extravasation, and attempting to secure the bleeding vessel at the injured point. In such cases compression is inefficient, and proximal ligature will probably be followed by gangrene. If the vessel cannot be found owing to the laceration and displacement of the surrounding structures, or if the bones are much comminuted and the soft parts crushed, amputation above the seat of fracture is the only resource. If the aneurism develops slowly and tends to assume a circumscribed form, compression or proximal ligature offers a good prospect of success. In wounds of the arteries of the leg, if the extravasation be not increasing with dangerous rapidity so as to threaten gangrene of the limb, there can be no reason why the effects of pressure upon the femoral artery by means of Cartes's or some other appropriate compressor should not be tried before proceeding to more severe measures. If this should fail to cure, and the aneurism should yet show some tendency to become circumscribed with return of pulsation, warmth and sensibility in the parts beyond, proximal ligature of the femoral artery in Scarpa's triangle offers a good prospect of success ; but should the swelling continue to increase and the foot remain

cold, no time should be lost in cutting down upon the injured vessel, a proceeding which has been attended with a very considerable amount of success, even before the introduction of antiseptic treatment and bloodless surgery. If the vessel cannot be tied it may possibly be seized in forcipressure-forceps, which may be left on for twenty-four or forty-eight hours. Failing this, the wound may be plugged. Amputation should be the last resource.

Venous Thrombosis and Embolism.—Wounds of veins in simple fractures rarely give rise to any extensive extravasation of blood, the rare examples of laceration of the subclavian vein in fractures of the clavicle being almost the sole exception. Thrombosis of the deep veins of a fractured limb, especially of the leg, is, however, probably far from uncommon. When we consider the bruising they must frequently suffer, the readiness with which coagulation takes place in the injured veins, and the interference with the venous flow by the prolonged rest of a fractured limb, it is surprising that extensive thrombosis is not more common. It occurs most frequently in the lower limb, though cases are occasionally met with in the arm. As the thrombosis is almost invariably limited to the deep veins, the only evidence of its occurrence is some oedema of the extremity, and perhaps some fullness of the superficial veins. As long as the patient is confined to bed, the elevated position of the limb and the pressure of the splints keep this oedema within very moderate limits, but when the patient begins to move about the swelling becomes more evident. It is probable that the persistent oedema, which is a not uncommon and very troublesome sequela of fracture of the leg, is due to this cause.

Accidental dislodgment of the clot and embolism of the heart or lungs is a very rare complication of simple fractures. Bruns has, however, collected the records of 35 cases, of which 30 were fatal. Thirty-two of these occurred in fractures of the lower extremity. Only one such case has occurred in University College Hospital in the last twenty years, and in that the patient, who had nearly recovered from a compound fracture of the internal malleolus, was suddenly seized with dyspnoea and great cardiac distress, followed by slight hæmoptysis. The symptoms subsided in a few hours, and recovery took place.

Injuries of Nerves in Simple Fractures.—Nerves may suffer a variety of injuries in fractures of the limbs. They may be bruised by the same force that causes the fracture; they may be crushed, or in rare cases even divided, by the sharp edge of a splinter; they may be compressed by a displaced fragment; and they have even been known to become interposed between the broken ends. As the fracture unites, a neighbouring nerve may occasionally become imbedded in the callus, and thus compressed. The most frequent complications of this kind occur in the upper limb, the musculo-spiral, from its intimate relation to the humerus, being peculiarly liable to suffer. The brachial plexus is occasionally injured in fractures of the clavicle and of the upper end of the humerus, the ulnar nerve in fractures of the lower end of that bone, and the external popliteal in injuries of the upper part of the tibia. Other nerves are but rarely affected. The symptoms are those already described in the chapter on injuries of nerves as occurring in consequence of wounds or pressure. If the impairment of function comes on at a later period, during repair of the fracture, it may be concluded that it is due to the pressure of callus. It is wiser, in all fractures in which an injury to a nerve is likely to

occur, to examine for it before applying the splints, otherwise it will be overlooked till the apparatus is finally removed, and it is then impossible to say whether the paralysis is due to an injury at the time of the accident or to the pressure of callus. No *treatment* is required beyond galvanism of the paralysed muscles when the injury is merely due to bruising at the time of fracture. If recovery does not take place spontaneously, and if there is reason to believe that the nerve is divided or surrounded by callus, an operation may be undertaken at a later period. Bruns mentions 30 cases in which such operations have been performed, in 20 of which the musculo-spiral was the nerve affected. In most of these it was necessary to remove the callus surrounding the nerve by means of a chisel. Complete restoration of function followed in 24 cases.

Comminution.—However extensively a bone may be **comminuted**, good union will take place provided the fracture be simple. I have seen the lower end of the femur crushed, as if by a sledge-hammer, into a multitude of fragments; and yet excellent union resulted, the fracture being simple. In such a case as this, if there had been the smallest wound to admit air into the limb, and decomposition of the effused blood had followed, the patient's limb, if not his life, would have been lost. It is, in fact, impossible to over-estimate the advantage of an injury of this kind being *subcutaneous*.

A serious complication of simple fractures consists in the **Implication of a Joint**.—The fracture may extend into a neighbouring articulation, and thus give rise to considerable inflammation; in strumous subjects this may lead to ultimate disorganization of the articulation, requiring excision, which I have several times had occasion to perform in these cases. But in healthy individuals a large articular surface may be traversed by lines of fracture in several directions, without material inconvenience resulting. This we see in impacted fractures of the condyles of the femur or of the lower end of the radius. In several instances of this kind in which I have examined the limb after death, no sign of disease of the part has been manifested beyond a moderate amount of injection of the ligaments: the fractured cartilage being united by plastic matter, and the synovia being clear and free from inflammatory exudation. But, although union of fractures extending into articulations takes place readily enough, it cannot be expected that the patient will recover with as mobile a joint as if the fracture had traversed merely the shaft. In fact, in the majority of these cases, the patient will be left with a joint that is weak, stiff, and painful; and, if in the lower extremity, the limb may be unable to support the weight of the body for some considerable time. Possibly also, in many of these instances, an impaired joint will be left through life, as the necessary and unavoidable result of the injury, though not unfrequently unjustly attributed to negligence and want of skill on the part of the Surgeon. Hence it is a wise precaution for the Surgeon when called to a case of fracture involving any one of the six larger articulations, viz., the shoulder, elbow, wrist, hip, knee, or ankle, to warn the patient that some degree of impairment of the use of the limb will probably result.

In cases of simple fracture occurring in the neighbourhood of, or implicating large joints, passive motion is very commonly recommended at the end of from four to six weeks: I think, however, with Vincent, that it is often apt to do more harm than good, and is seldom required, the natural action of the muscles of the part being fully sufficient to restore the movements of the articulation, with the assistance of friction and douches.

The occurrence of **Dislocation** at the same time as the fracture often causes great difficulty, as it becomes necessary to reduce the dislocated joint before the fracture is consolidated. In several instances of this kind which have come under my care, I have succeeded in reducing the dislocation at once, by putting up the limb very tightly in wooden splints, so as to give a degree of solidity to it, and to permit the lever-like movement of the shaft of the bone to be employed: and then, putting the patient under chloroform, I have replaced the bone without much difficulty. Should the Surgeon have omitted to reduce the dislocation in the first instance, he must wait until the fracture has become firmly united, and then, putting the limb in splints or in starch, he may try to effect reduction, which, however, will then be very difficult.

In addition to the foregoing complications I have met with many others, such as fracture in a limb which is the seat of an **Old Unreduced Dislocation**, or an **Ankylosed Joint**, or in the **Site of an Excised Joint** or in the **Stump of an Amputated Limb**. In such cases union has taken place readily, the splints being necessarily modified in such a way as to adapt them to the altered form of the limb.

Amputation is only required in simple fractures for gangrene either from tight bandaging, the direct effect of the injury to the soft parts, or wound of the main vessels. These complications are very rare, and I have never been obliged to amputate for a simple fracture. No amount of comminution will necessitate the operation if the skin and the main vessels are sound. I have had under my care a man, in whom the condyles of both femora and the left patella were crushed into numerous pieces by a fall from a great height on the knees, the limbs at the seat of the injury feeling like bags of loose fragments of bone: yet, as neither the skin was broken nor the main vessels injured, though both knee-joints appeared to be disorganized, the limbs were preserved, and good union ensued.

Compound Fracture.—A compound fracture is one in which there is an open wound leading down to the broken bone at the seat of fracture. Thus the term includes injuries varying in severity from a single fracture complicated by a small punctured wound of the skin made by one of the fragments to a complete smash of the whole limb, such as is made by a railway-train passing over it. Compound fractures therefore include many injuries far more severe than any simple fracture can possibly be; but, in a very large proportion of cases, the injury to the soft parts and the splintering of the bone are no greater than in many simple fractures, the sole difference being that, in the one case, there is a wound by which the causes of decomposition can find access to the decomposable blood-clot and inflammatory exudation surrounding the broken ends of the bone, while in the other they are excluded by the unbroken skin. As a consequence of this, unless special means are taken to prevent it, decomposition sets in, the blood-clot breaks down and is discharged, and the septic matter in the cavity of the wound excites inflammation, reaching the stage of suppuration, in the surrounding tissues. Portions of the bruised muscles and the torn periosteum, which in a simple fracture would either have recovered, or if too severely injured would have been penetrated by wandering cells and absorbed, may perish in consequence of the additional irritation caused by the septic matter and finally be cast off in sloughs. From the same causes portions of the ends of the bones which may

have become denuded of their periosteum, or detached splinters, undergo necrosis. In many cases also the external wound is too small to allow of efficient drainage, and consequently the pent-up septic matter burrows widely in the intermuscular spaces of the limb. If, therefore, the decomposition of the discharges cannot in some way be prevented, a compound fracture is not only far more tedious in its cure than a simple fracture, but infinitely more dangerous. It has to unite by a slow process of granulation instead of the more speedy mode of union already described as occurring in simple fractures. The chief dangers of a compound fracture, however, arise from the decomposition of the discharges. During the first week there may be severe septic fever; the stages of granulation and suppuration are often attended with profuse discharge of pus from the original wound and from abscesses forming amongst the surrounding muscles, maintained for a long time by exfoliation from the ends of the fractured bone. The patient may thus be worn out by the prolonged suppuration and the persistent absorption of the products of putrefaction; or the wound may become the seat of some infective process, and death may occur from septicæmia, pyæmia or erysipelas. In other cases the septic inflammation may spread to the medulla of the bone, causing diffuse osteomyelitis, followed by extensive necrosis, a condition frequently terminating in pyæmia. Thus a compound fracture leads not unfrequently to the eventual loss of life or limb. Besides these dangers, which may be looked upon as indirect, the violence that occasions a compound fracture often shatters the limb to such an extent as to lead to the immediate supervention of traumatic gangrene, to the loss of life by hæmorrhage, or to the certain and speedy disorganization of the limb, as the consequence of the subsequent inflammation.

Union of Compound Fracture.—If the superficial wound heal by the first intention, or if the evil effects of decomposition of the discharges can be prevented, a compound may unite in exactly the same way as a simple fracture. Under other circumstances union takes place more slowly by granulation, just as in wounds of the soft parts healing by the second intention. If the injury of the soft parts be but slight and the drainage good, the first process is an abundant inflammatory exudation from the vessels of the injured tissues. This coagulates, the serum draining away partly by the open wound and partly by the lymphatics, and the fibrin, entangling the white corpuscles in the meshes of its coagulum, forms a layer of plastic exudation which covers the injured soft parts and closes the intermuscular spaces. The exudation is very abundant round the bone, and the swollen and infiltrated periosteum, fused with the neighbouring tissues, soon forms a soft mass surrounding the broken ends, as in a simple fracture. Similar changes occur in the medulla. Then follow the formation of new vessels and the development of granulation-tissue; the wound slowly closes up from the bottom, the broken ends becoming by degrees completely imbedded in the growing granulation-tissue. Finally, ossification takes place. This commences in contact with the bone on each side in the granulation-tissue at the point furthest from the seat of fracture. It occurs without the previous formation of cartilage, even in the lower animals, or at any rate with the development of merely a few irregular islets. The intercellular substance increases in quantity, the cells assume the angular forms of osteoblasts, and then follow the deposit of lime-salts and the development of true bone. The

new bone gradually encroaches on the granulation-tissue, and the fractured ends are surrounded by it. The remaining changes are the same as those in a simple fracture. In cases in which the injury has been more severe and in which the process is complicated by the presence of portions of muscle which have either been directly killed by the violence which caused the fracture, or have perished from the combined effects of the injury and of the irritation of decomposing discharges, or by loose splinters, the process of union cannot take place till these are separated by ulceration from the surrounding living parts and are thrown off. In other cases in which the denuded ends of the bones perish, the process of separation may not be complete for many months after the injury. Under these circumstances the sequestra may be surrounded by a mass of new bone uniting the upper and lower fragments and perforated by openings for the discharge of pus from the granulations lining the cavity in which the dead bone lies, and thus a tolerably firm union may take place long before the wound has healed. This process necessarily, in the great majority of cases, occupies a much longer time than that which is required for the union of a simple fracture. The majority of compound fractures, however, unite without the occurrence of necrosis.

Question of Primary Amputation.—The first question that presents itself in a case of compound fracture is, whether the limb should be removed, or an attempt be made to save it. It is of great importance to settle this point at once; for, if amputation be determined upon, it should be done with as little delay as possible, there being no period in the progress of the case so favourable for operation as the first twenty-four hours.

That primary amputations are often fatal, especially when practised near the trunk, cannot be urged as an argument against their performance, as recourse should never be had to *primary* amputation unless it is evident that the patient's life must in all probability be sacrificed by an attempt to save the limb. In determining the cases in which immediate amputation should be performed, much must be left to the individual judgment and experience of the Surgeon. One will attempt to save a limb which another would condemn. But he must bear in mind that, though it is imperative to do everything in his power to save a limb, yet the preservation of the patient's life is the main point, and that course is the proper one which offers the greatest prospect of effecting this. A wise conservatism is much to be applauded, but decision in determining the expediency of amputation is equally characteristic of a good Surgeon. He must consider, not only the nature and extent of the fracture, but the age, constitution, and habits of the patient: and though he may be guided by those general rules which have already been laid down (pp. 338 and 358, when treating of amputation in contused wounds and in gunshot injuries, yet he will often show more wisdom in departing from the letter of the law in making a successful effort to save a limb, which, by strict surgical precepts, would be condemned: or in attempting to preserve the patient's life, by sacrificing a limb that is not injured to a degree that would usually be considered to justify amputation.

1. It may be laid down as a general rule to which there are few exceptions, that all compound fractures, the result of *indirect* violence, in which the wound is made by the fragments of the broken bone, should be saved, provided the main vessels of the limb are uninjured.

2. Fractures by *direct* violence in which the same force injures the soft

parts and breaks the bone, are, as a rule, less favourable. In such cases there is often *much laceration of, and extravasation into, the soft parts*. The integuments may be stripped off, portions of the muscular bellies may protrude, and the planes of areolar tissue between the muscles of the limb may be torn and infiltrated with blood. Injuries of this kind occurring in the lower extremity always necessitate amputation. In the upper limb, even after very extensive injuries of this kind, the limb may often be saved, unless the bones be greatly comminuted. The danger of the operation in these cases does not depend upon the degree of injury to the soft parts and bones, but upon the proximity of the fracture to the trunk (see pp. 86 and 361). Amputation of the thigh high up for fracture of the femur is very rarely followed by recovery.

3. The complication of a compound fracture with the **Wound of a Large Joint** is always serious, but does not in itself necessitate amputation, provided the patient be of sound constitution and be placed in such circumstances that efficient antiseptic treatment can be carried out and perfect rest and drainage maintained. If there be much crushing or splintering of the bones, with laceration of the soft parts, operative interference becomes necessary. In the lower limb amputation should be performed, unless it be the hip-joint that is damaged, when there will generally be so much injury of the pelvic bones and their contained viscera as to preclude the performance of any operation. In the upper limb, if the bones are comminuted, but the soft parts not too extensively injured, excision may be substituted for amputation, especially in the shoulder or elbow-joint. This operation is usually a somewhat irregular proceeding, consisting rather in picking out the shattered fragments of bones, and sawing off projecting and sharp-pointed fragments, than in methodical excision. In children recovery without operation may often be obtained in cases that would be hopeless in the adult.

Separation of an Epiphysis, with Protrusion of the End of the Shaft through the Skin, is occasionally met with in young people, and may be mistaken for a fracture implicating the joint, but in these cases, although the fracture is in close vicinity to the joint, the articulation is not affected, and careful examination will always prove its sound condition. Reduction is difficult, and it is sometimes impossible to maintain it without sawing off the projecting end of the shaft. This is easily done, and union takes place readily between the epiphysis and the remainder of the shaft. In two instances in which I have had to do this in lads—in one near the shoulder, in the other near the ankle—an excellent result without impairment of the joint followed the operation.

4. When one of the **larger Arteries of the Limb has been wounded** by the violence that occasions the fracture, or has been lacerated by the broken bone itself, there may be copious arterial hæmorrhage externally, as well as extravasation into the general areolar tissue of the limb. In such cases, whilst the patient is being examined, and preparation made for operation, dangerous loss of blood must be prevented by the application of a tourniquet. For want of this simple precaution, I have seen very large and even fatal quantities of blood gradually lost, by being allowed slowly to trickle from the wound.

The treatment of this complication will depend upon the amount of hæmorrhage and the size of the vessel wounded. If the vessel be small and the bleeding slight, elevation of the limb and the application of cold may be

tried. If these fail, or if the hæmorrhage be more copious, the Surgeon should freely enlarge the wound and endeavour to expose the artery at the bleeding point, and apply a ligature to the vessel above and below the seat of injury. Owing to the displacement of the parts and the infiltration of the tissues with blood, it may be impossible to find the injured vessel. Under these circumstances the search should not be prolonged to such an extent as materially to increase the disorganisation of the limb, but amputation should be performed.

Secondary hæmorrhage occurring in the course of treatment of a compound fracture of the lower extremity is very rare; if slight, it may be arrested by elevation and pressure. Should these simple measures fail, the Surgeon must be guided by the condition of the wound. If this be favourable it should be enlarged, and an attempt made to ligature the vessel at the bleeding point. If this should not succeed, or if the septic condition of the wound render the attempt impossible, the main artery of the limb should be tied at a higher level. Thus in many cases ligature of the superficial femoral has been successfully adopted in cases of secondary hæmorrhage complicating a compound fracture of the leg. Amputation should be delayed until after the consecutive employment and failure of other methods. Pearce Gould has recorded a case of compound fracture of the leg, complicated by secondary hæmorrhage from the anterior tibial artery on the 25th day, in which he successfully ligatured both ends of the vessel through a free incision.

5. Comminution or Splintering of the Broken Bone is always a serious complication, but if drainage can be established and decomposition prevented, it is robbed of most of its dangers. Should the wound become septic, extensive suppuration will set in; the splinters, if completely or nearly detached, will lose their vitality, and not only produce much irritation, but, if numerous, will, on their removal or separation, leave the member shortened and permanently deformed. The treatment of such cases will depend on the seat of the injury and the extent of the comminution. Compound and comminuted fractures of the femur may, except when occurring in the upper third, generally be looked upon as cases for immediate amputation (see p. 358); the only other exceptions being when the comminution is trifling, the splinters large and lying in the axis of the bone, and the subject young. In the arm, forearm, and hand, and in the leg, provided the knee and ankle-joints be not involved, much may be done in the way of removing splinters of detached bone, and sawing off smoothly the rugged ends of the main fragments. The larger attached and "secondary" pieces should be left, as they will throw out callus and become buttresses of support to the broken bone (see p. 358). If a considerable quantity of splintered bone have been extirpated from a limb, care must be taken that in putting up the fracture too complete extension is not maintained, lest a gap be left, which cannot be filled up by new bone, and a weakened limb result. It is better to place the bones in proper apposition, and to let the patient recover with a shortened but strong and otherwise useful limb.

6. In the case of a bad Compound Fracture requiring Amputation low down in a Limb, with a Simple Fracture high up, should the amputation be performed above the compound and below the simple fracture, or above both? The answer to this must depend on the condition of the limb between the fractures. Suppose that there be a badly comminuted and con-

pound fracture of the lower third of the leg, with a simple fracture of the middle of the thigh; or a crush of the hand or forearm, with simple fracture of the middle of the humerus. The proper course to adopt, if the intermediate soft parts are sufficiently sound, is to remove the limb just above the lower fracture, the upper fracture being treated on ordinary principles. But if there be extensive bruising of the limb with deep extravasation between the fractures, then it would clearly be useless to amputate low down, as not only would the stump have to be formed of severely injured tissues, but if septic inflammation set in at the seat of operation, it would speedily spread upwards to the higher fracture, converting it into a compound one of the worst kind. In such cases, therefore, the proper course is to remove the limb at or above the line of the higher fracture.

7. The complication of a **Dislocation high up, with a compound Fracture low down**, is not so serious. The dislocation having been reduced, the fracture is to be treated according to the principles already laid down. If amputation be required it may be safely performed, as in a case under my care some years since, in which I had occasion to amputate the forearm of a young man for a bad crush by machinery, the case being complicated by a dislocation of the humerus.

In some cases in which there is great doubt as to the possibility of saving the limb, especially in compound fractures of the upper limb and foot, the injured part may be dressed antiseptically, and amputation, if necessary, performed at a later period. The exclusion of putrefaction will prevent the septic fever, the spreading inflammation, and the dangers of general infection, which in former times made it safer to perform a primary amputation in all cases in which the prospects of recovery without operation were very doubtful.

TREATMENT OF COMPOUND FRACTURE.—In the management of a compound fracture, more especially of the lower extremity, special apparatus, such as McIntyre's, Thomas's, or bracketsplints, swing-boxes, and fracture-beds, are often necessary, in order to obtain access to the wound, and to place the limb in the best position for union. In many cases the starched or plaster bandage may very advantageously be used; but it requires caution, as swelling and consequent strangulation of the limb may take place under it.

There are several points that require special attention. These are: 1, the Reduction and the Management of Protruding Bone; 2, the Management of Splinters; 3, the Treatment of Oozing of Blood; 4, the Treatment of the Wound.

1. The **Reduction of compound fractures** must be accomplished with the same care and gentleness as that of simple ones. In the majority of cases, no great difficulty is experienced; and after reduction, the limb should be placed on a well-padded splint, properly protected in the neighbourhood of the wound with oiled silk, so as to prevent soiling of the pads by blood and discharge. In some cases, however, considerable difficulty arises in the reduction, from the protrusion of one of the broken fragments which has been driven through the skin at the time of the accident, or from careless handling of the limb in carrying the patient, or else from the muscular contractions dragging the lower fragment forcibly upwards, and thus causing perforation of the integument. The protruded bone, after being carefully cleaned with some antiseptic solution, must, if possible, be gently replaced, by relaxing the muscles of the limb. Sometimes, however, it is so tightly embraced by the

skin, that enlargement of the wound becomes necessary before it can be replaced. In other cases, again, reduction cannot be effected or maintained, unless the sharp and projecting point of bone be sawn off. The limb as I have found in several cases in which it has been necessary to have recourse to this procedure, is not ultimately weakened, or necessarily shortened by it.

2. In the **Management of Splinters** the Surgeon will be guided by the circumstances. If the splinter be completely loose and small it is always better removed. If it be very large, two inches or more in length, forming in fact rather a fragment of the bone than a splinter, it may be left, even when completely loose. If a splinter is still attached by periosteum it may usually be safely left, even when small.

3. **Treatment of Oozing of Blood.**—In cases in which there is evidently no important vessel wounded, blood often continues to ooze slowly from the wound, and it becomes a question whether anything should be done to arrest it. The only means at our command are elevation of the limb, cold, and pressure. The two former of these may be resorted to whenever the oozing may seem sufficient to render it necessary, but pressure should be avoided if possible. The blood is coming in all probability from the deep parts, very often from the bone itself; pressure, therefore, cannot be applied to the bleeding surface. If applied externally it merely causes the intermuscular spaces and the cavity of the wound to be distended with blood, and should decomposition follow the consequences are most serious. The oozing will always stop by itself after a few hours, and if the patient should lose a few ounces of blood in that way it is better than having the same quantity extravasated into the limb.

4. **Treatment of the Wound.**—After reduction the great object is, if possible, to obtain union of the external wound by the first intention or by healing under a scab, thus converting the compound into a simple fracture and avoiding the danger of suppuration. If the wound be small, clean-cut, and occasioned by the protrusion of the fragment rather than by the direct violence which occasioned the fracture, we may hope to succeed in our object. In order to do this the wound must on no account be washed with simple water, which would materially increase the risk of decomposition taking place in the extravasated blood or serum. If an efficient antiseptic solution be at hand, such as carbolic lotion (1 in 20), perchloride of mercury (1 in 1000), or tincture of iodine (5ij. to Oj), the wound and the surrounding skin should be cleaned with this and allowed to dry. If no such means are at hand, the blood should be wiped away with a clean dry linen rag. The opening may then be closed in a way recommended by Astley Cooper, by applying to it a piece of lint soaked in the blood and allowing it to dry. A better plan is to seal the wound with lint soaked in collodion or styptic collodion, or in compound tincture of benzoin. In this way an artificial scab may be formed beneath which union may take place. The dressing should be left undisturbed until it loosens of itself, at the end of a week or two, when the wound will probably be found to be closed. If, however, the patient after a few days begins to complain of pain, if the temperature rises and the leg becomes red, hot and swollen, the crust must at once be removed: and if pus flows from beneath it, it is safer at once to enlarge the wound freely.

Supposing the case to be one in which from the size of the wound, or the amount of swelling, it is evidently impossible to hope to close the wound by

scabbing, the Surgeon must then be guided by the same principles as in the treatment of any other open wound. The objects in view are, 1. To clean the wound thoroughly; 2. To provide good drainage; 3. To prevent decomposition of the discharges and infection of the wound; and 4. To maintain perfect rest.

It is better in all cases, whatever mode of dressing it is intended to adopt, to *syringe the wound out with some antiseptic solution*, as by this means any dirt which may have been forced into the wound at the time of the accident, or have adhered to the bone if it have been protruded, may be washed out. The best solutions for the purpose are carbolic acid and water (1 to 20); solution of perchloride of mercury (1 in 1000); tincture of iodine and water (1 to 80); or chloride of zinc (20 grs. to an ounce). The skin round the wound must also be cleaned with the same solution. In syringing out the wound, a glass syringe with a piece of stiff india-rubber tubing on the nozzle should be used. This will penetrate all parts of the wound and yet is not rigid enough to force its way amongst sound tissues. The lotion must be allowed to flow out freely, so as to avoid injecting the surrounding lymph-spaces with the irritating or poisonous antiseptic. In many compound fractures the air gets sucked in by the movements of the limb, and can be felt crepitating in the subcutaneous tissue for some distance on each side of the wound. In these cases it is not necessary to force the solution as far as the air has gone, as the latter seems to deposit its dust close to the wound, where it can easily be reached by the disinfectant. If the wound is many hours old or very dirty, it is well to put into it some iodoform in crystal to ensure a more permanent disinfecting action. Having cleaned the wound thoroughly, *provision must be made for efficient drainage*. In many cases the wound is large enough to allow of perfect drainage; if not, it may be enlarged, but it is scarcely ever justifiable, however large the wound may be, to insert stitches. If the skin is much undermined, a counter-opening may often be made with advantage, and a drainage-tube inserted. The *prevention of decomposition of the discharges and infection of the wound* is carried out by one of the methods of dressing already described in the Chapter on Wounds. In most cases the Surgeon will adopt that method of antiseptic dressing which he commonly uses for wounds in general. The mere fact that the wound is connected with a broken bone does not necessitate any special mode of treatment. The carbolic gauze dressing gave excellent results, but for reasons already given it has been largely replaced by the sal-alembroth and double cyanide gauzes, which possess the great advantage in the treatment of compound fractures that the first dressing can often be left undisturbed for many days or even weeks. For the same reason the dry absorbent dressings, such as iodoform-wool, salicylic wool, sublimate wool-wool, etc. give excellent results. In applying the dressing the gauze or wool should be wrapped smoothly round the limb in sheets so arranged that the dressing can be opened when it requires changing, while the limb is lying well supported and in a comfortable position. Thus in the case of a fracture of the leg treated by Cline's lateral splints, the edge of the dressing should be under the internal splint, so that it can be opened without disturbing the fracture while the leg lies on the outer splint. The dressings must be held in position by the splints; no bandage must be put on under the splints, as it is impossible to do this without disturbing the ends of the bone. In some cases the abundance of the serous discharge

renders it necessary to change the dressing at the end of twenty-four hours. Often, however, the first dressing can be left undisturbed for two weeks or more, when the wound will be found to have healed as if under a scab. If no discharge have soaked through the dressing, and if there be freedom from pain, no excessive elevation of temperature and no impairment of the circulation through the extremity of the limb, the Surgeon will be wise to leave the dressing quite undisturbed. Frequent dressing may undo much of the good done by the prevention of decomposition; for the greatest care cannot prevent some damage to the superficial blood clot and the growing granulation tissue.

The splints applied to a compound fracture should, as far as possible, be so arranged that the dressing can be changed without removing them. With this object the method suggested by Paul of Liverpool will be found most useful. Strips of soft iron covered with india-rubber are bent so as accurately to fit the contour of the limb. These are fixed to the limb by a paraffin or plaster of Paris bandage interrupted at the position of the wound, the edges being sealed with a mixture of bee's-wax and carbolic oil to prevent discharge from getting between the splint and the skin. The wound and the skin around it are thus exposed for the application of the antiseptic dressing. Splints made of perforated zinc may in the same way be purified and enclosed in the dressing. Packing the limb in a fracture-box with sawdust impregnated with perchloride of mercury is a cheap and efficient mode of treatment recommended by Thomas.

The open treatment, the iodoform treatment, and the application of terebene and oil, or carbolic oil, will also give good results if carefully carried out. The dressings may be changed with little or no disturbance to the limb, and thus good rest is maintained, but the prevention of putrefaction is not so certain as in the methods mentioned above.

If decomposition be prevented by one of the above means, and good drainage and rest be maintained, suppuration will be prevented entirely or reduced to an insignificant amount in the great majority of cases, and recovery will take place with but little more constitutional disturbance than in a simple fracture. Union is, however, in many cases delayed for a week or two beyond the time which is sufficient for the cure of a simple fracture even in cases that do well in other respects.

COMPLICATIONS OF COMPOUND FRACTURES. —Septic Inflammation and Suppuration.—This may arise from failure of the antiseptic means employed, or the Surgeon may be so placed that he has not the necessary materials at hand with which to undertake efficient antiseptic treatment. Under these circumstances the progress of the case will depend very much upon the nature of the injury. If the wound be of insufficient size to afford good drainage the intermuscular planes may become widely infiltrated with blood and inflammatory exudation; and as decomposition spreads in this, diffuse suppuration, with great swelling, pain and tension will be set up, accompanied by severe constitutional disturbance, possibly ending speedily in fatal septic poisoning, or at a later period in pyæmia. If the wound be larger, allowing free exit to the extravasated blood and the subsequent inflammatory exudation, the suppuration may remain limited to the wound, and be accompanied by but slight swelling of the limb or constitutional disturbance. It is, I believe, in consequence of the free vent thus afforded to the discharges that some of the

worst-looking cases of compound fracture, especially of the leg, eventually do the best.

Should septic inflammation and suppuration occur, an endeavour must be made to moderate the inflammation and lessen the constitutional disturbance. This is best effected by fixing the limb on a splint in such a way that, although the wound can be dressed, the apparatus shall be left undisturbed as long as possible. The great art in the treatment of a compound fracture under these circumstances consists in not disturbing the limb; for days or even weeks it may sometimes advantageously be left without interference when once it has been carefully put up. Should diffused swelling take place, the wound become sloughy, and much inflammation be set up in the limb, this may be moderated by the application of warm antiseptic applications, the best being boric acid lint moistened in warm boric lotion. The part should be elevated and but lightly covered, the bed-clothes being well raised by means of a cradle so as not to press on the limb; care being taken, at the same time, that the bandages be applied loosely, with only a sufficient degree of force to retain the limb upon the splint, as inflammatory infiltration, which might rapidly induce strangulation of the part, is apt to ensue. The constitutional irritation must be subdued by the administration of opiates, together with an aperient, repeated from time to time during the first few days. A moderate and cooling regimen must be employed, and the patient must be disturbed as little as possible. In many cases, if he be addicted to drink, symptoms of nervous irritation soon come on: in these circumstances, it is of great moment that support, and even stimulants, be freely given; they must be allowed from the very first, and increased in proportion to the depression of the patient's strength.

If there be much bruising and extravasation of blood, great tension of the limb, followed by sloughing, will take place in the neighbourhood of the wound; free incisions are then required to remove the tension, and, by letting out the decomposing blood and pus, to lessen the risk of gangrene, and diminish the fever resulting from the absorption of the products of putrefaction. If this be not done, deep infiltration takes place through the areolar planes of the limb, and the most extensive local mischief may result, pyæmia being almost certain to ensue. As soon as suppuration is fairly established, fomentations of boric lint, wet salicylic wool, or thick moist oakum dressing should be applied, and the wound may be sprinkled with iodoform; the burrowing of matter must be prevented by making counter-openings where necessary, and by attention to the position of the limb. The wound must be frequently syringed with carbolic acid lotion, Condy's fluid, or some other antiseptic. The fracture-apparatus must be kept scrupulously clean; the bandages changed as often as soiled, and the pads well protected with oiled silk. During this period various complications, such as septicæmia, pyæmia, erysipelas, inflammation of the lymphatics and veins, and septic pneumonia, are apt to occur, requiring special consideration and treatment: so also, if the discharge be abundant, symptoms of hectic may come on, requiring the free use of stimulants and the administration of the mineral acids and other remedies, according to circumstances. As the confinement to bed is necessarily very prolonged in these cases, often extending through many weeks and months, the state of the patient's back should be attended to, and he should early be placed upon a water-cushion or bed, lest sores supervene. As the wound

gradually heals, it may be dressed with some stimulating lotion such as the "red" or "blue" wash.

Septic Osteomyelitis was formerly a very common complication of compound fractures, but since the introduction of antiseptic dressing it is very rarely met with. The pathology, symptoms and treatment of this condition are described in the Chapter on Inflammation of Bone and its Effects (Vol. II. Chap. XLVI.).

Necrosis of the Ends of the Fragments.—In compound fracture in which suppuration has occurred the bone will often be observed lying white and bare, bathed in pus, at the bottom of the wound. But even in this apparently unfavourable condition it may recover, granulations gradually springing up on its surface and covering it in; in other cases, necrosis takes place, and perfect consolidation does not occur until the dead bone has separated. Curling has shown that those portions of necrosed bone which are connected with the lower fragment are slower in detaching themselves. In some instances a large quantity of provisional callus is formed, in which the necrosed bone is embedded, openings remaining through the shell thus formed for the exit of pus. In such cases it may be necessary to cut away some of the new bone to extract the necrosed portions when they are loose: but not uncommonly amputation becomes necessary, from the powers of the patient being unable to carry him through so prolonged a struggle.

The **time required for the consolidation** of a compound fracture in which suppuration has taken place varies greatly, according to the amount of injury done to the bones and soft parts, and the age and constitution of the patient. In the most favourable circumstances, it requires double or triple the time that is necessary for the union of a simple fracture. As soon as some union has taken place, the limb should be firmly put up in gutta-serena or leather splints, with a starched or plaster bandage, so as to enable the patient to be taken out of bed, to change the air of his room, and thus to keep up his general health. In fitting these splints, care must be taken to make an aperture opposite the wound, through which it may be dressed (Fig. 163).

Secondary Amputation may become necessary from the occurrence of traumatic gangrene, and then it must be done in accordance with the principles already laid down when speaking of that operation; it is also occasionally performed in the hope of preventing pyæmia when diffused septic osteomyelitis has set in; but more frequently it is required from failure of the powers of the patient in consequence of septic fever, induced by absorption of the products of putrefaction from the wound and the infiltrated parts around, or by hectic resulting from chronic suppuration. In these circumstances, by removing the source of the mischief in time and seizing an interval when the fever is at its lowest point, the patient's life will in all probability be preserved; the results of secondary amputation for compound fracture in these conditions being by no means unfavourable. Indeed it is remarkable how speedily the constitutional symptoms subside after the removal of the source from which the absorption of septic matter is taking place: the patient often sleeping well and taking his food with appetite the day after the operation.

The proper period to choose for the performance of secondary amputation in the earlier stages of the injury is often a most critical point. As a rule it may

he stated that, if the limb be not removed during the first twenty-four hours, eight or ten days must be allowed to elapse before the operation is done; as during that time the patient is suffering acutely from the early septic fever, and operations during this stage are notoriously fatal. But when granulations begin to spring up in the wound and oppose a barrier to the further absorption of septic matter, the fever subsides, and the limb may be removed with the best prospect of success. The thermometer is the great guide; as soon as it has decidedly fallen from the high septic fever point of from 104° F. to 105° F. to about 100° F. or lower, the operation may be safely undertaken. Should it appear, however, that the patient is becoming rapidly exhausted and will hardly survive to the desired time, amputation may be performed as a last chance during the period of septic fever. In these circumstances, however, the operation is seldom successful; the stump becomes sloughy, diffuse inflammation comes on, septicaemia or pyæmia may set in, and the patient speedily dies. In other cases, after the first fall of the temperature, it may frequently rise again owing to the formation of abscesses in the neighbourhood of the necrosed bone, or the burrowing of pus amongst the muscles; or the patient may gradually be worn out by the profuse discharge. In these cases the patient's power must not be allowed to sink to the lowest ebb before amputation is performed, as then the shock may destroy life; or, if he survive, the immediate effect of the operation in his weakened state predisposes him to be attacked by the various infective processes to which wounds are liable. Much as "conservative" surgery is to be admired and cultivated, and hasty or unnecessary operation to be deprecated, I cannot but think that the life of the patient is occasionally jeopardized, and even lost, by disinclination on the part of the Surgeon to operate sufficiently early in cases of compound fracture, and by too prolonged attempts to save the injured limb.

The success of the operation will in a great measure depend upon the *after-treatment*. Large quantities of stimulants and support are often required in London practice to prevent the patient from sinking. I have frequently given with the best results, eight or ten ounces of brandy, twelve or sixteen of port wine, or two or three pints of porter, in the twenty-four hours after these operations, with beef-tea, arrow-root, or meat, if the patient would take it; and have found it absolutely necessary to do so to obviate death from exhaustion.

At a later period, when, some weeks or months having elapsed, the fracture has not united, the bones are necrosing, and the patient is being worn out by hectic, amputation must be performed at any convenient moment, and is often done with great success if it be not deferred till too late; for here the cause of the mischief is entirely local, and the constitution, suffering only from the debility resulting from it, quickly rallies when it is removed.

MALPOSITION AFTER FRACTURE.—It may happen that at the end of two or three weeks a fractured bone is found in a faulty position. At this period the bond of union is soft and yielding, and the displacement, if angular, may usually be remedied by frequent re-adjustment of the apparatus, avoiding as far as possible the direct pressure of pads and bandages on the bone itself. If this period be allowed to pass by, and the fracture be allowed to become consolidated, it may be found to be so *badly set* that it is necessary forcibly to bend or break the callus, in order to improve the condition of the limb. When the displacement is angular, and the consolidation not very firm, as is usually

the case, this may be done readily enough; but if the displacement be longitudinal, and much time have elapsed since the occurrence of the injury, it will be difficult, if not impossible, to remove the deformity. The bending or breaking of the callus is best done under chloroform; the fracture being then put up again, speedy and perfect consolidation will ensue. In this way I have several times remedied a faulty position in fractured bones, although from six to ten weeks had elapsed from the occurrence of the injury.

Should the consolidation of the fracture be too firm to admit of this, *subcutaneous osteotomy* by Adams's narrow-bladed saw may be employed in some cases with advantage. I have thus divided the fibula into a badly-set Pott's fracture, where the bone had united at an angle pointing inwards, and thus throwing the outer edge of the foot upwards. In other cases again, it may be necessary to expose the bone at the seat of fracture by an incision, and to straighten it by simple division with a saw or chisel, or by the removal of a wedge.

A bone which does not appear to have been very skilfully set, and which presents a certain amount of deformity when the splints are removed, may gradually regain its proper shape. This it does by the muscles of the limb moulding the callus, whilst still somewhat soft and yielding, into a proper shape. The callus may be quite strong enough to bear the weight and to maintain the length of the limb in its full integrity after the removal of all apparatus, and yet be sufficiently yielding to become slowly and gradually shaped by the action of the muscles of the limb when they are left untrammelled by bandages.

But it more commonly happens that a limb which, when taken out of the splints at the proper period, appears to be straight and of good length, gradually yields under the weight of the body and the strain of the muscles: so that, at the end of a few weeks, most unsightly deformity occurs. In these cases the Surgeon is often unduly blamed; and to his unskilfulness is attributed that displacement which, in reality, is due to the faulty character of the callus. It must be remembered that there is every degree of firmness of the callus, from that which is of normal consistence to that which is quite unable to support the weight of the limb or body and which yields more or less quickly under the pressure to which it is subjected.

DELAYED UNION.—Occasionally, more particularly in cases of fracture of the femur, tibia, and humerus, the union between the fragments is *delayed* several weeks beyond the usual period. This arises, in the majority of cases, from constitutional debility rather than from local causes. Several cases of delayed union have been recorded in which repair readily took place after the administration of mercury; indeed, in syphilitic subjects the constitutional taint should always be treated. A not unfrequent cause of delayed union is "modelling" with the fracture, changing the apparatus, removing splints or frequently testing the solidity. When it is found at the expiration of six or eight weeks after the occurrence of simple fracture that the callus is still yielding, the general health should be improved by tonics, change of air, &c. and the limb securely put up in starched or plaster of Paris bandage. Indeed, I believe that delayed union is much less likely to occur in patients who have from the first been treated by the starched bandage, and allowed to move about, than in those who have been confined to bed or rather to the house in the ordinary way. Dunreicher recommends in these cases to constrict the limb for a short time above the fracture to such an extent as to

cause oedema and exudation round the broken ends. Swelling below is prevented by a flannel bandage reaching nearly to the seat of fracture.

UNUNITED FRACTURE.—A fracture is usually said to be ununited when the broken ends of the bone are not joined together solidly by new bone. There are three varieties of this condition:—1, *Independent Repair of the Fragments*, in which there is no union of any kind; 2, *Fibrous Union*, in which the fragments are bound together by firm fibrous tissue; and, 3, *False Joint or Pseudarthrosis*, in which there is no union between the fractured surfaces, but a capsule of fibrous tissue forms round them resembling the ligaments of a joint.

When the fragments undergo **Independent Repair**, the ends are rounded and the medullary canal closed by a thin plate of bone covered by a newly formed periosteum. In some cases after a time the ends become atrophied and somewhat pointed. This form of ununited fracture may be due to the wide separation of the fragments, as after great loss of bone in a compound fracture or the interposition of soft parts between the broken ends, or from various causes no callus may form; or the early formation of callus may have taken place, but owing to some peculiar general or local condition it may have become absorbed.

In **Fibrous Union** the ends of the bones are united by fibrous tissue, most commonly dense and ligamentous, but sometimes loose in structure. In this condition the early soft callus has formed, but instead of undergoing the normal development into bone it has been converted into fibrous tissue. This is usually the result of insufficient rest during treatment or of faulty position of the fragments. It is the most common form of ununited fracture.

In **False Joint or Pseudarthrosis** the two fragments are bound together by dense ligamentous tissue passing from one to the other, forming a more or less perfect capsule around the broken ends (Fig. 167). Between the actual surfaces of the fracture there is no union. They are smoothly rounded, the medullary canal being closed by a thin plate of new bone and invested with a layer of dense fibrous tissue or fibro-cartilage. The two surfaces are more or less adapted to each other like those of a normal articulation. In the humerus or femur one end is usually concave and the other convex; the false articulation thus resembles a normal ball-and-socket joint. In the forearm and leg, as lateral movement is prevented by the presence of two bones, the false articulation more closely resembles a hinge-joint. The inner surface of the capsule may be smooth, as if lined with a synovial membrane, and the cavity may be moistened with a glairy fluid resembling synovia. False joints of this kind are met with only in fractures of considerable standing, and it is probable that they are always preceded by fibrous union, and that the false joint is gradually developed by atrophy of the fibrous tissue between the ends of the bone, and more perfect development of that surrounding them. In very old false joints changes resembling arthritis of normal joints are

FIG. 167. False Joint in Humerus.

the case, this may be done readily enough ; but if the displacement be longitudinal, and much time have elapsed since the occurrence of the injury, it will be difficult, if not impossible, to remove the deformity. The bending or breaking of the callus is best done under chloroform ; the fracture being then put up again, speedy and perfect consolidation will ensue. In this way I have several times remedied a faulty position in fractured bones, although from six to ten weeks had elapsed from the occurrence of the injury.

Should the consolidation of the fracture be too firm to admit of this, *subcutaneous osteotomy* by Adams's narrow-bladed saw may be employed in some cases with advantage. I have thus divided the tibia into a badly-set Pott's fracture, where the bone had united at an angle pointing inwards, and thus throwing the outer edge of the foot upwards. In other cases again, it may be necessary to expose the bone at the seat of fracture by an incision, and to straighten it by simple division with a saw or chisel, or by the removal of a wedge.

A bone which does not appear to have been very skilfully set, and which presents a certain amount of deformity when the splints are removed, may gradually regain its proper shape. This it does by the muscles of the limb moulding the callus, whilst still somewhat soft and yielding, into a proper shape. The callus may be quite strong enough to bear the weight and to maintain the length of the limb in its full integrity after the removal of all apparatus, and yet be sufficiently yielding to become slowly and gradually shaped by the action of the muscles of the limb when they are left untrammelled by bandages.

But it more commonly happens that a limb which, when taken out of the splints at the proper period, appears to be straight and of good length, gradually yields under the weight of the body and the strain of the muscles : so that, at the end of a few weeks, most unsightly deformity occurs. In these cases the Surgeon is often unduly blamed ; and to his unskilfulness is attributed that displacement which, in reality, is due to the faulty character of the callus. It must be remembered that there is every degree of firmness of the callus, from that which is of normal consistence to that which is quite unable to support the weight of the limb or body and which yields more or less quickly under the pressure to which it is subjected.

DELAYED UNION.—Occasionally, more particularly in cases of fracture of the femur, tibia, and humerus, the union between the fragments is *delayed* several weeks beyond the usual period. This arises, in the majority of cases, from constitutional debility rather than from local causes. Several cases of delayed union have been recorded in which repair readily took place after the administration of mercury ; indeed, in syphilitic subjects the constitutional taint should always be treated. A not unfrequent cause of delayed union is "meddling" with the fracture, changing the apparatus, removing splints or frequently testing the solidity. When it is found at the expiration of six or eight weeks after the occurrence of simple fracture that the callus is still yielding, the general health should be improved by tonics, change of air, &c. and the limb securely put up in starched or plaster of Paris bandage. Indeed, I believe that delayed union is much less likely to occur in patients who have from the first been treated by the starched bandage, and allowed to move about, than in those who have been confined to bed or rather to the house in the ordinary way. Dumreicher recommends in these cases to constrict the limb for a short time above the fracture to such an extent as to

cause oedema and exudation round the broken ends. Swelling below is prevented by a flannel bandage reaching nearly to the seat of fracture.

UNUNITED FRACTURE.—A fracture is usually said to be ununited when the broken ends of the bone are not joined together solidly by new bone. There are three varieties of this condition:—1, *Independent Repair of the Fragments*, in which there is no union of any kind; 2, *Fibrous Union*, in which the fragments are bound together by firm fibrous tissue; and, 3, *False Joint or Pseudarthrosis*, in which there is no union between the fractured surfaces, but a capsule of fibrous tissue forms round them resembling the ligaments of a joint.

When the fragments undergo **Independent Repair**, the ends are rounded and the medullary canal closed by a thin plate of bone covered by a newly formed periosteum. In some cases after a time the ends become atrophied and somewhat pointed. This form of ununited fracture may be due to the wide separation of the fragments, as after great loss of bone in a compound fracture or the interposition of soft parts between the broken ends, or from various causes no callus may form; or the early formation of callus may have taken place, but owing to some peculiar general or local condition it may have become absorbed.

In **Fibrous Union** the ends of the bones are united by fibrous tissue, most commonly dense and ligamentous, but sometimes loose in structure. In this condition the early soft callus has formed, but instead of undergoing the normal development into bone it has been converted into fibrous tissue. This is usually the result of insufficient rest during treatment or of faulty position of the fragments. It is the most common form of ununited fracture.

In **False Joint or Pseudarthrosis** the two fragments are bound together by dense ligamentous tissue passing from one to the other, forming a more or less perfect capsule around the broken ends (Fig. 167). Between the actual surfaces of the fracture there is no union. They are smoothly rounded, the medullary canal being closed by a thin plate of new bone and invested with a layer of dense fibrous tissue or fibro-cartilage. The two surfaces are more or less adapted to each other like those of a normal articulation. In the humerus or femur one end is usually concave and the other convex; the false articulation thus resembles a normal ball-and-socket joint. In the forearm and leg, as lateral movement is prevented by the presence of two bones, the false articulation more closely resembles a hinge-joint. The inner surface of the capsule may be smooth, as if lined with a synovial membrane, and the cavity may be moistened with a glairy fluid resembling synovia. False joints of this kind are met with only in fractures of considerable standing, and it is probable that they are always preceded by fibrous union, and that the false joint is gradually developed by atrophy of the fibrous tissue between the ends of the bone, and more perfect development of that surrounding them. In very old false joints changes resembling arthritis of normal joints are

Fig. 167. False Joint in Humerus.

occasionally met with. The surfaces in contact become hardened and eburnated, bony outgrowths may form around the ends of the fragments, and pedunculated fibrous outgrowths have been found attached to the inner surface of the capsule.

All forms of non-union of fracture are undoubtedly rare. I have very seldom met with it in my own practice. The cases that have been under my care have almost all been sent up from various parts of the country. We probably exaggerate the frequency of non-union, if we say that it occurs in the proportion of one in a thousand cases of fracture of the limbs.

Causes.—The causes of ununited fracture are *constitutional* and *local*.

Constitutional Causes.—The constitutional causes that, independently of local conditions, lead to non-union of a fractured bone, are often very obscure, and in many cases none can be detected. Mere debility, independently of some definite constitutional disease, will not lead to want of union. In fact, in weakly children, fractures will unite with great readiness, or if union be delayed for a short time it will, on the improvement of the health, readily take place. The debility induced by the *acute specific diseases* seems in a few recorded cases to have been a cause of non-union, and an attack of *acute pneumonia* has had the same effect. *Syphilis* does not seem to influence the progress of a fracture during the primary and secondary stages of the disease, and it is probable that when it is a cause of non-union the bone was affected before it was broken. *Scurvy* always has an injurious influence on fractures, causing delay in union, if not complete want of repair, and the older writers assert that in severe cases fractures repaired many years before may become disunited. There is no evidence that *cancer* has any influence in delaying union, if the fracture be not actually due to a secondary growth in the bone. In *spontaneous fractures*, from whatever cause, union seldom takes place readily, and often fails altogether.

Pregnancy is said to have a tendency to interfere with the proper union of a fracture; this, however, I consider doubtful, as I have seen a considerable number of cases of fracture in pregnant women, which united in the ordinary time. Billroth and Bruns have made similar observations.

Age.—Failure of union in fractures is very rare in children, and when it occurs in them is seldom remediable, unless it be the result of neglect or of improper mechanical treatment. It is more common at the earlier adult and middle ages. Advanced age appears to exercise no adverse influence on the repair of fractures. I have on two occasions, in my own practice, known very firm consolidation of a fracture of the shaft of the femur to take place in women of ninety years of age.

The **Local Causes** are various and important. *Some bones are much more liable than others to non-union of fractures.* The patella seldom unites by bone in transverse fracture, and fibrous union is common in the lower jaw. Bruns has collected 1274 cases of ununited fracture of the long bones of the limbs with the following results:—409 occurred in the leg, 376 in the arm, 337 in the thigh, and 152 in the forearm. Relatively non-union is most common in the humerus and femur, as the following statistics prove. Of all recent fractures 15.5 per cent. occur in the humerus, but 29.5 per cent. of all ununited fractures are met with in that bone; the femur yields 17.7 per cent. of all fractures, and 26.4 of ununited fractures; the bones of the leg yield 32.1 per cent. of all fractures, and 32.1 per cent. of ununited fractures.

tures; the forearm 39.1 per cent. of all fractures, and only 11.9 per cent. of ununited.

Of 72 cases of ununited fracture of the long bones of children collected by D'Arcy Power, 6 occurred in the clavicle, 7 in the humerus, 2 in the forearm, 12 in the femur, and 45 in the leg; whilst statistics of fractures in children shew that of 1070 cases 227 were in the clavicle, 228 in the humerus, 328 in the forearm, 213 in the femur, and 74 in the leg.

The *nature of the fracture* has an important influence. About two-thirds of all cases follow compound fractures. In these fibrous union is the most common form, true false joint being rarely formed except in cases of simple fracture.

Want of proper apposition of the fragments may be a cause of non-union, especially when they are so situated that instead of the broken surfaces being in contact, flexion or rotation of one fragment has caused the periosteal aspects to touch. *Wide separation of the fragments*, such as occurs in some cases of fracture of the patella, is another cause, and in compound fractures loss of a large portion of the bone, either directly by the accident or subsequently by necrosis, is often followed by non-union.

The *interposition of soft parts between the fragments* may prevent union. Of this I saw an interesting instance some years ago, in which want of union in a fractured femur was due to perforation of the vastus muscle by the upper fragment, and its entanglement between the broken ends. In transverse fracture of the patella, the torn aponeurosis from the vasti that covers the bone may hang down between the broken surfaces, and thus interfere with bony union.

Extreme comminution is rarely a cause of want of union in simple fractures, but many cases have been recorded in which failure of union has occurred in the lower of two fractures occurring in the same bone at distant points or in the same limb in different bones.

Interference with the vascular supply of one or both fragments is probably not an uncommon cause. For proper union to take place, it is necessary that the callus be formed from both sides of the fracture. If one fragment be so situated that sufficient blood is not sent to it for this purpose, not only want of union, but necrosis, may occur. This is exemplified in fractures of the superior articular ends of the humerus and femur. In intracapsular fracture of the anatomical neck of the humerus, the globular head, being detached from all its vascular connections, may necrose. In intracapsular fracture of the neck of the femur, the head of the bone, still retaining some vascular connection through the medium of the ligamentum teres, has sufficient blood furnished to it to prevent its death, but not enough to form callus—hence fibrous union takes place. Guerin collected some statistics which seem to show that non-union is more common in fractures occurring in that portion of the bone from which the nutrient artery is directed. Thus in the humerus, in which the artery is directed downwards towards the elbow, ununited fracture is more common above the nutrient foramen than below, and this he attributed to a less perfect vascular supply of the upper part of the bone. A far more probable explanation of this fact is that fractures below the middle of the bone are more easily kept at perfect rest than those above.

The interference with the vascular supply by the *application of a bandage* directly and too tightly to the limb is another possible cause of imperfect repair.

Injuries to nerves seem to have but little effect on union, perfect repair of fractures commonly taking place in paralyzed limbs. Experimental investigations on animals have shown that division of the nerves leading to the injured limb does not interfere with the union of a fracture.

Imperfect rest during treatment is no doubt a very common and important cause of ununited fracture. The best evidence of this is the fact that a very large proportion of all ununited fractures met with in hospital practice are in patients who have been treated on board ship or in remote parts of the country where it has been impossible to procure proper attention or skilled treatment. In cases of compound fracture the disturbance during the dressings may be a cause of non-union.

In a large number of cases, however, the most careful investigation on the part of the Surgeon will fail to discover the cause of the failure of union.

In the **Treatment of Ununited Fracture** the *constitutional* measures are of the first importance. If callus have not been formed, or if, after formation, it have been absorbed under the influence of a cachectic state of the system, the improvement of the patient's health, at the same time that the fracture is put up again firmly so that the ends of the bone are brought into close apposition, may bring about perfect union. In some instances of ununited fracture or delayed union in syphilitic subjects, union speedily takes place after the administration of mercury or iodide of potassium, according to the stage of the constitutional affection. I had under my care a man with ununited fracture of the femur from absorption of the callus four months after the occurrence of the injury, under the influence of incipient phthisis and debility induced by want of food; perfect consolidation was brought about by giving him cod-liver oil and good diet, with rest in bed and a starched bandage to the limb. If there be no very evident cause for the want of union, it will occasionally suffice to put up the fracture firmly in leather or gutta-percha splints, or in a starched or plaster of Paris bandage, and then to allow the patient to move about upon crutches, so that his general health may not suffer, at the same time that a tonic plan of treatment is followed. I have seen several cases in which the want of union appeared to have resulted from too long confinement of the patient to his bed, and the consequent impairment of his health, consolidation taking place when a sounder hygienic system was enforced. This simple plan can, however, be useful only if a short time—at most some months—has elapsed since the occurrence of the injury. In some cases, the empirical administration of mercury is attended with success. In a case of ununited fracture of the humerus, fifteen weeks after the occurrence of the injury, under Liston, union was obtained within a month by putting up the limb in splints, and salivating the patient. When the want of union arises from malignant disease, nothing can be done.

Together with appropriate constitutional treatment, suitable *local means* must be employed to secure steady coaptation of the fragments. In the upper extremity, this may usually be done by means of splints of an ordinary kind. In the leg, the starched or plaster of Paris bandage will be found especially serviceable. Before putting up the limb in the plaster or starched bandage, it is a good plan to *rub the end of the bones forcibly together*, the patient, if necessary, being under the influence of an anæsthetic. In this way a certain degree of inflammation may be set up, which may be followed by a fresh formation of callus.

In the case of ununited fracture of the thigh special apparatus will be required to secure complete fixity. For this purpose the limb should be put in an apparatus, consisting of an outer and an inner iron rod having hinge-joints opposite the hip and ankle, and attached above to a strong pelvic band, and below to the sole of the boot. The thigh part should be provided with well-padded splints, which may be screwed down in opposite directions against the two fragments, so as to hold them firmly in contact. This instrument should be worn for several months; by means of it Smith, of Philadelphia, has succeeded in curing ten out of fourteen ununited fractures in the lower extremity. One great recommendation is, that this plan of treatment is entirely devoid of danger, and enables the patient to take exercise whilst under treatment. In cases with much shortening of the limb and over-riding of the fragments, which are especially apt to occur in the thigh, it will be necessary to employ extension of the limb as well as compression of the fragments against one another. This extension may be made by the lateral iron rods of the above-described apparatus being constructed so as to slide, by means of a rack-and-pinion or screw-mechanism, by which the limb may be gradually lengthened to any required extent (Fig. 168).

When the failure of union has become very chronic, or a false joint has been formed, it will be necessary to employ operative procedure before union can be obtained. All operations that are undertaken in these cases are conducted on one of two principles: either, 1, *to excite a localised traumatic inflammation in the false joint and the neighbouring tissues leading to exudation, which, as in the process of union of a recent fracture, may be followed by the development of callus*; or else, 2, *by removing the false joint altogether, to convert the case into a recent compound fracture, and to treat it as such*. It can easily be understood that these operative procedures are too serious to be lightly undertaken, or to be had recourse to until other measures have failed.

1. Among the first set of operations,—those that have in view the **Excitation of Inflammation**,—the simplest procedure consists in the **introduction of acupuncture needles**, or in the **subcutaneous section** of the ligamentous band with a tenotome. In this way I have known union effected in a patient of Laxton's who had a false joint in the shaft of the femur; though not until after the fracture had been converted into a compound one, and much danger and suffering gone through. Four years afterwards the patient was admitted into the Hospital, under my care, with fracture of the same bone two inches lower down; on this occasion, union took place in the usual time.

Percussion of the ends of the bone has been employed in these cases by H. O. Thomas. The method consists in protecting the skin with a piece of felt, and then percussing the seat of fracture forcibly with a copper mallet. The percussion may be continued under anaesthesia for several—as many as ten—minutes; it may be required only once, or may need several

Fig. 168. Apparatus for Ununited Fracture of Femur.

repetitions. The effect is a good deal of local swelling and irritation. The limb should be put up as for recent fracture, and a cure may be expected in from four to six weeks.

The **Subcutaneous injection of irritating fluids** has been practised in a considerable number of cases with a fair measure of success. Tincture of iodine has been most frequently used, about 13 to 30 minims being injected between the broken ends if possible. Bruns has collected 11 cases of this treatment, 7 of which were successful. It seems to be quite free from danger.

Dieffenbach proposed to excite the requisite degree of irritation by **driving, with a mallet, three or four conical ivory pegs** into holes bored by means of a drill into the ends of the fractured bone, which are exposed for this purpose. The holes may be bored with the Archimedean drill (Fig. 169), but a common bradawl will do just as well. The soft parts are then to be laid down, and after a few weeks the pegs, which have loosened in consequence of the absorption of the surrounding bone, and also partly of the pegs themselves, should be taken out. It is not necessary to attempt to put together the ends of the broken bone, but merely to introduce the pegs into

Fig. 169.—Archimedean Drill for perforating Bone.

the extremities of both fragments near to the seat of fracture. I have practised this operation with success in several instances of ununited fracture of the humerus. Bruns has collected 130 cases of this operation, of which 71 were successful, 55 failed, amputation was performed in 1, and 3 died. The operation was most successful in the leg, two-thirds of the cases being cured, while in the arm almost exactly half failed. In the femur, 10 out of 19 were cured, 6 failed, 1 was amputated, and 2 died.

2. The operation of *Removing the False Joint* is the last expedient when simpler means have failed. This was formerly extremely dangerous, and cannot now be regarded as anything but serious, especially when the femur is the bone to be operated on. By the proper use of antiseptics, however, and good drainage and rest, the operation may be robbed of most of its dangers. Bruns has collected 140 cases, the results of which were as follows:—Arm 187, cured 98, improved 3, failed 78, died 5, unknown 8; forearm 65, cured 12, improved 1, failed 17, died 1, unknown 4; thigh 98, cured 30, improved 2, failed 25, died 19, unknown 2; leg 90, cured 47, failed 36, died 4, unknown 3. Probably a large number of the deaths were from causes which we now regard as preventible. The operation is thus performed: The false joint is truly exposed by an incision so placed as to do the least possible injury to the surrounding soft parts. The periosteum is then carefully raised by means of a periosteal elevator from the part it is intended to remove. To facilitate the

perfect exposure of the ends of the fragments, the fibrous tissue forming the false joint may be cut through if necessary. The end of one of the fragments being thoroughly cleaned, it must be sawn off either obliquely or transversely, according to the line of the fracture, or, if more convenient, a chisel and mallet may be used to cut it through. As a rule, a smooth and more regular surface is obtained by using the saw. The opposite fragment is then treated in the same way. The two ends are next brought in contact and wired or pegged together. In wiring the fragments a hole must be drilled obliquely from the surface of each into the medullary canal. A strong piece of thick, tolerably soft, silver wire must be passed through the holes, and the fragments drawn into accurate apposition. The wire may be quite safely left in the wound, and the two ends cut short and hammered down flat on the bone, so as to leave no projecting points.

In all cases some shortening of the limb must necessarily result, but if solid union can be obtained, this is of little consequence. In operating on the forearm or leg, if both bones are affected, care must be taken to remove an equal length from each. If the fracture be very oblique, the section of the bone must be in the same line so as to cause as little shortening as possible.

Nussbaum, in a case of gunshot fracture of the ulna with loss of substance, cut away the rounded ends of the fragments and the fibrous tissue uniting them, and transplanted into the space thus formed a slice of the compact tissue of the upper fragment with the periosteum covering it, leaving a bridge of that membrane undivided. Good bony union resulted.

Operations for ununited fracture rarely succeed when the disunion is owing to other than local causes. They may, however, succeed in old people. I have united a femur that had been disunited for nearly twelve months in a man between sixty and seventy by Dieffenbach's method. The more thickly the bone is covered by the soft parts, the more likely will an operation be to succeed. Hence, the humerus and femur are more favourable for operation than the tibia.

On reviewing the various methods that have been recommended for the treatment of ununited fracture, it would appear that if the period of normal union has been exceeded by but a few weeks, rubbing the ends of the bones forcibly together, constriction, or percussion may be tried, followed by the application of a plaster of Paris bandage. Should these measures have no effect, further efforts may be made to excite a sufficient degree of inflammation by injection of iodine or by subcutaneous section and scraping of the ends of the fragments. Should this fail, the seat of fracture should be cut down upon, and if it be found that there is firm fibrous union, the insertion of Dieffenbach's pegs might be sufficient, as if the proper amount of irritation be set up, the intervening fibrous tissue becomes converted into bone: but if there is a distinct false joint, it had better be removed and the bevelled ends wired or pegged together. If union should fail, much may be done to relieve the patient by properly devised apparatus, but if the false joint be situated in the femur or tibia, the limb may be so useless and cumbersome to him, that amputation may be required as a last resource.

CHAPTER XXI.

SPECIAL FRACTURES.

In considering the special fractures, we shall confine our attention to those of the Bones of the Face, Trunk, and Extremities. Injuries of the Bones of the Head and Spine derive their principal importance from their complication with lesion of the contained organs; hence the consideration of these will be deferred to special Chapters.

FRACTURES OF THE BONES OF THE FACE.

NASAL BONES.—These are usually fractured near their lower ends by direct violence (Fig. 170). There may be no displacement, but more commonly the

Fig. 170.—Fracture of Nasal Bones.

Fig. 171. Spring-Clip for straightening the Nose.

lower fragments are depressed, the bridge of the nose being beaten in. The fracture is nearly always compound, from wound of the mucous membrane. The swelling and ecchymosis that usually attend this injury often render its detection difficult, and interfere with efficient treatment. The depressed bone should be raised with the narrow end of a director by which, guided by the finger outside, the fragment may be forced into proper position. To do this thoroughly it is often necessary to administer an anæsthetic. It may be necessary to insert one blade of a well-padded pair of polypus forceps into the nostril, and seize the depressed fragment between this and the other blade applied externally. Union of the bone takes place very rapidly. It is often moderately firm at the end of a week and solid in two weeks.

The nose without being exactly broken is often twisted to one side, more particularly if the organ be naturally long and pointed. This deformity completely alters the expression of the face, often producing a somewhat ludicrous appearance. When recent, and more especially when the patient is young, it

may be remedied by the use of a spring-clip (Fig. 171), which presses the distorted end of the nose back to the straight line.

If the **septum** alone be broken, the same treatment must be adopted; the nose being supported and moulded into shape. As a rule, after it has been replaced, the position is maintained; but in some cases, where there is a tendency to sinking of the soft parts of the nose, the introduction of a plug of oiled lint round a piece of catheter, left open for breathing, will be required to retain the organ in proper shape. The hæmorrhage, which is usually rather abundant at first, may be stopped by the application of ice; but occasionally the nostrils require plugging, in order to prevent it from continuing to a dangerous extent. If the **lachrymal bone** be broken together with the nasal, the ductus *ad nasum* may be obstructed, and the course of the tears diverted. In an injury of this kind, I have seen extensive emphysema of the eyelids and forehead occur on attempting to blow the nose. In some cases, the injury inflicted on the nasal bones extends through the ethmoid to the base of the brain, and may thus occasion death. This I have seen happen from a severe blow on the face with a piece of wood.

MALAR AND UPPER JAW-BONES.—These are seldom broken except by great and direct violence; and their fracture is usually accompanied by external wound, as in gunshot injuries of these parts. More commonly the alveolar processes are detached, and the teeth loosened. The treatment then consists in binding the teeth together with silver wire. In fractures of the *zygoma*, which are very rare, there will be difficulty in mastication from injury to the origin of the masseter, and possibly from fragments, which may require removal, being driven into the temporal muscle.

In some rare cases, **all the bones of the face** appear to have been smashed, and separated from the skull by the infliction of great violence. Thus, South relates the case of a man who was struck on the face by the handle of a crane, and in whom all the bones were separated and loosened, "feeling like beans in a bag." Some years ago I had under my care a patient who had fallen thirty feet over the balusters of a spiral staircase and had struck his face in the fall. He lived about two hours after the accident and on examination the following injuries were found. The lower jaw was fractured through the left ramus, and through the body between the right molar teeth. In the upper jaw a transverse fracture ran completely across from one side of the face to the other, at about the level of the inferior border of the anterior nares. It passed through both superior maxillary bones, the vertical part of the palate bones, the pterygoid processes of the sphenoid on both sides, and the vomer; so that the whole of the alveolar portions of the superior maxilla and the palate formed one piece. This was displaced backwards into the pharynx. The *zygoma* was fractured on both sides, and a vertical fracture ran on each side from the margin of the orbit through the walls of the antrum; so that on each side there was one large fragment composed of part of the *zygoma*, the malar bone, and the part of the superior maxillary bone with which it is articulated. The nasal bones, the nasal processes of the superior maxillary bones, the *os unguis* on each side, and the ethmoid, were smashed into numerous small fragments. There was no fracture visible from the interior of the skull; and no other injuries of importance were found. In another case a woman falling out of a third story window struck her face against the area-railings. The superior maxillæ were broken across trans-

versely above the line of the teeth, so that these and the hard palate could be moved backwards and forwards. She died from a splinter of the roof of the sphenoidal sinus having penetrated the dura mater. I have, however, known several cases of transverse fracture of one superior maxillary bone do well. In such cases the teeth may be tied together with silver wire or the aid of the dentist may be required to fix the displaced fragments by means of vulcanite moulds. The question of feeding the patient is usually one of difficulty, and the food often requires to be introduced by means of a tube.

In **Gunshot Injuries of the Face** there is usually great splintering of the bone. As, however, the vitality of the part is great, necrosis is not likely to ensue: and the partially detached and loosened fragments may be put back into position, and will usually become fixed. There are two principal dangers in these cases: hæmorrhage, either primary or secondary, and abundant fetid muco-puriform discharge. The hæmorrhage, when primary, usually ceases spontaneously, or on the application of cold. If secondary, it may be arrested by cold, by plugging, and by pressure; or, if continuous, and from deep sources, it may possibly require ligature of the external carotid. The foetid discharge from these wounds is a source not only of great discomfort to the patient, but of positive danger, as a cause of septic pneumonia: and, drainage being difficult, he may also suffer from absorption of the septic matter from the raw surface. This risk is best obviated by repeated injections of warm antiseptic solutions, of which the solution of permanganate of potash or boric acid is the best. Whenever it is possible to reach the raw surface in any way, it must, after it has been well washed, be dusted over with iodoform. This exerts a far more powerful and lasting antiseptic influence than any lotion.

LOWER JAW.—This bone is frequently broken, owing to its prominent situation; though its arched shape and great strength enable it to resist all but extreme degrees of violence. All fractures of this bone which implicate the alveolar border are necessarily compound, the laceration of the gum causing them to communicate with the external air. In other cases an external wound, as in gunshot fractures, may communicate with the fracture. Not unfrequently they are comminuted.

Fracture of the lower jaw may occur in various situations. I have seen it most frequently in the **body of the bone**, between the lateral incisor and the canine teeth. The **symphysis** itself is not so commonly fractured, the bone being thick in this situation. The **angle** is more frequently broken. The **coronoid process** can suffer fracture only from the most severe and direct external injury, as from a bullet-wound. The **neck of the condyle** is occasionally broken across.

Fractures near the symphysis are usually vertical, but pass through the bone in a direction from within forwards and outwards, so that the posterior fragment tends to overlap the anterior. Those near the angle are commonly oblique from before backwards, so that a long spiculum of the outer table is connected with the upper fragment.

These fractures are sometimes double: either symmetrically, or, more frequently, one on the side near the symphysis, and the other near the angle.

The **Signs** of fracture of the lower jaw are obvious. The abnormal mobility of the fragments, the crepitus, the irregularity of the line of the teeth and of the arch of the jaw, laceration of the gums, bleeding and dribbling of saliva, indicate the nature of the injury. The displacement and

mobility of the fragments are greater the nearer the fracture is to the symphysis. If the bone happen to be broken on both sides of this line, the middle fragment is much dragged out of place by the depressor muscles attached to it: indeed, in all double fractures, the displacement is very great. In fracture about the angle and lower part of the ramus, the deformity is not so great, owing to the muscles that coat and protect each side of the bone in this situation preventing the fragments from being displaced. When the neck of the condyle is broken through, that process is often much displaced by the action

Fig. 172. Fracture of Lower Jaw.

Fig. 173. Four-tailed Bandage applied to Fracture of Lower Jaw.

of the external pterygoid; there is great pain at the seat of fracture and the chin may be drawn to the same side.

When the fracture is near the symphysis, the dental canal escapes; but when it is further back in the body of the bone, and especially near the angle, the canal must necessarily be implicated. It is remarkable, however, that the inferior dental nerve escapes injury or division in many cases altogether, in others for several days, until, perhaps, owing to great displace-

Fig. 174. Gutta Percha Splint. Original Shape.

Fig. 175. Gutta Percha Splint, rounded to shape of Jaw.

ment or to some effort in reduction, it may be torn across. When this happens, the soft parts of the lower lip, supplied by the mental branch of the inferior dental, are necessarily for a time deprived of sensation, but they soon recover. I have never known any permanent mischief from this cause, nor from the hæmorrhage following laceration of the inferior dental artery.

The **Treatment** is simple in principle, but often not easy of accomplishment. It consists in maintaining the parts in apposition for four or five weeks, during which time mastication must be forbidden—the patient living

on fluid nourishment—and talking being prohibited. In a simple case in which good position is easily maintained the *four-tailed bandage*, applied as shown in Fig. 173, often answers admirably. Pick suggests that by carrying the upper ends of the bandage behind the occiput, rather than to the nape of the neck

as usually recommended, the tendency to displacement of the anterior fragment backwards is avoided. In some cases a *guth-percha splint* (Fig. 174), moulded to the part (Fig. 175) is of service. It should be lined with lint, and applied with a four-tailed bandage.

The teeth in these cases require special attention. Any that are loosened must be left in, as they will soon contract adhesions, and fix themselves firmly; if necessary, they may be tied to the sound teeth with silver wire, or dentist's silk. Care must be taken that any tooth that may

have dropped between the fragments be removed; in one case in which a tooth was overlooked in this position, no union of the fracture took place till it had been removed.

In any case of fracture of the body of the lower jaw, in which a sufficient number of firm teeth are present, *Hammond's splint* (Fig. 176) gives excellent

results, and has largely replaced other methods. A stout piece of tinned iron wire is made accurately to surround the whole of the teeth of the lower jaw, and its ends are soldered together. The wire may be conveniently moulded to a cast of the teeth, which can easily be prepared with wax and plaster of Paris. This stout iron wire frame is firmly fixed in position by fine binding wire, which passes separately around individual teeth and binds the splint to them. No support should be

Fig. 176.
Hammond's first method of fixing fracture of the lower jaw. A, B, wires passed through drill holes and coiled by the key, Fig. 178.

Fig. 178.

taken from the teeth immediately adjoining the fracture, as these are likely to be loosened.

When depression, especially near the symphysis, is considerable, Lonsdale's *clamp apparatus*, which fixes the chin and line of teeth, answers the purpose of steadying the fragments extremely well. When the fracture is double, one fissure occurring near the symphysis, the other near the angle, there is also

very considerable difficulty in bringing the fragments into anything like good position, without the aid of some special apparatus. In such cases a cast should be taken of the teeth in gutta-percha, while the fragments are held in accurate position, and from this a metal plate should be modelled, fitted to the teeth, and attached to Lonsdale's clamp or to a stem, and fixed to a horseshoe-shaped splint placed under the jaw, so as to keep the whole steady and solid.

Some cases in which there is unusual difficulty in maintaining apposition, especially if the fracture be double, may be treated by joining the fragments, as advocated by H. O. Thomas.

The bone is drilled on each side of the fracture, and the fragments fixed by means of thick plant silver wire. Thomas found that the ordinary cross-twist did not hold; he therefore coiled the wire at each side (Figs. 177, 179). In order to facilitate this operation, he devised a set of instruments, comprising a tubular needle to return the wire, and a key for coiling it (Fig. 178). Union generally takes place perfectly in fractures of the jaw, though it is somewhat slow at first, and the fragments continue mobile for some weeks.

Fig. 179.—Thomas's second mode of uniting fracture of the Lower Jaw by Twisted and Coiled Wire.

Fig. 180.—Form of the Coil of Wire.

The cure is often delayed by the separation of necrosed fragments. If there should be any offensive discharge the patient must wash out his mouth with Condy's fluid and water, after which iodoform must be sprinkled on the wound.

In Fractures of the Body of the Lower Jaw by Gunshot Injury there is great comminution and splintering of the bone, followed by copious fetid discharge, which necessitates the free use of disinfectants, and especially of iodoform. In extreme cases the wound may be enlarged and the splinters removed, but no formal excision of any part of the bone should be undertaken.

FRACTURE OF THE HYOID BONE is of rare occurrence; and, though usually the result of direct violence, as a forcible grasp, it has been known to occur from muscular action. The fracture most commonly occurs at the junction of the body and great cornu. The fragments form a sharp salient angle: there is much pain and irritation, increased by speaking and deglutition. There is salivation from interference with the movements of the tongue and cough; and considerable difficulty in breathing may be present. *Reduction* is accomplished by pressing the fragments into position, either externally or by passing the finger into the mouth. Should one piece of the bone be driven much in, it may possibly require to be drawn forwards with a *Lancet*. The neck should then be fixed with a stiff pasteboard collar to prevent displacement.

FRACTURES OF THE UPPER EXTREMITY

Fractures of the upper extremity may occur from direct or from indirect violence. When from *direct* violence any portion of any bone from the tips of the fingers to the trunk may be broken. But indirect violence is the more common cause; and the seat of the fracture depends on the way in which the violence is directed.

The CLAVICLE is more frequently broken than any other bone in the body, except the radius. For this there are three reasons. First, it is exposed to the influence of direct violence; secondly, it receives all shocks transmitted through the shoulder in a horizontal direction to the trunk; and, thirdly, being the only direct osseous support of the upper extremity, it receives by transmission through the scapula every shock that is communicated to the hand when the arm is extended. Notwithstanding its exposed position, it is comparatively seldom broken by direct injury. The great majority of the fractures occur from indirect violence, such as falls on the shoulder and on the hand. This bone would be more frequently broken than it is, were it not that it resembles two segments of a circle looking in opposite directions, so as to form an S-shape which admirably enables it to withstand indirect violence. The clavicle is occasionally fractured by muscular action—more particularly from the swing of the arm, as in a back-handed blow. When the accident occurs from this cause, it is usually about the middle of the bone, and on the right side. Compound fracture of the clavicle can occur only from bullet-wounds, or some similar severe and direct injury inflicted upon the bone.

Fractures from direct violence are usually transverse, and often comminuted; from indirect violence they are oblique. The latter are attended with much greater deformity than the former. Fractures of this bone in infants and young children are usually transverse; sometimes the bone is merely bent, or is fractured on one side only. The injury is usually occasioned by falling out of bed. Such accidents are frequently overlooked by careless nurses; but the child's crying whenever the arm is moved directs attention to the part, and the Surgeon then finds some deformity, with a node-like swelling about the middle of the bone.

Both clavicles are occasionally, though rarely, fractured. In one such case which was under my care, the patient, a young man of 20, had twelve ribs broken as well, in a railway accident, notwithstanding which he made an excellent recovery.

Complications.—In simple oblique fracture of the clavicle, there is rarely any serious complication. But when the fracture is the result of direct violence, the same force that breaks the bone may injure subjacent parts of importance. The subclavian vein may be compressed or wounded, or the brachial plexus of nerves may be compressed or torn; the first rib may be broken by the crushing violence, and the pleura wounded. In a case recorded by Bowly partial rupture of the subclavian artery occurred (p. 407).

The clavicle may be fractured at any point between its acromial and sternal ends. 1. Most frequently the **Great Convexity** is broken; the bone bent here when pressed upon from its extremity, the curve becoming increased, and at last giving way. This fracture may arise from direct violence, but usually is the result of falls on the hand or shoulder. 2. It may be fractured

nearer the acromion between the two **Coraco-clavicular Ligaments**. 3. Its **Outer End** may be broken off externally to the outermost point of insertion of the trapezoid ligament, between it and the acromion. These latter two fractures can scarcely occur from indirect, but are almost always the result of direct, violence. 4. The clavicle may be broken internally, that is, to the **Sternal Side of the Rhomboid Ligament**, usually about three-quarters of an inch from its sternal articulation. This injury is of very rare occurrence. R. W. Smith, although admitting its possibility, states that there is no actual proof, from dissection, of its having occurred. According to J. Hutchinson, Junr., there are but three cases on record of separation of the epiphysis of the clavicle. The epiphysis joins the shaft about the 25th year.

The **Signs** will depend upon the seat of fracture. When the bone is broken *between the conoid and trapezoid ligaments*, there is little, if any, displacement, but pain on pressure, some crepitus on moving the shoulder, and slight irregularity on running the finger along the bone are usually present. When the fracture is *external to the coraco-clavicular ligaments*, there is a remarkable displacement of the scapular fragment, which is turned forwards and inwards, with a slight inclination downwards, nearly at right angles to the rest of the bone, apparently by the dragging of the weight of the shoulder, the point of which is rounded forwards (Fig. 181). When the fracture occurs *about the middle of the bone*, or at any part on the *sternal side of the scapular ligaments*, there is a well-marked deformity, owing to a triple displacement of the inner end of the outer fragment inwards, downwards, and slightly backwards, while the outer end is rotated forwards (Fig. 182). This displacement is due to two causes, one of which is mechanical and the other muscular. The displacement downwards is due chiefly to the weight of the arm, but the contraction of the deltoid would also aid in depressing the inner end of the outer fragment. The displacement inwards is due to the action of the muscles passing from the chest to the arm and scapula, the pectoralis major and minor, and the latissimus dorsi; the rotation forwards and the pointing of the sternal end of the outer fragment backwards is due to the more powerful action of the pectoral muscles. The outer extremity of the inner fragment appears to be elevated, the skin being drawn tensely over it; but this is owing rather to the depression of the outer portion of the bone; it is usually kept fixed by the antagonism between the sterno-cleido-mastoid and great pectoral muscles. It may, however, in some cases be raised. This is when the clavicular portion of the sterno-cleido-mastoid muscle is unusually strong, and when the fracture has taken place just outside its insertion into the clavicle; or it may be raised and pushed forwards, by the inner end of the outer fragment getting below or behind it. On looking at a patient with fracture of the clavicle in this situation, the nature of the injury is at once evident. The approximation of the point of the shoulder towards the sternum; the prominence formed by the outer end of the inner fragment, over which the skin is stretched; the sudden depression under this, and the crepitus, which can easily be induced by elevating and rotating the shoulder at the same time that the elbow is pressed to the side, indicate the nature of the injury. The attitude of the patient is remarkable; he sits, leaning his head down to the

Fig. 181. Fracture of Clavicle, outside of Coraco-clavicular Ligament.

affected side, so as to relax the muscles, and supports his elbow and forearm in the sound hand, in order to take off the weight of the limb; he is unable to raise his arm from the side, and any attempt to do so causes severe pain.

When the fracture occurs near to the sternal end of the bone, it is usually, if not always, transverse. If it occur internally to the rhomboid ligament, the outer fragment is displaced forward, but remains on the same horizontal level as the sternal fragment. If the triple displacement of the outer fragment, characteristic of fractured clavicle, viz., in a direction downwards, forwards, and inwards, have occurred, then R. W. Smith believes that, however near the joint the fracture may appear to be, it must in reality

Fig. 182.—Preparation showing Anatomical Relations of Fracture of Middle of Clavicle. *sm*, sternal muscle; *tr*, trapezius; *e*, external; *d*, deltoid; *p.ma*, pectoralis major; *p.mi*, pectoralis minor; *rh*, rhomboid ligament; *v*, axillary vein; *a*, axillary artery; *n*, brachial plexus; *l*, first rib.

have occurred externally to the costo-clavicular ligament, which is too strong to admit of this displacement, or to be ruptured, and so to allow it to take place.

In ordinary simple fracture of the clavicle the blood-vessels passing under the bone are very rarely, if ever, injured or even compressed. This is owing to the manner in which the outer fragment is displaced, its sternal end being pushed in front of them and to their inner side.

Comminuted Fracture of the Clavicle is the result of severe direct violence. It is a dangerous accident, as the subclavian vein and adjacent plexus of nerves, or the upper part of the pleura, may be seriously injured. In a case that was under my care, the subclavian vein was apparently

wounded, great extravasation of blood taking place about the shoulder and neck, and the circulation through the veins of the arm being so much interfered with as to threaten gangrene. The case, however, did perfectly well under the continuous application of evaporating lotions to the shoulder, and attention to the position of the arm. But in another case, gangrene of the arm took place, leading to amputation at the shoulder joint. The patient died of pyæmia, and a fragment about one inch long separated from the posterior part of the clavicle was found lying upon, and compressing, the subclavian vein. Dr. John Ogle relates a case of comminuted fracture of the clavicle from direct violence, in which the right internal jugular vein was lacerated by one of the fragments, there being great extravasation of blood.

I have known only one instance in which the subclavian artery was injured. The left clavicle was broken by direct violence, a cart-wheel having passed over the shoulder. An aneurism rapidly formed in the subclavian artery, whether however by direct injury or as the result of severe strain was uncertain. C. Heath, under whose care the patient was, amputated at the shoulder-joint.

Compound Fracture of the Clavicle can of course be produced only by direct violence, and in such cases any amount of injury may be done to the underlying and neighbouring parts by the force that breaks the bone or by fragments driven in. The vein, artery, or nerves may be injured, and their liability to injury will, for obvious anatomical reasons, be in the order named.

Treatment of Simple Fracture of the Clavicle.—There are few fractures for the cure of which so great a variety of ingenious and complicated contrivances has been devised as those of the clavicle, and there are few in which so much ingenuity has been displayed in vain; for, however perfect the apparatus may appear to be, it seldom answers the purpose intended, viz., to cure the fracture without deformity. I believe that more may be done, with a little skill and patience, by simple means than by the most elaborate mechanical contrivances.

When the fracture occurs at the tip of the acromial end of the clavicle, the tendency to rotation of the shoulder forwards may be corrected by fixing the arm to the side with plaster of Paris or strapping in the manner to be described for fractures of the middle of the bone. When the bone is broken between the coraco-clavicular ligaments there is but little displacement and the same treatment will suffice.

But when the fracture is situated towards the middle of the bone, or indeed at any point to the inside of these ligaments, the case is more difficult, and numerous methods of treating it have been invented. The objects aimed at in all are to draw the outer fragment outwards, to force its outer end backwards, and by supporting the weight of the limb to correct the displacement downwards. It is impossible to mention here more than the few methods of treatment that seem most practically useful.

Treatment by Plaster of Paris.—This may be carried out as follows: The patient lies on his back on a flat table, with his head and shoulders projecting, and supported on a narrow board which passes beneath the spine. The shoulders now fall backwards, and by bringing the elbow of the affected limb to the side and usually somewhat forwards, the fragments of the broken clavicle can as a rule be well adjusted. A flannel bandage is now carried around the chest and the affected limb, including the board behind, and over

this a sufficient number of turns of a plaster of Paris bandage securely fix the limb to the side of the chest. The plaster bandages should be carried circularly around the arm and the chest, and obliquely over the flexed elbow, the forearm and the opposite shoulder. Finally, when all is firm, the board is slipped down from under the bandages. This method, which will be found especially useful when there is unusual difficulty in maintaining the parts in apposition, depends for its success upon the well-known fact that the deformity of a fractured clavicle is often best reduced by placing the patient in bed with a narrow pillow beneath the spine.

Sayre's Treatment by Adhesive Plaster.—Lewis A. Sayre of New York recommends the following mode of treatment, which has been found to act extremely well. Two strips of plaster, spread on strong calico or moleskin, are to be cut, each about three and a half inches wide or less, according to the size of the patient. One of these is to be long enough to encircle the arm, and afterwards to pass one and a half times round the body. A loop in this is first passed round the arm immediately below the axillary

Fig. 183. Strap drawing back Shoulder.

Fig. 184. Strap drawing Shoulder.

border. The non-adhesive side of the plaster must be towards the skin, and the loop must be secured by stitches. It must be quite loose, so that there shall be no risk of compressing the vessels. When this has been made fast, the elbow must be drawn well *backwards*, and the strip of plaster is carried firmly round the body and its end brought up and secured as in the figure. A few stitches may be inserted to render its hold more secure (Fig. 183). The second strip must be of sufficient length to pass from the sound shoulder obliquely round the chest beneath the elbow of the injured side, and to overlap for some six or eight inches. A slit must be cut in it for the olecranon. Before applying this the elbow must be raised and at the same time drawn well *forwards and inwards*, when the shoulder will be thrown backwards and outwards, the first strip of plaster acting as a fulcrum. In most instances this will place the fragments in good position, but in each individual case the Surgeon must endeavour to adjust the limb in such a way as best to relieve the deformity, and he may find that this is sometimes most satisfactorily accomplished by keeping the elbow in the mid-axillary line, or even directing it slightly backwards. The position must be maintained by

The application of the second strip of plaster, which passes obliquely from the sound shoulder across the back to beneath the elbow, and thence over the forearm and hand to the sound shoulder again, as in Fig. 184. Finally, a calico bandage is passed alternately round the chest and arm, and obliquely beneath the forearm and over the opposite shoulder.

Treatment by the Pad in the Axilla.—In this method a thick wedge-shaped pad in the axilla is used as a fulcrum to bring the shoulder into the desired position. The method has given good results, but it has one serious drawback, viz., the risk of the production of gangrene by the undue pressure of the pad on the vessels of the limb. This can hardly occur if the Surgeon sees the case frequently and observes the state of the circulation in the fingers. But, unfortunately, patients do not always present themselves when told to do so, and thus three or four days may pass without the case being seen. During this time gangrene may have set in unaccompanied by any pain, the limb being numbed by the pressure on the brachial plexus in the axilla. More than one such case has occurred, and as excellent results can be obtained by other methods without this danger, the treatment by the hard pad in the axilla had better be abandoned.

Treatment by the figure-of-8 Bandage.—This consists in drawing the shoulders forcibly backwards by a bandage passing beneath the arm-pits, over the shoulders, and crossing in the middle line of the back. The arm is then supported in a sling. However carefully the axilla be padded, the treatment is extremely irksome to the patient and cannot be recommended. A modification of this method, recommended by Syme, and known as the *treatment by the three handkerchiefs*, may sometimes be useful as an immediate application. A large handkerchief, folded diagonally till it is about one inch and a half wide, is placed round each shoulder so that it shall lie in front in the hollow between the coracoid process and the head of the humerus. The two ends are secured by a single turn behind the shoulder, and then twisted together so as to form a single cord. These cords are then knotted firmly together in the middle line, while the shoulders are forcibly pulled backwards; a folded towel must be put along the spine to prevent the knot hurting the patient. The third handkerchief is then put on as a sling firmly supporting the elbow.

In *children*, in whom these fractures often occur, there is frequently a difficulty in keeping the bandages properly applied; in these circumstances the stretched apparatus will be found very useful, care being taken to re-apply it as often as it becomes loose, lest deformity result. In young children, especially if the fracture be of the "greenstick" variety, it is often unnecessary to do more than fix the arm to the side and raise the elbow with a flannel bandage. Fractured clavicles occurring in females, to whom any irregularity of union in this situation would be very annoying, are best treated by keeping the patient lying flat on her back in bed, with the arm fixed to the side, for the first two or three weeks. By this plan, which is as old as the days of Hippocrates, I have seen better results produced than by any other.

When *both* clavicles are broken, the patient should be kept in bed, with the arms fixed to the side, or in some cases both limbs may be fixed by means of plaster of Paris applied in the manner already described.

In **Comminuted Fracture of the Clavicle**, it must always be remembered

detached along with it. Mobility of the coracoid would, therefore, be a valuable sign of this rare fracture. The **Treatment** of such an injury, if it were recognised, would consist in keeping the whole arm well raised and fixed to the chest, with a pad in the axilla.

FRACTURES OF THE HUMERUS.—In studying the fractures of the humerus, we must divide that bone into three parts—the Upper Articular End, the Shaft, and the Lower Articular End.

1. **Fractures of the Upper Articular End of the Humerus** not unfrequently occur, constituting an important class of injuries which have been carefully studied by Astley Cooper, and more recently by R. W. Smith.

Five kinds of fracture of the humerus are met with in the immediate vicinity of the shoulder-joint: Fractures of the Anatomical Neck, Simple and Impacted; Fractures of the Surgical Neck—Simple and Impacted; and Separation of the Great Tuberosity.

Fracture of the Anatomical Neck of the Humerus.—The head of the bone is detached from the shaft, a little above or at the line of insertion of the capsule, and thus the fracture may or may not be purely *intracapsular*. This fracture is occasioned by severe falls or blows on the shoulder. A fall on the hand or elbow may dislocate the humerus, or fracture its shaft, but it cannot break its upper articular end.

This injury is very rare, and the signs of it are by no means distinct, though much light has been thrown upon them by the labours of R. W. Smith. There is loss of motion in the shoulder, with some swelling and considerable pain, together with slight deformity; an irregularity, produced by the upper end of the lower fragment, can be felt towards the inner side of the joint; crepitus is easily produced; and there is, on measurement from the acromion to the olecranon, shortening to the extent of about one-third of an inch.

When this fracture is *impacted*, the upper fragment penetrates the lower one. In consequence of this, the axis of the humerus is directed somewhat inwards towards the coracoid process; here also some irregular osseous swelling may be detected. The head of the bone can be felt in the glenoid cavity, but is not in the axis of the limb, the elbow projecting slightly from the side, while there is at the same time a hollow some little distance under the acromion. There is consequently more deformity about the joint in the impacted than in the simple *intracapsular* fracture, with the same impairment of motion, but crepitus is wanting, or a slight grating may be felt, on firmly grasping the shoulder and rotating the elbow.

In fracture of the anatomical neck of the humerus the portion of bone broken off may be completely loose, like a foreign body in the joint. Under these circumstances, theoretically, it might necrose and give rise to destruction of the articulation, but there is no recorded case of such a complication. In most cases, so far as the evidence of museum specimens goes, the injury is not *intracapsular*, the line of fracture passing outside the capsule towards the greater tuberosity, the fragment being then attached to the capsule at its upper part. In other cases it is impacted, and new vessels penetrate it from the lower fragment. A case recorded by Boyer shows that when loose it may be gradually absorbed, and there is also evidence that if perfect rest be maintained, the loose fragment may form new adhesions. But even if it remains free there is no reason why it should cause inflammation and suppuration any more than a loose piece of cartilage chipped off the femur.

head, so as to touch the crown, owing to some of the fibres of the deltoid having lost their points of attachment; and it may be determined by the existence in a minor degree of some of the preceding signs, which prevent the accident from being confounded with paralysis of the deltoid from contusion; and especially by the tip being felt to be detached. But as has already been stated, this may be a congenital defect, to which perhaps attention has been directed only when the shoulder has been bruised or otherwise injured.

The **Treatment** consists in raising the elbow so as to take off the weight of the limb, and to push up the acromion by the head of the humerus. If the extremity only be broken off in front of the acromio-clavicular articulation, a pad may be placed between the elbow and the side in order to direct the arm somewhat upwards and inwards, and the limb must be fixed in this position by a bandage and sling. Should the fracture have taken place at or behind the line of the clavicular articulation, the treatment must be the same as that for fractured clavicle.

When the base of this process is broken across, there is not much separation between the fragments, and union usually takes place by bone. When the apex is detached, fibroid or ligamentous union generally occurs, the fragments being widely separated.

3. The **Coracoid Process** is but seldom broken, there being not more than ten or twelve unequivocal cases on record. It can rarely happen except by very direct violence. There is in the Museum of University College a recent preparation showing a fracture of the base of this process, implicating the glenoid cavity, and complicated with fracture across the base of the acromion; and another specimen, from a subject in the dissecting-room, showing a fracture through the middle of the process united by a fibrous band three-quarters of an inch in length. In spite of the attachment of such powerful muscles as the pectoralis minor, biceps, and coraco-brachialis, the displacement is not great as the process is kept in position by the coraco-clavicular ligaments. The only **Treatment** that can be adopted is to put the arm in a sling and fix it to the side.

4. **Fracture of the Neck of the Scapula** immediately behind the glenoid cavity is a rare injury. Its existence has been doubted; A. Cooper and South have stated that cases so described are, in reality, fractures of the upper end of the humerus. A case, however, recorded by Spence puts the occasional occurrence of the injury beyond doubt. A man was brought into the Edinburgh Infirmary, who had fallen on his shoulder while intoxicated. There was falling of the limb towards the axilla, with projection of the acromion and flattening of the deltoid; and crepitus was felt. The contour of the shoulder was restored by drawing the arm from the side and raising the limb. The man died some days afterwards from meningitis, the result of an injury to the head received during the fall. On examining the shoulder, "the fracture was found to pass obliquely from below upwards and forwards, commencing about half-an-inch behind the origin of the long head of the triceps, and separating the neck and four-fifths of the lower part of the glenoid cavity from the scapula. The long head of the biceps and the whole of the glenoid ligament had also been torn from the upper fragment of the glenoid cavity, and carried along with the displaced portion." In fracture through the neck of the scapula, the coracoid process would necessarily follow the glenoid cavity, being

detached along with it. Mobility of the coracoid would, therefore, be a valuable sign of this rare fracture. The **Treatment** of such an injury, if it were recognised, would consist in keeping the whole arm well raised and fixed to the chest, with a pad in the axilla.

FRACTURES OF THE HUMERUS.—In studying the fractures of the humerus, we must divide that bone into three parts—the Upper Articular End, the Shaft, and the Lower Articular End.

1. **Fractures of the Upper Articular End of the Humerus** not unfrequently occur, constituting an important class of injuries which have been carefully studied by Astley Cooper, and more recently by R. W. Smith.

Five kinds of fracture of the humerus are met with in the immediate vicinity of the shoulder-joint: Fractures of the Anatomical Neck, Simple and Impacted; Fractures of the Surgical Neck—Simple and Impacted; and Separation of the Great Tuberosity.

Fracture of the Anatomical Neck of the Humerus.—The head of the bone is detached from the shaft, a little above or at the line of insertion of the capsule, and thus the fracture may or may not be purely *intracapsular*. This fracture is occasioned by severe falls or blows on the shoulder. A fall on the hand or elbow may dislocate the humerus, or fracture its shaft, but it cannot break its upper articular end.

This injury is very rare, and the signs of it are by no means distinct, though much light has been thrown upon them by the labours of R. W. Smith. There is loss of motion in the shoulder, with some swelling and considerable pain, together with slight deformity; an irregularity, produced by the upper end of the lower fragment, can be felt towards the inner side of the joint; crepitus is easily produced; and there is, on measurement from the acromion to the olecranon, shortening to the extent of about one-third of an inch.

When this fracture is *impacted*, the upper fragment penetrates the lower one. In consequence of this, the axis of the humerus is directed somewhat inwards towards the coracoid process; here also some irregular osseous swelling may be detected. The head of the bone can be felt in the glenoid cavity, but is not in the axis of the limb, the elbow projecting slightly from the side, while there is at the same time a hollow some little distance under the acromion. There is consequently more deformity about the joint in the impacted than in the simple *intracapsular* fracture, with the same impairment of motion, but crepitus is wanting, or a slight grating may be felt, on firmly grasping the shoulder and rotating the elbow.

In fracture of the anatomical neck of the humerus the portion of bone broken off may be completely loose, like a foreign body in the joint. Under these circumstances, theoretically, it might necrose and give rise to destruction of the articulation, but there is no recorded case of such a complication. In most cases, so far as the evidence of museum specimens goes, the injury is not accurately *intracapsular*, the line of fracture passing outside the capsule towards the greater tuberosity, the fragment being then attached to the capsule at its upper part. In other cases it is impacted, and new vessels penetrate it from the lower fragment. A case recorded by Boyer shows that when loose it may be gradually absorbed, and there is also evidence that if perfect rest be maintained, the loose fragment may form new adhesions. But even if it remains free there is no reason why it should cause inflammation and suppuration any more than a loose piece of cartilage chipped off the femur

in the knee. Croft and Clutton have each recorded a case in which the head of the bone, separated at the anatomical neck, was dislocated into the axilla and subsequently removed by operation.

Fracture of the Surgical Neck of the Humerus.—In this injury, the bone is broken below the tuberosities, but above the insertions of the pectoralis major, latissimus dorsi, teres major, and deltoid muscles. This accident is most frequent in adults, but it may occur in children as well, the separation then taking place through the line of junction between the epiphysis and the shaft of the bone. The upper fragment is slightly abducted by the

Fig. 186. Preparation showing Anatomical Relations of Fracture through the Surgical Neck of the Humerus. *s*, scapular spine; *b.l.*, long head of biceps; *b.s.*, short head of biceps; *t.m.*, teres major; *d.*, deltoid; *p.ma.*, pectoralis major; *a.c.*, anterior circumflex artery; *p.c.*, posterior circumflex artery; *br.*, brachial plexus.

supraspinatus, but probably undergoes little or no rotation (Fig. 185). The shaft is drawn inwards by the pectoralis major, latissimus dorsi, and teres major, and upwards and forwards into the axilla, and towards the coracoid process, by the biceps, coraco-brachialis, triceps, and deltoid.

The **signs** of this fracture are sufficiently obvious. The glenoid cavity is filled by the head of the bone, which can be felt in it, but cannot be made to move by rotating the shaft. Below this there is a depression causing some flattening of the shoulder, but there is no prominence of the acromion; crepitus is easily produced if extension be made to bring the rough surfaces in contact, and there is great mobility of the lower fragment, with shortening

of the limb to the extent of from three-quarters to one inch; but the most remarkable sign is the prominence formed by the upper end of the shaft of the humerus, which projects under the integuments, and can readily be felt under the coracoid process, when the elbow is pushed upwards and rotated. The axis of the bone also is directed obliquely upwards and inwards towards this point. In consequence of the irritation of the nerves of the brachial plexus by this fragment, which is often very sharp and angular, a good deal of pain is complained of in the arm and fingers. This sign, however, is rarely met with in children, when the epiphysis is separated from the shaft, owing to the greater smoothness of the fractured surfaces. There is often very great extravasation of blood in this fracture, owing to laceration of branches of the circumflex arteries.

Impacted Fracture of the Surgical Neck of the Humerus has been especially treated of by R. W. Smith. In this injury, the upper fragment being penetrated by the lower, the continuity of the bone and its firmness are in a great measure preserved; hence the usual signs of fracture, such as

mobility, displacement, and crepitus, are not readily obtainable, and indeed the signs of this injury are chiefly negative. Thus, there is impairment of motion, with slight deformity about the joint and upper part of the arm; and occasionally crepitus is obtainable, with difficulty, by firmly grasping the head of the bone whilst the elbow is rotated. There is, as a rule, slight shortening, amounting to less than half an inch.

Fig. 186.—Apparatus for Fracture of the Neck of the Humerus.

In patients under twenty years of age separation of the epiphysis from the shaft may occur, and care must be taken not to confound this accident with a dislocation. In children under puberty dislocation of the head of the humerus scarcely ever occurs. In the fracture, the head can be felt in the glenoid cavity; but above all the broad end

of the shaft, for the line of separation is transverse, may be felt drawn up under the coracoid process, and cannot be mistaken.

Treatment of Fractures of the Neck of the Humerus.—If there be much swelling from contusion, evaporating lotions should be applied for a few days. A small pad may then be placed in the axilla, and the arm bandaged to the side whilst the elbow is drawn slightly forwards, so as to throw the upper end of the shaft backwards and outwards towards the head of the humerus. This position of the elbow applies chiefly to fracture of the surgical neck. The hand and wrist only are now supported in a narrow sling, which allows the weight of the arm to counteract the displacement upwards. The whole is then steadied by a carefully-fitted poroplastic shoulder-cap (Fig. 186).

In the management of some of these fractures, I have found a very convenient apparatus in a leather splint about two feet long by six inches broad, bent upon itself in the middle, so that one half of it may be applied lengthwise to the chest, and the other half to the inside of the arm; the angle formed by the bend, which should be somewhat obtuse, is well pressed up into

the axilla, and filled with padding to maintain its shape. In this way the limb is steadied, and the tendency to displacement inwards of the lower fragment is corrected.

The examination and reduction of these fractures must be conducted without violence, lest any impaction of the fragments be disturbed, or portions of untorn capsule be broken through. In some cases, fracture of the neck of the humerus is followed by atrophy of the bone, though good union has taken place. In some cases of separation of the epiphysis the difficulty of reduction is very great, especially if some time has elapsed before the nature of the injury has been recognized. Helferich records a case of this kind in which he succeeded in effecting reduction by exposing the site of the separation and enlarging the slit in the periosteum in which the end of the shaft was engaged.

Compound Fracture of the Surgical Neck of the Humerus is not of common occurrence. I have had a case under my care in which this accident happened to a lad from a fall out of a window. The fracture was transverse, and the upper end of the lower fragment was driven upwards, and protruded through the deltoid, to the extent of an inch and a half. It was reduced, with difficulty; as great irritation was set up around the seat of injury, and as there was a tendency to recurrent protrusion of the upper extremity of the lower fragment, this was turned out by enlarging the wound, and about an inch and a half of it sawn off. Union took place between the fragments, and a cure, with a very useful arm, was effected.

Separation of the Great Tuberosity of the Humerus occurs occasionally from falls and blows upon the shoulder; but more commonly as the result of the violent action of the three muscles inserted into it. In this injury there is a double displacement; the tubercle is carried upwards and somewhat backwards away from the head of the bone, and under and towards the posterior part to the acromion process; the head is drawn upwards and inwards by the muscles passing from the trunk to the arm, as well as by the flexors of the arm, in such a way that it lies upon the inner edge of the glenoid cavity under the coracoid process, and is indeed almost luxated. The consequence of this double displacement is a great increase in the breadth of the shoulder, which is nearly double its natural size; on examination, a rounded tumour—the head of the bone—movable on rotating the arm, can be felt under the coracoid process, whilst another osseous mass—the great tuberosity—may be felt at the outer and back part of the joint; between these a sulcus is perceptible, and above them the acromion is abnormally prominent. Crepitus may be felt by bringing the two portions of bone into apposition and rotating the arm. This accident, which is rare, has been most carefully described by Guthrie and Smith.

The **Treatment** consists in an attempt to bring the detached tuberosity into contact with the head of the bone, and retain it there. This may be done by placing a small pad in the axilla, and bringing the elbow to the side so as to throw out the head of the bone, at the same time that, by means of a compress, the tuberosity is pressed into proper position, the arm being supported in a sling. Another method consists in elevating and extending the arm from the trunk; in carrying this out, it is necessary that the patient be confined to bed, the arm being supported on a pillow.

The **Period of Union in a Fracture of the Neck of the Humerus** is about five weeks, at the end of which time the apparatus may be removed,

injury is apt to be mistaken for dislocation of the forearm backwards, which is also common in young subjects.

Transverse Fracture of the Lower End of the Humerus, just above the condyles, occurs occasionally in adults. The displacement backwards of the forearm and lower fragment, the pain, and crepitus, indicate the nature of the accident.

Fracture of either Condyle of the Humerus may arise from blows and falls on the elbow. There is considerable pain about the seat of the injury, but usually not much displacement; unless, as shown in Fig. 188, there be a transverse fracture of both condyles, constituting what may be termed the T-shaped fracture of the lower epiphysis of the humerus. Crepitus, however, may readily be felt by rotating the radius, if it be the external condyle that is injured; or by flexing and pronating the forearm, if it be the internal condyle that has been detached.

The **Treatment** of all these injuries must be conducted on very similar principles. The swelling, which rapidly supervenes, usually requires the

Fig. 188. T-shaped Fracture of Lower Epiphysis of Humerus.

Fig. 189. Angular Splint applied to front of limb.

application of cold lotions, or of irrigation; the arm being flexed, and supported in an easy position on a proper splint. After the subsidence of the swelling, the fractured bone, whatever be the precise nature of the injury, is best maintained in position by being put in an angular splint applied to the anterior aspect of the limb (Fig. 189); the forearm being kept midway between pronation and supination, and well supported in a sling.

It is in these particular fractures that passive motion should be had recourse to early, some degree of rigidity of the joint being otherwise often left. The motion should be begun in adults at the expiration of a month or five weeks; in children, at the end of three weeks after the occurrence of the accident. Union usually takes place readily. I have, however, seen one instance of an ununited fracture of the external condyle of the humerus in a boy about ten years old.

Period of Union.—These fractures unite quickly, bony union being complete in four weeks, but it is seldom that the patient recovers the use of before the end of the sixth week.

Y of Nerves in Fracture of the Humerus.—In simple fracture

of the shaft of the humerus, it may happen that the trunk of the musculospiral nerve, where it winds round the bone, may be damaged, either by the fracture itself or by becoming involved in the subsequent formation of callus so as to be paralysed. So also when the fracture is lower down, and the external condyle is broken off, the posterior interosseous branch of that nerve may be injured, whilst very rarely the median and ulnar nerves are damaged. When the musculospiral is paralysed, supination is imperfect, and extension of the hand and fingers is entirely lost; the forearm becomes pronated, and the hand and fingers flaccid, so that a form of *wrist-drop* ensues; all the muscles supplied by the musculospiral nerve being paralysed. Some degree of supination, however, can be effected by the action of the biceps. Although the extensors of the wrist and fingers have become paralysed, yet, when the fingers are flexed into the palm (Fig. 190 *a*), they can be extended rapidly, and with some degree of force, at the first interphalangeal articulations, as far as is represented in Fig. 190 *b*. This limited movement of extension is due to the action of the interossei and lumbricales which, being supplied by the ulnar and median nerves, do not participate in the paralysis, for, as pointed out by Duchenne of Boulogne, the interossei extend the second and third phalanges and flex the first phalanx, flexion of the two distal phalanges being accomplished entirely by the long flexors.

Fig. 190. Paralysis of Hand (Wrist-Drop) after Fracture of Humerus.

When the posterior interosseous nerve only is paralysed, the loss of supination and extension is necessarily less complete: these movements being still practicable to a limited extent, through the medium of the long supinator and the long extensor of the wrist, which are supplied from the main trunk. If

Fig. 191. Permanent Flexure from Paralysis after Fracture of Humerus.

Fig. 192.—Apparatus for Wrist-Drop after Fracture of the Humerus.

the paralysis of the extensors and supinators be allowed to continue for some time, the forearm and hand are drawn into a state of permanent flexion and pronation by secondary shortening of the muscles that act in those directions (Fig. 191).

The treatment of this complication of simple fracture of the humerus must be conducted on the principles laid down in the Chapter on Injuries of Nerves. The patient should be encouraged to use the hand as much as possible as soon as the state of the fracture will allow of it, and a splint may be applied at night to prevent the occurrence of deformity. In order to overcome the

flexion of the hand and fingers, due to the unopposed action of the long flexors, a splint with a handpiece admitting of upward movement may be employed to raise the hand and extend the fingers forcibly (Fig. 192).

In a case of pressure on the musculo-spiral nerve by one of the fragments or by the callus, Ollier of Lyons removed a portion of the callus with a chisel and mallet, so as to expose the nerve, and also excised a portion of bone (apparently of the lower fragment), which was strangulating the nerve. At the end of six and a half months, the patient had regained considerable power of extending his wrist. Many cases of the same kind have since been recorded.

Compound and Comminuted Fractures of the Elbow-Joint are necessarily serious accidents. They are commonly occasioned by falls on the point of the olecranon, which is the process of bone most frequently and extensively fractured. In some cases the olecranon escapes injury, whilst the lower epiphysis of the humerus is splintered into many pieces; and more commonly, perhaps, both bones, the ulna as well as the humerus, are injured. As the integuments over the point of the elbow are thick and hard, very extensive comminution of the bones may occur with very little apparent injury of the soft parts. When these fractures are the result of gunshot injury, the soft parts may be extensively torn, and the bones greatly shattered. In the cases that occur in civil practice, I have seldom seen much laceration of the soft parts.

The **Treatment** of these accidents must depend on the amount of injury done both to bones and soft parts. If the articulation be simply opened with little laceration of the surrounding soft parts, and no comminution of the fractured bone, the limb should be saved. If the bones be much shattered, the soft parts not being seriously implicated, removal of the splinters, or resection of the injured joint, will enable the Surgeon to save the rest of the limb; but if the soft parts be extensively contused and torn, the bones at the same time being comminuted, amputation of the arm may be required. If an attempt be made to save the joint without operation, great attention must be paid to drainage, rest, and prevention of decomposition. If the cavity become filled with septic matter, not only will there be severe septic fever, but abscesses will form in front of and around the joint, the splintered fragments will necrose, and excision, or possibly amputation of the limb, will be necessary in a few weeks. These cases, however, as a rule, do very well when treated antiseptically.

Perfect rest may in these cases be obtained by the plan recommended by H. O. Thomas of slinging the hand up over the upper part of the chest by a bandage secured by a clove hitch to the wrist, and tied round the neck.

If the comminution be such as to render removal of the splintered fragments necessary, or if it be evident that recovery can take place only with a stiff elbow-joint, resection should be performed. In these cases the question may arise whether partial or complete removal of the articulation should be practised. This will depend in great measure upon circumstances. If the comminution be such as to require the removal of a considerable length of the humerus, it is better, if possible, to leave the bones of the forearm untouched, otherwise a flail-like arm is certain to result. If but little length of bone has to be removed, there is some danger of a stiff elbow resulting unless the whole cartilage-covered surfaces of the bones are removed. In cases in which a secondary excision becomes necessary after an attempt to save the joint has

failed, it is better to follow the ordinary rule of removing all the articular surfaces even if only one is injured, as in these cases the cartilages have often necrosed from the irritation of the septic discharges, and would seriously delay the cure. When primary resection is determined on, the sooner the operation is done the better; when a secondary operation is necessary, after septic inflammation has followed the accident, the Surgeon must wait till the septic fever begins to subside, and suppuration is fully established, and then he should do it with as little delay as possible, lest hectic or pyæmia supervene. The operation as performed differs in no material respect from the same operation for disease of the articulation, which will be described in Chapter XLIX. In primary excision great care must be taken to save the periosteum as much as possible, otherwise a flail-like joint may result. In secondary operations, as the periosteum is loosened by the inflammation, it usually is saved without difficulty.

FRACTURES OF THE FOREARM.—1. The only fracture of the bones of the forearm that commonly occurs in the vicinity of the elbow-joint, is that of the **Olecranon**; this happens most commonly from falls upon the elbow, but it may occur from muscular action. Bardenhauer and König describe fracture of the olecranon by indirect violence from forced over-extension of the elbow in falls on the hand. The displacement is sometimes considerable, the detached fragment being

Fig. 103. - Fracture of Olecranon.

drawn upwards by the triceps muscle. Frequently, however, when the ligamentous expansion from the tendon of this muscle to the fascia of the forearm is not torn through, there is but little separation of the fragments. There is always effusion of blood into the joint, which necessarily prevents the close approximation of the fragments. In the majority of cases, as the injury takes place from direct violence, there is much swelling about the joint: and not unfrequently the fracture is comminuted or compound.

Fig. 104. Apparatus for Fractured Olecranon

The **Treatment** is best conducted by moderately straightening the arm, and maintaining it in that position by means of a well-padded light wooden splint laid along its fore part. But, although the arm should be kept nearly straight, it should not be quite extended. The best and most easy position in which to put it up is that into which the arm naturally falls when hanging by the side; in this there will be seen to be slight flexion at the elbow (Fig. 104). If the forearm be too rigidly extended on the arm, it may be carried back-

flexion of the hand and fingers, due to the unopposed action of the long flexors, a splint with a handpiece admitting of upward movement may be employed to raise the hand and extend the fingers forcibly (Fig. 192).

In a case of pressure on the musculo-spiral nerve by one of the fragments or by the callus, Ollier of Lyons removed a portion of the callus with a chisel and mallet, so as to expose the nerve, and also excised a portion of bone (apparently of the lower fragment), which was strangulating the nerve. At the end of six and a half months, the patient had regained considerable power of extending his wrist. Many cases of the same kind have since been recorded.

Compound and Comminuted Fractures of the Elbow-Joint are necessarily serious accidents. They are commonly occasioned by falls on the point of the olecranon, which is the process of bone most frequently and extensively fractured. In some cases the olecranon escapes injury, whilst the lower epiphysis of the humerus is splintered into many pieces; and more commonly, perhaps, both bones, the ulna as well as the humerus, are injured. As the integuments over the point of the elbow are thick and hard, very extensive comminution of the bones may occur with very little apparent injury of the soft parts. When these fractures are the result of gunshot injury, the soft parts may be extensively torn, and the bones greatly shattered. In the cases that occur in civil practice, I have seldom seen much laceration of the soft parts.

The **Treatment** of these accidents must depend on the amount of injury done both to bones and soft parts. If the articulation be simply opened with little laceration of the surrounding soft parts, and no comminution of the fractured bone, the limb should be saved. If the bones be much shattered, the soft parts not being seriously implicated, removal of the splinters, or resection of the injured joint, will enable the Surgeon to save the rest of the limb; but if the soft parts be extensively contused and torn, the bones at the same time being comminuted, amputation of the arm may be required. If an attempt be made to save the joint without operation, great attention must be paid to drainage, rest, and prevention of decomposition. If the cavity become filled with septic matter, not only will there be severe septic fever, but abscesses will form in front of and around the joint, the splintered fragments will necrose, and excision, or possibly amputation of the limb, will be necessary in a few weeks. These cases, however, as a rule, do very well when treated antiseptically.

Perfect rest may in these cases be obtained by the plan recommended by H. O. Thomas of slinging the hand up over the upper part of the chest by a bandage secured by a clove hitch to the wrist, and tied round the neck.

If the comminution be such as to render removal of the splintered fragments necessary, or if it be evident that recovery can take place only with a stiff elbow-joint, resection should be performed. In these cases the question may arise whether partial or complete removal of the articulation should be practised. This will depend in great measure upon circumstances. If the comminution be such as to require the removal of a considerable length of the humerus, it is better, if possible, to leave the bones of the forearm untouched, otherwise a flail-like arm is certain to result. If but little length of bone has to be removed, there is some danger of a stiff elbow resulting unless the white cartilage-covered surfaces of the bones are removed. In cases in which a secondary excision becomes necessary after an attempt to save the joint has

failed, it is better to follow the ordinary rule of removing all the articular surfaces even if only one is injured, as in these cases the cartilages have often necrosed from the irritation of the septic discharges, and would seriously delay the cure. When primary resection is determined on, the sooner the operation is done the better; when a secondary operation is necessary, after septic inflammation has followed the accident, the Surgeon must wait till the septic fever begins to subside, and suppuration is fully established, and then he should do it with as little delay as possible, lest hectic or pyæmia supervene. The operation as performed differs in no material respect from the same operation for disease of the articulation, which will be described in Chapter XLIX. In primary excision great care must be taken to save the periosteum as much as possible, otherwise a flail-like joint may result. In secondary operations, as the periosteum is loosened by the inflammation, it usually is saved without difficulty.

FRACTURES OF THE FOREARM.—1. The only fracture of the bones of the forearm that commonly occurs in the vicinity of the elbow-joint, is that of the **Olecranon**; this happens most commonly from falls upon the elbow, but it may occur from muscular action. Bardenhauer and König describe fracture of the olecranon by indirect violence from forced over-extension of the elbow in falls on the hand. The displacement is sometimes considerable, the detached fragment being

Fig. 193. —Fracture of Olecranon.

drawn upwards by the triceps muscle. Frequently, however, when the ligamentous expansion from the tendon of this muscle to the fascia of the forearm is not torn through, there is but little separation of the fragments. There is always effusion of blood into the joint, which necessarily prevents the close approximation of the fragments. In the majority of cases, as the injury takes place from direct violence, there is much swelling about the joint; and not unfrequently the fracture is comminuted or compound.

Fig. 194. —Apparatus for Fractured Olecranon.

The **Treatment** is best conducted by moderately straightening the arm, and maintaining it in that position by means of a well-padded light wooden splint laid along its fore part. But, although the arm should be kept nearly straight, it should not be quite extended. The best and most easy position in which to put it up is that into which the arm naturally falls when hanging by the side; in this there will be seen to be slight flexion at the elbow (Fig. 194). If the forearm be too rigidly extended on the arm, it may be carried back-

wards beyond the straight line, owing to loss of the resistance of the olecranon against the fossa at the back of the humerus. In order to facilitate the approximation of the fragments, Lauenstein recommends puncture of the joint with antiseptic precautions and evacuation of the blood and serum. The fluid could be more safely removed with the aspirator, and the treatment certainly deserves further trial.

As a rule, union takes place by firm fibrous tissue, but bony union has sometimes been obtained. Should the union be so loose as to render the arm useless, it has been recommended to cut down on the seat of fracture, freshen the bony surfaces, and apply a wire suture as in the treatment of ununited fractures elsewhere. In order to do this without the risk of suppuration, the strictest antiseptic precautions must be observed. The operation has been successfully performed by Lister, MacCormac, and others; but the cases in which such an operation could be required are rare.

Period of Union.—A simple fracture of the olecranon is usually united with sufficient firmness to allow of the splint being abandoned in from four to five weeks, after which passive movement must be carefully carried out to get rid of the stiffness of the joint.

In **Compound Fracture of the Olecranon**, the joint must be syringed out with an antiseptic solution, and treated by some form of antiseptic dressing. The fragment should be fixed to the ulna by wire sutures, care being taken to provide drainage from the joint on each side of it. In cases in which suppuration has taken place, and where there is a probability of ankylosis, the semi-flexed would be preferable to the straight position. If destruction of the joint follow, excision may be necessary.

Fracture of the Coronoid Process of the Ulna has been supposed by many Surgeons to be a common complication, and, indeed, a cause of dislocation of the ulna backwards. There is every reason, however, to believe that this is an error, and that, in point of fact, it is one of the rarest accidents—at least, if we judge by the small number of recorded cases or of preserved specimens of this injury. Hamilton states that there are but eight cases on record in which there was reason to believe that this accident had occurred; that in not one of these cases were the symptoms unequivocal; and that in none did dissection afford an opportunity of demonstrating this fracture. There are but four preparations in existence, according to Hamilton, illustrative of this injury, and all these are doubtful. In the cases in which this accident has been supposed to have occurred, the injury has arisen from falls on the palm of the hand, by which the ulna has been driven backwards, and the coronoid process, striking against the lower end of the humerus, splintered off. In a case related by Liston, the injury is said to have been produced by muscular action in a boy, who, hanging for a length of time by his hands from a high wall, fell to the ground, and was supposed to have sustained this fracture. Whether the fracture actually occurred is doubtful; and, if it did, it is still more doubtful whether it was occasioned by the contraction of the brachialis anticus muscle, or by the violence of the fall.

In the present uncertain state of our knowledge, I forbear to speak of the supposed symptoms of this accident. If it were suspected, the proper treatment would consist in placing the limb in angular splints.

2. **Fractures of the Forearm** are very common, and both bones are usually broken. The deformity varies much, but there is often marked angula-

formity and some shortening. If one bone only, commonly the ulna, be fractured, more attention will be required in establishing the precise nature of the injury.

In the **Treatment** of fractures at or below the middle of the forearm, the position midway between pronation and supination should be chosen, as this gives the greatest natural interval between the two bones, and brings the lower fragment into a position corresponding to that of the upper (Fig. 195). A fractured forearm is usually put up while the patient is seated, with the arm raised to the level of his head and the elbow bent at a right angle. In this position the bones are midway between pronation and supination when the thumb points towards the face. Plain wooden splints are applied to the ulnar and dorsal surfaces of the forearm. They must be equal in breadth to the greatest transverse measurement of the limb, so that the bandages may not press on the soft parts between the edges of the splints, and thus ap-

Fig. 195. Preparation showing Anatomical Relations of Fracture of Radius below the Insertion of the Pronator radii teres. *b*, biceps; *o.l.*, supinator longus; *a.b.*, supinator brevis; *p.q.*, pronator quadratus; *p.t.*, pronator teres; *i.l.*, interosseous ligament; *o.l.*, orbicular ligament.

proximate the broken bones. If the bones be put up in an improper position and squeezed together, a mass of callus may unite them across the interosseous space, and thus prevent pronation and supination (Fig. 196). The splints must be evenly padded, and in applying them care must be taken that they be held perfectly parallel.

If the fracture of the radius be situated above the insertion of the pronator radii teres the upper fragment is supinated, and therefore during the treatment the hand must also be kept supinated so that the lower fragment is brought to a corresponding position. With the arm hanging by the side and the elbow flexed at a right angle, the palm of the hand will be directed upwards, and this position is best maintained by the application of a palmar splint to the forearm and a dorsal rectangular splint to the arm and forearm.

The splints should always be removed and the limb examined without disturbing the fracture at the end of every second day for the first week, as the pressure of the pad between the bones is apt to cause sloughing without any other sign of mischief. In such cases the slough may extend to the skin and muscles, and the median and ulnar nerves may become paralysed by pressure. When the slough separates, the flexor muscles may be exposed and become involved in the scar in healing, thus leading to forced flexion and

stiffness of the wrist and fingers. I have seen more than one case in which this has happened.

Green-stick fracture of the forearm in children is far from uncommon, and the bones should be enwrapped completely through before the splints are applied, otherwise angular deformity is almost certainly left.

Fig. 196.—Obliteration of the interosseous space in a fracture of the forearm.

In a case of fracture of the upper end of the ulna, under the care of Marcus Beck, there was marked angular deformity backwards, caused by the action of the triceps. This deformity could be reduced only by putting up the limb with the elbow extended.

Period of Union.—The average time of union in the forearm is five weeks.

Compound Fractures of the Forearm seldom give much trouble or require amputation, but they very commonly lead to obliteration of the interosseous space, and thus impair the utility of the limb, by preventing pronation and supination.

3. **Fractures of the Lower Extremity of the Radius**, near the wrist, are very frequent, especially in women after the age of 45. Their importance, not only from a diagnostic point of view, but also in reference to treatment, has caused them to be carefully studied; and their nature and pathology have been specially investigated by Colles, Nélaton, R. W. Smith, and Gordon.

The lower end of the radius is liable to several different kinds of fracture. The most common of these is that which is generally called "**Colles's Fracture**," after the eminent Surgeon who first fully described it. In this fracture the carpal end of the radius is broken across, usually by a fall on the palm of the hand, the lower fragment being displaced backwards. Gordon, who gave great attention to the mechanism of this fracture, states that, in twenty-seven old specimens examined by him, the line of fracture posteriorly varied from $\frac{3}{4}$ to $1\frac{3}{4}$ inch, and anteriorly from $\frac{1}{2}$ of an inch to two inches above the carpal border of the radius, being in ten one inch and under, in ten more than one inch but not over $1\frac{3}{4}$ inch, in the others undefinable. The fracture is usually oblique from before backwards. Besides Colles's, three other fractures are met with in this situation: 1. Simple Transverse; 2, with comminution of the Lower Fragment; and 3, with firm Impaction of the Upper into the Lower Fragment.

The **Signs** of fracture of the lower end of the radius vary greatly, according to the nature of the injury. In an uncomplicated case, there is usually no very great displacement; but there will be noticed some tumefaction about the wrist, a swelling at its dorsal aspect, loss of the movement of the radius and crepitus on rotating the bone whilst the hand is drawn down. When the fracture is *comminuted*, and still more so when *impacted*, the deformity is very marked and characteristic; so much so, that it may be looked upon as diagnostic of these forms of this accident. The displacement gives rise to a remarkable undular distortion of the wrist. On looking sideways at the hand and forearm held midway between supination and pronation, it will be seen that there is a considerable dorsal prominence apparently situated just above

the back of the carpus (Fig. 197) ; immediately underneath this, on the palmar aspect of the wrist, opposite the annular ligament, there is a remarkable hollow, confined to the radial side of the limb : a little above this—that is to say, on the lower part of the anterior aspect of the forearm—there is another rounded prominence, not nearly so large, however, as the one on the dorsal aspect. The hand is abducted and rotated outwards, so that its axis is oblique to that of the forearm ; the inner border being somewhat convex, and the styloid process

Fig. 197.—Fracture of Lower End of Radius. Side View.

of the ulna projecting sharply under the skin (Fig. 198). The radial side of the wrist is, on the contrary, somewhat concave and shortened.

The pain is very severe, and is greatly increased by moving the hand, especially by making any attempt at supination. The hand is perfectly useless, the patient being unable to support it. All power of rotation is lost, the patient moving the whole of the arm from the shoulder, and thus apparently, but not really, pronating and supinating it. Crepitus can readily be felt when the fracture is unimpacted or comminuted ; but when it is impacted, the most careful examination fails to elicit it. Simultaneous fracture of the radius on both sides of the body is a rare occurrence.

Fig. 198. Fracture of Lower End of Radius. Back View.

The *Cause of the Deformity* has been the subject of much discussion, owing to the rarity of opportunities of dissecting recent fractures of this kind. Surgeons are now agreed, however, that the dorsal prominence is due to the lower fragment, carrying the carpus with it, being displaced backwards and upwards ; whilst that on the palmar aspect is due to the projection forwards of the lower end of the upper fragment, which is thrown into a state of pronation. The pronation of the upper fragment is evidently due to the pronatores quadratus and radii teres ; but to what is the displacement of the lower fragment due ? Is it to the peculiar manner in which the two fragments are locked into one another ? or is it due to muscular action ? Some years ago I had an opportunity of dissecting the limb of a woman who died from other causes in University College Hospital twelve days after meeting with this accident. On examining the left arm, which presented all the signs of this injury in a marked degree, and from which Fig. 198 was taken, a transverse fracture of the radius was found about an inch above its articular surface. The lower fragment was split into three portions, between which the upper fragment was firmly impacted to the depth of more than half an inch. The three portions into which the lower fragment was split were of very unequal size ; the two

posterior ones being small, consisting merely of scales of bone; the third fragment, the largest, comprising the whole of the articular surface of the radius, which was tilted somewhat upwards and backwards, carrying the hand with it. To this fragment were attached the supinator longus, and part of the pronator quadratus; the ligaments and capsule of the joint were uninjured.

Fig. 199.—Fracture of Lower End of Radius. Displacement of Articular Surface.

This case presented the appearance usually met with in this kind of injury; the lower fragment being displaced in such a way that its articular surface looked slightly backwards, and somewhat outwards, so as to be twisted as it were upon its axis. The upper fragment was found in a state of pronation, and was driven into and firmly impacted in the lower one.

That the deformity in this case was the result of impaction, there could be no doubt; and that this is so in many cases, is proved by an examination of several specimens preserved in the London Museums, and by the difficulty of accounting in any other way for the occasional impossibility of properly reducing these fractures. The great traction that is usually required to remove the deformity, and the absence of distinct crepitus until after forcible traction has been employed, indicate the existence of this impaction.

Mechanism.—The mode in which the accident occurs, and the position of the hand at the moment of its coming into contact with the ground, will, I think, materially influence the kind of fracture as well as the amount and character of the resulting deformity. When a person falls on his hands outstretched to save him, the limb is usually not completely pronated. It is half-way between complete pronation and the mid-state between pronation and supination. Complete pronation is a forcible muscular effort which is not carried to the full extent at the moment of danger. The hand is in fact three-quarters

Fig. 200.—An old Colles's Fracture of the Radius. Showing the dorsal prominence made by the lower fragment and the Carpus, and the pulvinate projection caused by the anterior part of the lower end of the Upper Fragment.

pronated—not wholly so. The effect of this position is, that the ulnar border is directed slightly downwards and first comes into contact with the ground, and the fracturing force is directed in a line that is somewhat towards the radial side, as well as backwards and upwards. Hence the hand is driven from the ulna towards the radius, causing the strongly marked projection of the styloid process of the ulna; and, the radius being broken across at its lower end, the fragment, carrying with it the carpus and hand, is driven backwards, upwards, and slightly outwards, causing the double deformity of a projection

at the back of the forearm immediately above the carpus, and the concavity along the outer line of the radius.

But if, as sometimes happens, the hand be forcibly pronated at the moment when it touches the ground, then the shock, which is received principally on the ball of the thumb and the radial side of the wrist, impinges in a direction obliquely from before backwards, and from without inwards, as well as from

below upwards, and thus has a tendency, as soon as the bone is broken, to rotate the lower fragment on its own axis, and to tilt the articular surface somewhat upwards and outwards. As the upper fragment descends, its posterior surface of compact tissue is forced into the cancellous structure of the lower fragment until the two posterior portions of compact tissue come into contact; and thus the upper line of compact tissue is driven into the lower fragment, to an extent corresponding to the degree with which the fragment is rotated upwards and backwards. If the bone be brittle, or the force be continued after this

Fig. 201 - Fracture of Lower End of Radius: Displacement of Lower Fragment.

amount of impaction has taken place, the lower fragment will be splintered. The prominence of the styloid process of the ulna in this case is the result of the shortening of the radial side of the wrist and hand, consequent upon the impaction.

Fig. 202 - A section of the bone from which Fig. 201 was taken, showing the impaction of the compact tissue of the posterior aspect of the Upper Fragment into the cancellous tissue of the Lower.

When the fracture is unimpacted, or when it is comminuted without impaction, I agree with R. W. Smith that the displacement of the lower fragment is the result of muscular action alone. This I have had an opportunity of observing in the following case. A man, 64 years of age, fell from a height of twenty-five feet, breaking the left radius just above the wrist, and at the same time receiving such serious injuries of the pelvis and abdomen, that he died in an hour after admission into the Hospital. On dissecting the arm about twenty-four hours after death, I found that the radius was fractured transversely about half an inch above its lower end, and that the lower fragment was completely comminuted. The wrist, which presented all the signs of this fracture in a marked, but not an extreme degree, could not be restored to its normal shape by any amount of traction. On exposing the muscles of the limb, it was found that the supinator longus was attached to the lower, and the pronator quadratus to the upper fragment: the latter muscle being slightly lacerated at its lower part. The upper fragment was strongly pronated. The main obstacle to reduction was found to exist in the two radial extensors of the wrist, the tendons of which were excessively tense; next to these, the special extensors of the thumb presented most tension, and then the supinator longus, which was far less tense than either of the other sets of muscles, but especially than the radial extensors, the tendons of which were strongly defined. On dividing these tendons, and on pressing the lower end of the upper fragment outwards, reduction was easily effected. Here the

displacement was evidently due to two causes. The upper fragment was forcibly pronated by the action of its special pronators; and the hand, with the lower fragment attached, was drawn upwards and backwards by the radial extensors of the wrist. There was no impaction or interlocking of fragments, but perfect mobility, and hence muscular action was enabled to come into play.

In another case which I have since dissected, the muscles chiefly at fault were the radial extensors; next to these the extensors of the thumb; the supinator longus being but slightly if at all contracted.

Besides this injury, R. W. Smith has described a fracture of the lower end of the radius from falls upon the back of the hand, in which the inferior fragment is displaced forwards. In these cases the character of the deformity indicates the nature of the injury. It can readily be reduced by traction.

In another variety of fracture in this situation, the lower end of the radius and that of the ulna are broken off, resembling very closely dislocation of the wrist backwards. But the existence of grating, the ready reduction of the swelling, and the attachment of the styloid processes of the radius and of the ulna to the carpus, with which they move, will be sufficient to establish the diagnosis.

In the **Treatment** of the ordinary fracture of the radius near the wrist, numerous methods are employed by different Surgeons. In all cases the deformity must be reduced, if possible, by extension and counter-extension, and if there be impaction, considerable force may be required to disentangle the fragments and remove the dorsal prominence. Whatever splint be used, prolonged fixation of the wrist and fingers must be avoided.

Carr's splint will be found most efficient in overcoming the deformity, and comfortable to the patient (Fig. 203). It consists of a narrow splint slightly hollowed out to fit the radius, obliquely across the end of which is a cylinder of wood about four inches long by half an inch in diameter. This is thinly padded with folded lint and applied to the forearm in such a way that the cylinder corresponds to the metacarpophalangeal articulations. The displacement must be reduced and the hand well drawn towards the ulnar side as the splint is applied. The fingers are now bent down so as to make them firmly grasp the cylinder of wood. A short splint, about two inches wide, is then placed on the back of the forearm, and both are secured by strapping and bandage. The bandage may at first be applied so as to keep the fingers in the flexed position, grasping the cylinder, but after the first week it must not extend beyond the carpo-metacarpal articulation, the fingers being left perfectly free to move. By the use of this apparatus the tendency to stiffness of the fingers is greatly diminished.

Pistol-splint.—This consists of a wooden splint of the shape represented in Fig. 204. It should be carefully padded, the padding being made thicker opposite the lower fragment, and then, with the straight portion held very

Fig. 203. — Carr's Splint.

Pistol-splint.—This consists of a wooden splint of the shape represented in Fig. 204. It should be carefully padded, the padding being made thicker opposite the lower fragment, and then, with the straight portion held very

cally, the head of the splint should be fixed to the back of the hand. Gentle extension should then be made, and the hand bent to the ulnar side by raising the straight portion of the splint to the horizontal position, so as to make it lie against the back of the forearm, where it should be held, while another straight splint, extending from the elbow to the lower end of the upper fragment, is placed on the front of the forearm. Both splints should then be fixed by means of a roller, care being taken to have the anterior splint well padded along the radial border, so as to counteract the tendency to pronation of this part of the bone. The arm must then be placed in a sling. The

Fig. 204.—Pistol-Splint.

pistol-splint should be worn for a fortnight or three weeks. At the end of this time a gauntlet of gutta-percha, or other plastic material, may be moulded to the wrist and worn instead of the splint. All apparatus should be discontinued at the end of five weeks in the adult, a week or two earlier in children. The fracture unites in the course of a month or five weeks. After the first week it is well, especially in elderly people, to leave the fingers free, and to encourage movement of them, lest that painful stiffness result which is so common a sequela of the accident. Passive motion of the wrist-joint may, however, often be commenced, with great advantage to the patient, before the union of the fracture. If the hand and fingers be kept fixed on the splint until the fracture is fully united, very troublesome and painful stiffness will result. It is frequently fully three months before this is so far diminished, even by the use of friction and douches, as to enable the patient to use the fingers, the stiffness of the wrist being often due to the extension of a fissure into the joint.

Gordon's splint is represented in Fig. 205. The lower end of the dorsal splint, and the process of the palmar splint which fits the ulnar border of the

Fig. 205.—Gordon's Splint

hand, are curved forwards, so as to remedy the backward displacement of the lower fragment. The bevelled portion attached to the palmar splint is intended to fix the upper fragment.

FRACTURES OF THE METACARPUS AND FINGERS are of so simple a character as scarcely to call for detailed remarks. There is only one accident to a metacarpal bone that can lead to any difficulty in diagnosis. This is the case in

which the neck of the bone is broken transversely, so that the head is carried forwards with the finger, and thus simulates closely a dislocation of the finger towards the palmar surface. A comparison of the line of the bent knuckles, together with crepitus on rotation, will determine the nature of the injury. The *Treatment* of a fracture of the metacarpal bone of the thumb is best carried out by the application of a narrow plaster of Paris bandage as a spica to the thumb and wrist. In the case of the others a leather or gutta-percha gauntlet may often suffice, but in some instances the deformity is best reduced by the use of an anterior wooden splint or by bandaging the fingers over a roller bandage or ball-shaped pad placed in the palm. In compound fracture of these bones, every effort should be made to save the part; if removal become necessary, it should be as limited in extent as possible (p. 100).

Period of Union.—A fracture of one of the bones of the hand is firmly united by the end of the third week, when splints will no longer be required.

FRACTURES OF THE PELVIS AND THE LOWER EXTREMITY.

FRACTURES OF THE PELVIS.—The pelvic bones can be broken only by great and direct violence. The complete circle which they form, their solidity, and the strength of their articulations, enable them to resist all indirect causes of fracture. In civil life these bones are usually broken by crushes of the body, as between a cart and a wall, by falls of rock in mining accidents, or by the crushing force of railway collisions.

When broken, the pelvis usually gives way at the rami of the pubes and ischium in front, and across the ilium, at or near the sacro-iliac synchondrosis behind, usually on the side opposite to that of the fracture in front (Fig. 200). The pubes may be, but rarely is, broken across its body, and the symphysis is seldom torn through. When one side of the pelvis is thus broken away from the rest of the bone, it and the attached lower extremity are necessarily connected with the rest of the body only by the soft parts that unite the pelvis to the spinal column and trunk. These are consequently liable to severe stretching, laceration, and other injury.

In some cases, portions of the crest of the ilium only are detached. In others, the rami in front may be broken without corresponding posterior fracture. Such injuries can, however, arise only from gunshot wounds, or similar forms of direct violence. When the fracture results from a crush, double fracture, back and front, must necessarily occur.

The danger in simple fracture of the pelvis arises from the injury to the important soft parts contained within it. Muscles, nerves, and blood-vessels may be stretched or torn. The bladder may be wounded by a splinter of bone from the pubes or ischium; or the urethra may be torn, perhaps completely across, from the same cause. When the urethra is torn, a slight oozing of blood will usually be observed at its orifice, with possibly much deep ecchymosis of the perineum.

The nature of the injury is usually apparent from the great degree of direct violence that has been inflicted upon the part; from the pain that the patient experiences in moving or in coughing; from the inability to stand, in consequence of a feeling as if the body were falling to pieces; and from the ready mobility of the part and crepitus on seizing the brim of the pelvis on each side and moving it to and fro, or on rotating the thigh of the affected

side. Blood effused into the iliac fossa may extend forwards and produce discoloration along the line of Poupart's ligament. In examining a patient with suspected fracture of the pelvis, care should, however, be taken not to push the investigation too closely, lest injury be inflicted by the movement of the fragments. In those cases, indeed, in which the fracture does not extend completely across the pelvis, or in which it is seated in the deeper parts of the ischium, an exact diagnosis may be very difficult, and should not be attempted.

Treatment.—As the great danger in fracture of the pelvis consists in the possibility of the urethra having been torn or the bladder wounded, the first thing to be done is to pass a gum catheter. If the urine be clear, it may be concluded that the urinary apparatus has not been injured, and the catheter may be withdrawn. If it be bloody, the catheter must be tied in, and an india-rubber tube applied by which the urine may drain away. The next thing is to keep the part perfectly quiet, so as to bring about union. With

Fig. 206 — Fracture of the Pelvis through Ramus in front, and Sacro-tuberous Synchondrosis behind.

this view, a padded belt, or a broad flannel roller, should be tightly applied round the pelvis, the patient lying on a hard mattress, or plaster of Paris may be applied in a manner similar to that recommended for the treatment of fractured spine (p. 810). The knees may then be tied together, and a leather or gutta-percha splint moulded to the pelvis and thighs, so as to prevent all displacement of the fragments. If the urethra have been lacerated, however completely the patient may recover from the fracture, he will most certainly become eventually the subject of the most intractable form of stricture—the traumatic.

Period of Union.—Bony union usually takes place in the pelvis about the end of the sixth week. The patient must, therefore, be kept on his back with absolute immobility of the lower limbs for at least seven or eight weeks. He may then, wearing a padded belt, move about on crutches. However good the union may be, lumeness is apt to result from the injury inflicted on the psoas and iliacus muscles, and those that closely bind the thigh to the pelvis, such as the pectineus, the obturators, &c.

Fracture of the Acetabulum is an accident that can occur only as the result of very great violence directly applied to the hip. It may take place in two situations: either through the floor of the cavity, or only through the

rim, a portion of which is detached. It is probably occasioned in most instances by the head of the thigh-bone being driven forcibly against the surface of the acetabulum. Hence, when the rim is broken, it is usually the posterior part that is detached, and the head of the femur slips out upon the dorsum ilii.

Fracture through the floor of the acetabulum is usually complicated with such extensive comminution of the pelvic bones and serious internal injury, as to be soon followed by death. In the University College Museum is a preparation of a fracture of the acetabulum, with comminution of its floor and of the ilium. Sanson and Astley Cooper have seen the bone resolved into its three primitive parts; and in some cases the comminution has been so great that the head of the femur has been thrust into the pelvic cavity. In such extensive and grave injuries as these, the Surgeon can do little more than support the pelvis with a padded belt, and place the limb on a long splint.

When a portion of the rim of the acetabulum is detached, as the result of direct violence, the head of the femur will slip out upon the dorsum ilii, and the signs of one of the forms of dorsal dislocation will manifest themselves. In a case of this kind, in a muscular man aged about thirty, which was under my care, the shortening and inversion of the limb and displacement of the head of the bone towards the sciatic notch were all well marked. Traction readily effected reduction, with distinct crepitus; but, as soon as extension was discontinued, the head of the bone slipped back into its former position.

The **Treatment** consists in the application of the long splint with a broad padded belt, so as to secure steadiness of the head of the bone. But with every care a return of displacement will readily take place, and an unsatisfactory result can scarcely be avoided; shortening of the limb, and consequent lameness, being almost inevitable.

FRACTURES OF THE SACRUM are excessively rare, except as the result of gunshot injury. When occurring from other causes, such as falls, they are almost invariably associated with fracture of the pelvic bones, and then they have always been fatal. The records of surgery contain but very few observations, probably not more than six or eight, of uncomplicated fracture of the sacrum arising from other causes than gunshot. I have had two cases of fracture of the sacrum under my care, both of which had a rapidly fatal issue. In one there was also fracture through the pubic bone; in the other, the sacrum was the only bone injured. In that case, the fracture was the result of a blow on the lower part of the back from the buffer of a railway carriage. The preparation is in the University College Museum. The only other preparation with which I am acquainted is one in the Museum of the College of Surgeons. These fractures are almost invariably transverse, with displacement forwards of the upper margin of the lower fragment. This was the case in both the instances under my care; but Richerand has published a case in which the bone was split vertically in consequence of a fall on the face; and crucial and multiple fractures of it have been described by others. The injury can necessarily arise only from severe direct violence, and is attended with much extravasation and pain, together with neuralgia along the course of the posterior sacral nerves, which may be implicated in or irritated by the fracture. The *Treatment* is the same as for fractured pelvis, and consists in the application of a padded pelvic band.

The **Coccyx**, though more exposed, is seldom broken. But fracture of it

may occur from falls backwards, or from direct blows on the part, the tip being not forcibly forwards. The displacement forwards is maintained by the action of the coccygei. The pain in these cases is excessively severe, owing to the raising of the ligamentous and tendinous expansions that cover the bone. It is greatly increased in sitting and walking, and in defæcation, or in any violent expiratory effort, as sneezing or coughing. It is sometimes removed by reducing the displaced fragments by pressure through the rectum, but it may continue for months or years. South relates the case of a gentleman who broke his coccyx by sitting on the edge of a snuff-box, and who suffered such severe pain, that he was obliged to wear a pad on the tuberosity of each osium, in order that the coccyx might be free from pressure when he sat.

Under the term **Coccydynia**, J. Y. Simpson described a painful affection of the coccyx and its neighbouring structures, which occurs chiefly in women, commonly as the result of injury, and is often very severe and permanent, so as to prevent the patient from sitting, or even walking with comfort. The pain closely resembles that occasioned by fissure or ulcer of the rectum. It usually arises from a blow on the part, but appears sometimes to originate independently of external violence.

In some cases the coccyx may be in its normal position, but in others the whole bone is found to have been displaced, and to be bent forwards almost at right angles to the sacrum. It can be felt projecting into the rectum, and is maintained in its abnormal position chiefly by the action of the coccygei. This condition is in fact rather a dislocation than a fracture. The bone can usually be forced into its normal position with the finger in the rectum, but the displacement returns as soon as the pressure is removed.

The **Treatment** recommended by Simpson consists in the free subcutaneous division, by means of a tenotome, of the muscular and tendinous structures connected with the coccyx. The section is made first on one side, then on the other, and finally around the tip, so as completely to isolate the bone. I have often performed this operation, and have as often as not been disappointed in the results. When it succeeds the good effects are immediate. When it fails the bone may be removed by a longitudinal incision over its middle, exposing its posterior surface. This operation is free from danger, and may give relief, but is not certain in its results.

FRACTURES OF THE THIGH-BONE may occur in the Upper Articular End of the bone, in its Shaft, or in its Lower End. In these different situations, every possible variety of fracture is met with.

1. **Fractures of the Pelvic End of the Bone** may be divided into those that occur *through the Neck Within the Capsule* of the joint, those that occur *outside the Capsule*, and those that implicate the *Trochanters* alone.

Intracapsular Fracture of the Neck of the Thigh-bone may be either simple, the bone being merely broken across; or impacted, the lower portion of bone being driven into the upper fragment.

This intracapsular fracture may almost be looked upon as an injury peculiar to advanced life, being but seldom met with in persons under fifty. Thus Estley Cooper states that, of 251 cases with which he met in the course of his practice, only two were in persons below this age. It may, however, happen at an early period of life; Stanley has recorded the case of a lad of eighteen who met with this injury, and Hamilton has described it as occurring in a girl aged sixteen and in a man aged twenty-five. A remarkable circumstance in

connection with this accident is, that it commonly happens from very slight degrees of violence, indeed almost spontaneously. Thus, the jarring of the foot in missing a step in going downstairs, catching the toes under the carpet, tripping upon a stone, or entangling the foot in turning in bed, are sometimes sufficient to occasion it.

Cause.—The occurrence of this fracture in old age is owing indirectly to the changes in structure, shape, and position of the head and neck of the femur with advancing years. The cancellous structure becomes expanded, the spaces large and loaded with soft fat. The compact structure becomes thinned, and proportionately weakened, especially about the middle and under part of the neck, which, appearing to yield to the weight of the body, is shortened; and the angle between the neck and the shaft is generally said to become lessened, although the investigations of Humphry throw considerable doubt on this

Fig. 207. Intracapsular Fracture of the Neck of the Femur.

Fig. 208. Attitude of Limb in Intracapsular Fracture of the Neck of the Thigh-Bone.

belief. In consequence of these changes it becomes less able to bear any sudden shock, and snaps under the influence of very slight degrees of violence. When it breaks, the capsule may remain uninjured, but the prolongation of it which invests the neck of the bone is usually torn. In some cases, however, this cervical reflection is not ruptured, the lower portion especially often remaining for some time untorn, but at last giving way under the influence of the movements of the limb, or from inflammatory softening.

The fragments are almost always so separated that the fractured surfaces are not in apposition; the upper end of the lower fragment is drawn above and behind the head of the bone, and at the same time is twisted so that its broken surface looks forwards. The head remains in the acetabulum, attached by the ligamentum teres, and sometimes preserving a connection with the lower fragment, through the medium of some untorn portions of the fibrous membrane investing the neck. R. W. Smith has observed that in some instances the two

fragments become interlocked or as it were dovetailed into one another, in consequence of the line of fracture being irregular and dentated.

Signs.—These are, alteration in the shape of the hip, crepitus, pain at the seat of injury and inability to move the limb, with shortening and eversion of it. These we must consider separately, as important modifications of each are sometimes noticed. From the indirect and slight nature of the violence which caused the injury there are no signs of superficial bruising over the hip.

The **Alteration in the Shape of the Hip** is evidenced by flattening of the part. The trochanter is not so prominent as usual, and is approximated to the crest of the ilium; and, on rotating the limb, it is felt to roll under the hand in a smaller circle than on the sound side. In the sound limb, the trochanter describes the segment of a circle having a radius equal to the length of the head and neck of the bone; on the injured side, the circle has a radius equal only to the length of that portion of the neck that still remains attached to the shaft of the bone. During this examination *crepitus* will usually be felt, though this occasionally is very indistinct and even absent, more especially if the limb be not well drawn down so as to bring the fractured surfaces into apposition; and great *pain* is produced by any movement of, or pressure upon, the joint.

The **Attitude of the Limb** is so peculiar, as in general to indicate at once what has happened. There is a striking appearance of helplessness about it. As the patient is lying on his back, it is everted, with the knee semi-flexed; the patient's attempts to lift it up are ineffectual, and he at last ends by raising it with the toe of the opposite foot, or with his hands. In the upright position the injured limb hangs uselessly, with the toes pointing downwards, and the heel raised and pointing to the inner ankle of the sound side (Fig. 208). In some cases, however, the patient can lift the limb somewhat, but with much exertion, from the couch on which he is lying; or can even manage to walk a few paces, or to stand for a few minutes upon it, with much pain and difficulty. This is owing either to the cervical reflection of the capsule being uncom-
mon, or else to the fragments having become impacted; and it usually occurs in those cases in which the other and more characteristic signs of this fracture are not well marked.

Eversion of the limb is an almost invariable symptom, and is most marked in those cases in which the shortening is most considerable. This eversion has usually been attributed to the action of the external rotator muscles, which are inserted into the upper end of the lower fragment. But I cannot consider this as the principal cause; for, not only is it very difficult to understand how these muscles can rotate the limb outwards after their centre of motion has been destroyed by the fracture of the neck of the femur, their action being rather in a direction backwards than rotatory under these circumstances; but we find that the limb falls into an everted position in those cases in which, the fracture being in the shaft and altogether below the insertions of these muscles, no influence can be exercised by them on the lower fragment. I look upon eversion in cases of fractured thigh as being simply the natural attitude into which the limb falls when left to itself. Even when the bone is unbroken, eversion takes place spontaneously whenever muscular action is relaxed, as during sleep, in paralysis, or in the dead body; and in the injured limb, in which there is, as it were, a suspension of muscular action, it will occur equally. Indeed, the shortening that takes place will specially tend to relax

the external rotators, and thus still more prevent their influencing the position of the limb.

Inversion of the foot in cases of intracapsular fracture has sometimes been noticed. I have seen two instances: Smith, Stanley, and other Surgeons, have also recorded cases. This deviation from the usual symptoms of the injury has been attributed by some to the cervical reflection of the capsule not having been torn through at its inner side, but that, as Stanley observes, while it may prevent eversion, cannot occasion inversion; by others it has been attributed to the fact of the lower fragment in these cases being found always in front of the upper one. This circumstance, which is much insisted on by R. W. Smith, appears to me to be rather the result than the cause of the inversion; for any traction inwards of the lower fragment by the adductor muscles of the thigh would have a tendency to draw the upper end of this fragment to the anterior, or in other words, the inner side of the upper one. I am rather disposed to think that this inversion is owing, in some cases at least, to the external rotators being paralysed by the violence they receive from the injury that occasions the fracture, and that thus the adductors, acting without antagonists, draw the thigh, and with it the leg, inwards. In both the cases that came under my observation, and in some of those that have been published, the fracture resulted from severe direct injury to the hip, and was not occasioned by the patient jarring his foot, or by any direct violence operating at the end of the limb.

The **Shortening** is at first seldom more than from half an inch to an inch. It cannot, indeed, very well exceed the width of the neck of the bone, as the capsule is usually not torn through. After the fracture has existed some time, the capsule of the joint may yield, allowing greater separation between its fragments, and then it may amount to two, or even two and a half, inches. It not uncommonly happens that the shortening, which is at first but very slight, about half an inch, suddenly increases to an inch or more; this is accounted for on the supposition that the cervical reflection of the capsule, which had not at first been completely ruptured, at last gives way entirely; or it may be owing to the fragments which were originally interlocked becoming separated. It is in those cases in which there is but slight separation of the fragments, and consequently little shortening, that the other signs of fracture are not very strongly marked, and that the patient preserves some power over the movements of the limb.

The ordinary method of measuring the limb is to apply one end of the tape to the anterior superior spinous process of the ilium, and the other to the inner malleolus. The two limbs must be put as accurately as possible in the same position, as flexion and extension will considerably alter the distance between these points. Two other methods have been recommended for more accurately determining the position of the trochanter, both of which are of great diagnostic value in injuries, whether fractures or dislocations, of the hip. The first is known as Nelaton's line; the second, as Bryant's femoral rectangle.

Nelaton's Diagnostic Line (Fig. 209 A, A) consists of a line drawn from the anterior superior spine of the ilium to the most prominent part of the tuber ischi. The importance of this line is, that when the head of the femur is in its normal situation, the line touches the summit of the trochanter when the thigh is raised to a right angle with it. If the trochanter be

displaced in any direction, a corresponding change in its relation to this line will ensue. This mode of measurement is, however, open to the fallacy that abduction raises the trochanter above the line, and adduction brings it below it.

Bryant's Ilio-femoral Rectangle (Fig. 209, A, B, C) is formed by placing the patient in the recumbent position; then, drawing a line (A, B) from the anterior superior spine of the ilium across the outer surface of the hip vertically to the horizontal plane, and a second line (C, D) from the summit of the trochanter upwards at right angles to the first line. In all cases in which the neck of the femur is shortened or the head of the bone displaced upwards, as in some dislocations, the test line (C, D) will be found in measurement to be shorter than on the sound side. In this method there is the same fallacy as

Fig. 209.—Nélaton's Line—dark. Bryant's Ilio-femoral Rectangle—dotted.

in Nélaton's—that abduction and adduction of a healthy limb alter the length of the test line.

Another method of measurement has been recommended by Giraud-Teulon which, although somewhat complicated, appears to be free from all source of error. It is founded upon the fact that the middle of Nélaton's line corresponds to the centre of the acetabulum. Any shortening of the femur by fracture, or any dislocation, will necessarily alter the distance between the lower end of the femur and this point. The measurement is thus carried out. Find the distance from the anterior superior spinous process to the tuberosity of the ischium, and from the same point to the inner condyle, and from the tuberosity to the inner condyle. Then draw a triangle on a sheet of paper, the three sides of which are equal to these three measurements; find the middle point of the line corresponding to the measurement between the tuberosity and the spine, and from that draw a line to the apex of the triangle. This line corresponds to the distance of the inner condyle from the centre of the acetabulum, and must be contrasted with a similar line obtained by measurement of the sound side. This mode of measurement is most useful in cases of dislocation and disense in which abduction or adduction with flexion is often met with.

Whatever mode of measurement is adopted, the Surgeon must never neglect to examine and compare the two sides carefully and simultaneously, with one hand on each hip.

the external
of the limb.

Inversion

noticed. I have also seen injury has been attributed in front of R. W. Smith; for of the the ante-disposed external that antagonized that can be established, occasionally at the

to im- su- be a- g-

t

in old people, though trifling at first, and the injury frequently terminates in metastatic pneumonia, an asthenic state of the system, and confinement to bed. Hence this injury

of these fractures turns in great measure on the mode of union, and on the constitutional state of the patient. In some cases no union occurs, but the head of the femur is hollowed into a smooth, hard, cup-shaped form, which has become rounded off and polished, in the majority of cases, however, union takes place, owing to two causes:—first, that the blood supply is not cut off; and secondly, that the supply of blood to the vessels of the ligamentum teres is not cut off.

Union does take place. This can happen only if the ligament being untorn, or the fracture being in apposition, and the supply of blood to the fragments by that carried to it through the blood vessels between the fragments in the process of union. The head of the femur will usually be found that it looks towards the lesser trochanter of the fragment.

Fractures do not unite by bone unless the fragment is so placed as to confine the patient to bed for any long time. The amount of shortening, indicate considerable shortening, or if the patient be very aged and feeble, and general confinement to bed most commonly produces weakness which it exercises on the general health, inducing bed-sores. It is therefore best to keep the patient in bed for two or three weeks, until the limb has become firm. The tendency to muscular spasms, which is often met with, should be removed. The patient should be laid flat on his back on a suitable couch properly provided with a pan for urine. This is most important, for if the urine and feces be so managed so as to wet the buttocks, bed-sores will be the result. The utmost attention to dryness and cleanliness should be given to them. The knees should be bent at an angle of 90 degrees, and tied together. At the end of from two to four weeks the limb should be fitted to the hip, and the patient should be able to get up on crutches. There will be lameness during the remainder of the life of a stick and a properly adjusted splint, but little disability.

The mode of treatment is the application of a properly fitted hip-splint. (See Diseases of the Hip, Vol. II.) The patient must be kept in bed, either with the leg extended, or with a weight-extension apparatus to diminish the weight on the limb and prevent eversion. A splint should be applied, if the patient be old and feeble, he may be got up on crutches, if there is no fear of

of hypostatic congestion of the lungs he is better in bed for a fortnight or three weeks.

When the fragments do not appear to be much separated, there being but little shortening and indistinct crepitus, and more particularly if the patient be not very aged and in other respects sound and well, an attempt may be made to procure osseous or at least close ligamentous union. This is most likely to be obtained by the use of Thomas's hip-splint, with prolonged rest in bed, but should this apparatus not be procurable the long thigh-splint may be applied in the same way as for fracture of the shaft; or if this cannot very readily be borne, recourse should be had to the double inclined plane, with a padded belt strapped round the hips, the patient being kept in bed for at least two or three months, when a leather splint may be put on, and he may move about on crutches. During the whole of the treatment, a generous diet should be ordered, and the patient kept on a water-bed or cushion. In these fractures of the neck of the femur, the starched bandage will often be found most useful. It may be applied as in fractured thigh, but should have additional strength in the spica part. When the patient begins to move about, great comfort will be derived from the use of a well-padded leather or gutta-percha case, made in two pieces, one for the hip, the other for the thigh, united by a hinge-joint, which can be set fast in the erect posture by dropping a slot over it. When this is raised it can be flexed, so as to allow of the patient sitting in comfort. In old people, this plan of treatment is especially advantageous, as it enables them to sit up or even to walk about, and thus prevents all the ill effects of long confinement in bed.

Impacted Intracapsular Fracture is a rare accident, and can scarcely be distinguished from a similar injury outside the capsule. In it the upper end of the neck is driven into the cancellous tissue of the separated head. In a case under the care of Gay, of the Massachusetts General Hospital, which is recorded by Bigelow, the nature of the injury was proved by *post-mortem* examination, death having occurred from pneumonia at the end of two weeks. The following were the symptoms. The patient, aged 76, fell, striking the right trochanter. He thought he had received only a bruise, and crawled upstairs to bed unaided. Two days after, when admitted to the hospital, the right leg was found to be shortened by half an inch; the foot was everted, and could not be inverted beyond the perpendicular: the thigh could be flexed and extended without difficulty, but with pain; the trochanter was less prominent than that of the other side. Before he died he could raise his foot some inches from the bed without assistance. After death the head was found to be "broken from the articular extremity of the neck, which was short and thick, the fracture behind being almost at the line of junction of the articular cartilage and the bone, while in front it ran irregularly across the neck from a quarter to half an inch below this line. The head was bent obliquely backwards and downwards towards the lesser trochanter—the tilting of the head opening the fracture on the outside of the neck—and was so firmly impacted that considerable force was required to withdraw it." Bigelow also records a case under the care of Cushing, of Dorchester, U.S.A., in which the exact nature of the impacted fracture was proved by examination after death, which occurred nearly five years after the accident. The patient was seventy years of age. The fracture closely resembled that just described, and union had taken place by bone. It is

evident that these cases cannot be distinguished during life from impacted fractures of any other part of the neck. The treatment is the same as that of extracapsular impacted fracture.

Extracapsular Fracture of the Neck of the Thigh-Bone commonly occurs at an earlier age than the injury which has just been described, but it is met with also at advanced periods of life. It is the result of direct violence to the hip, and is equally common in both sexes. In young subjects it occurs only as a consequence of great violence, but in old people it may result from a simple fall on the hip.

This fracture may be of two kinds: the *unimpacted* or the *impacted*. In both cases the neck of the bone is commonly broken at, or immediately outside, the insertion of the capsule of the joint. The fracture is almost invariably comminuted when it occurs in a young subject or as the result of great violence. Indeed, I have never seen a case of this kind in which the greater trochanter was not either detached or splintered into several fragments. In many instances the lesser trochanter is detached, and the upper end of the shaft injured (Fig. 210). This splintering of the trochanter is due to the same violence that breaks the bone forcing the lower end of the neck into the cancellous structure of this process, and thus, by a wedge-like action, breaking it into fragments. When the neck continues locked in between these, we have the impacted form of fracture. In older subjects,

Fig. 210.—Simple Extracapsular Fracture of the Neck of the Thigh-Bone: Detachment of the Trochanter.

however, whose bones are atrophied and softened by age, it is common to meet with extracapsular impacted fractures without any splintering of the trochanter.

The *Signs* of extracapsular fracture vary according as it is simple or impacted; but in both cases they partake of the general character of those of fracture within the capsule. The individual signs, however, present certain well-marked differences.

The hip will usually be found *bruised and swollen* from extravasation of blood, often considerably so.

In the **unimpacted fracture**, the *crepitus* is readily felt on laying the hand upon the trochanter, and moving the limb. The separate fragments into which the trochanter is splintered may occasionally be felt to be loose. The *pain* is very severe, and greatly increased by any attempt at moving the joint, which to the patient is impossible. The *eversion* is usually strongly marked, and the position of the limb is characteristic of complete want of power in it. *Inversion* occurs more frequently in this fracture than in those within the capsule. Smith found that of 7 cases of inversion of the limb in fractures of the neck of the femur, 5 occurred in the extracapsular fracture and in 15 cases of intracapsular fracture, this condition was met with in 8. When there is much comminution of the trochanter, the foot will sometimes remain in any position in which it is placed, but generally it has a tendency to rotate outwards. The *shortening* of the limb is never less than an inch and a quarter, and sometimes amounts to two inches and a half, or three inches.

In the extracapsular fracture of the neck of the femur, death occasionally results from the severity of the injury, and the consequent shock to the system. The extravasation of blood into the tissues of the limb has been known to be sufficient to account for the fatal result. When the patient survives, bony union takes place, large irregular stalactitic masses being commonly grown out by the inferior fragment, so as to overlap the several splinters of the superior, and thus give the appearance of great thickening and projection of the trochanter. This callus is most abundant posteriorly in the intertrochanteric space (Fig. 214).

The **Impacted Extracapsular Fracture** of the neck of the femur occurs when, in consequence of a heavy fall on the hip, the neck is broken across at its root, and the upper fragment is driven into the cancellous structure of the lower one, often splitting up and detaching the trochanter

Figs. 211, 212.—Sections of Impacted Extracapsular Fractures of Neck of Femur; showing the degree of Impaction and of Splintering in different cases.

(Figs. 211, 212). It is not an uncommon accident about middle life, and even in old age. Its most common cause is a severe fall, as upon the ice in skating.

The *Signs* of this form of fracture are often somewhat negative, rendering the diagnosis extremely difficult. There is *pain* about the hip, with *eversion* of the foot. The degree of eversion varies considerably; sometimes it is so great that the outer side of the foot can scarcely be raised from the bed without giving the patient intense pain, and in other cases it can be recognized only by the limitation of inversion when contrasted with the opposite limb. There is *slight shortening*, usually about half an inch, and never exceeding one inch, and occasionally as little as a quarter of an inch. As a rule, there is no *swelling*, but occasionally, owing to the looseness of the impaction, some may be obtained with difficulty. When the impaction is firm, the patient can raise the foot a few inches off the couch on which it is laid, and even walk a short distance upon it with a hobbling motion, though with much pain. Some thickening over the trochanter is usually perceptible—sometimes an increase in girth from before backwards—and, on pushing the fingers in deeply behind the trochanter, the posterior intertrochanteric fossa can sometimes be felt to be filled up. In consequence of the impaction the limb cannot be restored by traction to its proper length, and hence incurable lameness always results from this injury.

The **Constitutional Disturbance** in old people, though trifling at first, often eventually becomes considerable; and the injury frequently terminates fatally, from the supervention of hypostatic pneumonia, an asthenic state of system, or sloughing of the nates from confinement to bed. Hence this injury must always be considered dangerous.

Mode of Union.—The treatment of these fractures turns in great measure upon the view that is taken of their mode of union, and on the constitutional condition of the patient. In some cases no union occurs, but the head of the bone remains in the acetabulum, being hollowed into a smooth, hard, cup-shaped cavity, in which the neck, which has become rounded off and polished, plays as in a socket. In the great majority of cases, however, union takes place by fibrous tissue. This is owing to two causes:—first, that the fractured surfaces are not in apposition; and secondly, that the supply of blood to the head of the bone through the vessels of the ligamentum teres is insufficient for the proper production of callus.

In some cases, however, bony union does take place. This can happen only when, in consequence of the cervical ligament being untorn, or the fracture being impacted, the surfaces are kept in apposition, and the supply of blood to the head of the bone is speedily augmented by that carried to it through the medium of the vascular tissue formed between the fragments in the process of repair. When bony union occurs the head of the femur will usually be found to be somewhat twisted round so that it looks towards the lesser trochanter, owing to the eversion of the lower fragment.

Treatment.—As these fractures do not unite by bone unless the fragments be in good contact, it is useless to confine the patient to bed for any long period, if the signs, especially the amount of *shortening*, indicate considerable separation between the fragments, or if the patient be very aged and feeble. In these circumstances, lengthened confinement to bed most commonly proves fatal by the depressing influence which it exercises on the general health, causing hypostatic pneumonia or inducing bed-sores. It is therefore best to keep the patient in bed only for two or three weeks, until the limb has become somewhat less painful, and the tendency to muscular spasms, which is often very distressing, has passed away. The patient should be laid flat on his back, on a fracture-bed or a suitable couch properly provided with a pan for the reception of the excreta. This is most important, for if the urine and faeces be passed under the patient so as to wet the buttocks, bed-sores will infallibly result. In fact the utmost attention to dryness and cleanliness is needed in order to prevent them. The knees should be bent at an angle of 15° over pillows and the legs tied together. At the end of from two to four weeks a leather splint should be fitted to the hip, and the patient should be allowed to get up upon crutches. There will be lameness during the remainder of life; but, with the aid of a stick and a properly adjusted splint, but little inconvenience will be suffered.

A most excellent mode of treatment is the application of a properly fitted and well-padded Thomas's hip-splint. (See Diseases of the Hip, Vol. II.) Until the splint is ready the patient must be kept in bed, either with the leg bent, as before described, or with a weight-extension apparatus to diminish shortening, and sandbags to steady the limb and prevent eversion. As soon as the splint is applied, if the patient be old and feeble, he may be got out of bed, and, if possible, may move about on crutches. If there is no fear

of hypostatic congestion of the lungs he is better in bed for a fortnight or three weeks.

When the fragments do not appear to be much separated, there being but little shortening and indistinct crepitus, and more particularly if the patient be not very aged and in other respects sound and well, an attempt may be made to procure osseous or at least close ligamentous union. This is most likely to be obtained by the use of Thomas's hip-splint, with prolonged rest in bed, but should this apparatus not be procurable the long thigh-splint may be applied in the same way as for fracture of the shaft; or if this cannot very readily be borne, recourse should be had to the double inclined plane, with a padded belt strapped round the hips, the patient being kept in bed for at least two or three months, when a leather splint may be put on, and he may move about on crutches. During the whole of the treatment, a generous diet should be ordered, and the patient kept on a water-bed or cushion. In these fractures of the neck of the femur, the starched bandage will often be found most useful. It may be applied as in fractured thigh, but should have additional strength in the spica part. When the patient begins to move about, great comfort will be derived from the use of a well-padded leather or gutta-percha case, made in two pieces, one for the hip, the other for the thigh, united by a hinge-joint, which can be set fast in the erect posture by dropping a slot over it. When this is raised it can be flexed, so as to allow of the patient sitting in comfort. In old people, this plan of treatment is especially advantageous, as it enables them to sit up or even to walk about, and thus prevents all the ill effects of long confinement in bed.

Impacted Intracapsular Fracture is a rare accident, and can scarcely be distinguished from a similar injury outside the capsule. In it the upper end of the neck is driven into the cancellous tissue of the separated head. In a case under the care of Gay, of the Massachusetts General Hospital, which is recorded by Bigelow, the nature of the injury was proved by *post-mortem* examination, death having occurred from pneumonia at the end of two weeks. The following were the symptoms. The patient, aged 76, fell, striking the right trochanter. He thought he had received only a bruise, and crawled upstairs to bed unaided. Two days after, when admitted to the hospital, the right leg was found to be shortened by half an inch; the foot was everted, and could not be inverted beyond the perpendicular; the thigh could be flexed and extended without difficulty, but with pain; the trochanter was less prominent than that of the other side. Before he died he could raise his foot some inches from the bed without assistance. After death the head was found to be "broken from the articular extremity of the neck, which was short and thick, the fracture behind being almost at the line of junction of the articular cartilage and the bone, while in front it ran irregularly across the neck from a quarter to half an inch below this line. The head was bent obliquely backwards and downwards towards the lesser trochanter—the tilting of the head opening the fracture on the outside of the neck—and was so firmly impacted that considerable force was required to withdraw it." Bigelow also records a case under the care of Cushing, of Dorchester, U.S.A., in which the exact nature of the impacted fracture was proved by examination after death, which occurred nearly five years after the accident. The patient was seventy years of age. The fracture closely resembled that just described, and union had taken place by bone. It is

evident that these cases cannot be distinguished during life from impacted fractures of any other part of the neck. The *treatment* is the same as that of extracapsular impacted fracture.

Extracapsular Fracture of the Neck of the Thigh-Bone commonly occurs at an earlier age than the injury which has just been described, but it is met with also at advanced periods of life. It is the result of direct violence to the hip, and is equally common in both sexes. In young subjects it occurs only as a consequence of great violence, but in old people it may result from a simple fall on the hip.

This fracture may be of two kinds: the *unimpacted* or the *impacted*. In

FIG. 210.—Simple Extracapsular Fracture of the Neck of the Thigh-Bone: Detachment of the Trochanter.

both cases the neck of the bone is commonly broken at, or immediately outside, the insertion of the capsule of the joint. The fracture is almost invariably comminuted when it occurs in a young subject or as the result of great violence. Indeed, I have never seen a case of this kind in which the great trochanter was not either detached or splintered into several fragments. In many instances the lesser trochanter is detached, and the upper end of the shaft injured (Fig. 210). This splintering of the trochanter is due to the same violence that breaks the bone forcing the lower end of the neck into the cancellous structure of this process, and thus, by a wedge-like action, breaking it into fragments. When the neck continues locked in between these, we have the impacted form of fracture. In older subjects,

however, whose bones are atrophied and softened by age, it is common to meet with extracapsular impacted fractures without any splintering of the trochanter.

The *Signs* of extracapsular fracture vary according as it is simple or impacted: but in both cases they partake of the general character of those of fracture within the capsule. The individual signs, however, present certain well-marked differences.

The hip will usually be found *bruised and swollen* from extravasation of blood, often considerably so.

In the **unimpacted fracture**, the *crepitus* is readily felt on laying the hand upon the trochanter, and moving the limb. The separate fragments into which the trochanter is splintered may occasionally be felt to be loose. The *pain* is very severe, and greatly increased by any attempt at moving the joint, which to the patient is impossible. The *eversion* is usually strongly marked, and the position of the limb is characteristic of complete want of power in it. *Inversion* occurs more frequently in this fracture than in that within the capsule. Smith found that of 7 cases of inversion of the limb in fractures of the neck of the femur, 5 occurred in the extracapsular fracture; and in 15 cases of intracapsular fracture, this condition was met with in 3. When there is much comminution of the trochanter, the foot will sometimes remain in any position in which it is placed, but generally it has a tendency upwards. The *shortening* of the limb is never less than an inch, and sometimes amounts to two inches and a half, or three-

In the extracapsular fracture of the neck of the femur, death occasionally results from the severity of the injury, and the consequent shock to the system. The extravasation of blood into the tissues of the limb has been known to be sufficient to account for the fatal result. When the patient lives, bony union takes place, large irregular stalactitic masses being commonly thrown out by the inferior fragment, so as to overlap the several splinters of bone and thus give the appearance of great thickening and projection of the trochanter. This callus is most abundant posteriorly in the intertrochanteric space (Fig. 214).

The **Impacted Extracapsular Fracture** of the neck of the femur occurs when, in consequence of a heavy fall on the hip, the neck is broken across at its root, and the upper fragment is driven into the cancellous structure of the lower one, often splitting up and detaching the trochanter

Figs. 211, 212.—Sections of Impacted Extracapsular Fractures of Neck of Femur; showing the degree of Impaction and of Splintering in different cases.

(Figs. 211, 212). It is not an uncommon accident about middle life, and even in old age. Its most common cause is a severe fall, as upon the ice in skating.

The *Signs* of this form of fracture are often somewhat negative, rendering the diagnosis extremely difficult. There is *pain* about the hip, with *eversion* of the foot. The degree of eversion varies considerably; sometimes it is so great that the outer side of the foot can scarcely be raised from the bed without giving the patient intense pain, and in other cases it can be recognized only by the limitation of inversion when contrasted with the opposite limb. There is slight *shortening*, usually about half an inch, and never exceeding one inch, and occasionally as little as a quarter of an inch. As a rule, there is no *crepitus*, but occasionally, owing to the looseness of the impaction, some may be obtained with difficulty. When the impaction is firm, the patient can raise the foot a few inches off the couch on which it is laid, and even walk a short distance upon it with a hobbling motion, though with much pain. Some flattening over the trochanter is usually perceptible—sometimes an increase in breadth from before backwards—and, on pushing the fingers in deeply behind the trochanter, the posterior intertrochanteric fossa can sometimes be felt to be filled up. In consequence of the impaction the limb cannot be restored by traction to its proper length, and hence incurable lameness always results from this injury.

Pathology.—The deformity accompanying this injury has been shown by Bigelow to be due in great measure to the anatomical structure of the femur. If a series of horizontal sections be made of the neck of the bone, "it will be found that at the upper part the anterior and posterior walls are of nearly equal thickness, but that, as we approach the lower surface, the anterior wall becomes of great thickness and strength, while the posterior wall remains thin, especially at its insertion beneath the posterior intertrochanteric ridge, when it is of the thinness of paper." The result of this is that, when severe direct violence is applied to the trochanter, the posterior wall yields, crushes up, and becomes impacted, while the anterior "serves as a sort of hinge upon which the shaft rotates to allow the posterior impaction." This causes the rotation outwards. The shortening Bigelow explains by obliquity of the neck of the femur, which causes the limb to be shortened in proportion to the rotation. That this is the true explanation of the deformity in all the slighter cases of this injury is highly probable. In the more severe crushes of the trochanter,

Fig. 213.—Union in Impacted Extracapsular Fracture of Neck of Femur.

Fig. 214.—Impacted Extracapsular Fracture of Neck of Femur: Abundant Formation of Callus.

the anterior wall of the neck as well as the posterior may be driven among the splintered fragments.

The **Treatment** of the extracapsular fracture may very conveniently and efficiently be conducted by means of the long splint, a padded belt, if necessary, being strapped firmly round the hips underneath it: or the plan recommended by Astley Cooper, of placing the patient on a double inclined plane, with both feet and ankles tied together, and a broad belt, well padded, firmly strapped round the body, so as to press the fragments of the trochanter firmly against one another, will be found an excellent mode of keeping the limb of a proper length, and the fragments in contact. In many cases a Thomas's hip-splint, applied as soon as the swelling has subsided, will be found a most efficient and comfortable apparatus. In impacted extracapsular fracture nothing can be done to diminish the deformity. Solid bony union always takes place, even in aged subjects. The patient remains throughout life more or less crippled, chiefly by the eversion, the amount of shortening being of little consequence.

In these cases a Thomas's hip-splint may be used from the first: or after three weeks' rest in bed a leather splint may be applied, and the patient allowed to move about on crutches.

The **Diagnosis** of the different forms of fracture of the neck of the thigh-bone from one another, and from other injuries occurring in the vicinity of the hip-joint, is a matter of considerable importance, and often of no slight difficulty.

Between the unimpacted intracapsular and the ordinary extracapsular fractures there can be no difficulty in diagnosis; all the signs of the latter being much more strongly marked than those of the former injury, as may be seen by the annexed table, the difference of age and the degree of violence required to break the bone being also important elements in the diagnosis.

Diagnosis between unimpacted Intra- and Extra-capsular Fractures of the Neck of the Thigh-bone.

Intracapsular.

1. Cause generally slight and indirect, such as catching the foot in the carpet or slipping off the kerbstone.
2. Force usually applied longitudinally or obliquely.
3. Age, rarely below fifty; most commonly in feeble aged persons.
4. Pain and constitutional disturbance slight.
5. No apparent injury to soft parts about hip.
6. Crepitus often obscure.
7. Shortening, at first, usually not more than one inch.

Extracapsular.

1. Cause usually severe and direct violence, such as falling from a height or a blow on the hip.
2. Force usually applied transversely.
3. Age, usually below fifty; chiefly in vigorous adults.
4. Pain and constitutional disturbance usually considerable.
5. Considerable extravasation, ecchymosis, and signs of direct injury to hip.
6. Crepitus very readily felt.
7. Shortening at least two inches or more.

The distinction between *intracapsular fracture* and the *impacted fracture of the neck* is also easy. In the former case the crepitus can be obtained by extending and rotating the limb, the eversion is more marked, and the injury occurs usually from indirect violence; in the latter, traction cannot restore the limb to its proper length, crepitus is wanting, and the fracture is always the result of direct violence applied to the trochanter.

In *impacted fractures of the neck of the femur* it is, as a rule, impossible to determine whether the injury is within or without the capsule. The separation of the head and the impaction of the neck into it occur only in old people, and, judging from the few recorded cases, the shortening and eversion are slight. Fracture of the root of the neck with impaction into the trochanter occurs at all ages after middle life. Its symptoms vary from scarcely appreciable displacement to extreme eversion with one inch of shortening. Should the trochanter have been fissured or splintered, this may be ascertained on careful examination, and the nature of the injury could then be recognised with certainty.

Severe contusions of the hip are sometimes followed by eversion of the limb with inability to move it, so that at first sight it might be supposed that the bone was broken. In these cases, however, the absence of shortening and crepitus will always establish the diagnosis. But though no immediate and sudden shortening can occur without fracture, these contusions may be followed at a remote period by shortening of the limb from atrophic changes in the head and neck of the femur. When the injured hip-joint has been the seat of *chronic rheumatic arthritis*, and the limb is already somewhat shortened by the changes that occur in the head and neck of the femur in this disease, the difficulty of diagnosis becomes great: especially as there may also be,

as the result of the disease, some thickening of the trochanter, with rough grating, almost like true crepitus, on moving the joint. Here, however, the history of the case, the fact of the shortening not being of recent occurrence, the possible affection of other joints, the character of the grating and the absence of acute pain with it, will be sufficient to establish the nature of the injury. The diagnosis of these injuries from *dislocations* will be considered in a subsequent chapter.

Occasionally the fracture extends **through the trochanter major and upper part of the shaft** without implicating the neck of the bone. Here there is shortening by about three-fourths of an inch, or an inch, with much eversion, and crepitus is readily felt. This fracture, which unites firmly by bone, must be treated in the same way as the last.

Compound Fractures of the neck of the Thigh-bone can occur only from bullet wounds. In these cases the choice lies between amputation at the hip-joint, resection of the injured portion of bone, or treating the case as an ordinary compound fracture. The choice of the Surgeon, for reasons stated at p. 359, lies between the latter two alternatives, which alone afford a reasonable hope of safety to the patient.

Fracture of the Trochanter Major, by which this process is broken off from the rest of the bone, is described by Astley Cooper, Aston Key, and Nélaton as always being the result of direct violence. It may be single or comminuted. The fragment is usually drawn upwards and backwards, rarely forwards; and more rarely it remains fixed by fibrous bands in its normal place. The symptoms are separation between the fragments, and crepitus, which is most readily obtained by flexing and abducting the thigh and rotating it outwards, at the same time that the fragments are firmly pressed together. There is no shortening of the limb. The exact nature of the injury is often concealed by the swelling from extravasated blood. It is very rare without accompanying fracture of the neck. In children the epiphysis of the trochanter has been known to be separated by direct violence.

2. **Fractures of the shaft of the Thigh-bone** are of very common occurrence, especially in children, forming, according to Bruns, one-quarter of all fractures in children under ten. They steadily decrease in frequency with age. Excluding those implicating the neck, one-third of all fractures of the femur occur under 10, and about the same between 10 and 30.

In adults they are always oblique, unless they are the result of direct violence; in children, especially when the child is very young, the fracture is more often transverse or nearly so. The most common seat of fracture from indirect violence is the middle third, and the obliquity is such that the sharp point of the upper fragment is directed forwards and outwards.

The *Signs* are well marked. There is shortening, usually to a considerable extent, with eversion of the limb, crepitus readily produced, and much swelling from the approximation of the attachments of the muscles. The lower fragment is always drawn upwards, and somewhat to the inner side of the upper, and is rotated outwards. When the fracture is at or above the middle of the thigh, there is a great tendency to angular deformity, in consequence of the projection forwards of the lower end of the upper fragment. In all cases there is this forward projection, and in most an outward displacement, or abduction, as well of the upper fragment. But in some very rare cases, it is drawn inwards as well as forwards.

The common displacement is caused in the following way. The upper fragment is abducted chiefly by the *gluteus minimus*, it is rotated outwards by the external rotators attached to the trochanter and flexed by the *psaos* and *iliacus*. The lower fragment is drawn upwards chiefly by the flexor muscles of the leg and the adductor magnus, and to a less degree by the *vasti*; it is drawn inwards by the adductor magnus and adductor longus if the latter muscle be attached to it. As the obliquity of the fracture, when from indirect violence, is almost invariably from below, upwards and backwards, and somewhat inwards, it is evident that as the lower fragment is drawn upwards by the muscles passing from above to below the fracture it will tend to the inner side of the limb and will tilt the upper fragment forwards and outwards. In rare cases in which the obliquity is in the opposite direction, the lower fragment may ride in front of the upper.

Synovial effusion into the knee-joint is an almost constant phenomenon in fracture of the femur. It becomes evident soon after the accident and disappears in about a week. It is probably due to a violent strain of the articulation by the same violence that causes the fracture.

The *Treatment* of fractures of the shaft of the thigh-bone may be conducted

Fig. 215.—Liston's Long Splint.

in different ways, each of which presents advantages in particular cases. Whatever treatment is adopted, and however carefully it may be carried out, the Surgeon must not be disappointed if, in the adult, a certain amount of shortening be left. This is more particularly the case where the fracture is oblique and high up; the more transverse and the nearer the condyles the less will be the liability to shortening. In children, union may almost always be obtained without shortening. But a slight diminution in the length of the limb is in reality of no consequence, and gives rise to no inequality of gait; the pelvis remedying this by the obliquity it assumes. It is only when the shortening exceeds half or three quarters of an inch that it is important and occasions deformity. The rotation outwards of the lower fragment, however, if not corrected by treatment, seriously cripples the patient, as it leaves the toes and the patella directed outwards, so that the movements of both the knee and the ankle are rendered almost useless in walking.

1. Extension by means of Desault's or Liston's *long splint* will be found a most efficient plan of treating fractures of the thigh, especially those in the middle part of the bone. The splint must be of sufficient length to extend about six inches below the sole, and nearly as high as the axilla. The long splint is now commonly used merely for extension and to fix the hip and knee-

mounts, the fracture being adjusted by short splints applied to the thigh. These are four in number: the anterior, reaching from the groin to the patella; the posterior, from the folds of the nates to the upper part of the ham; the inner, from the perineum to just above the prominence of the inner condyle; and the outer, from just below the trochanter to above the outer condyle.

Extension is made to the lower end of the long splint by a strong bandage, attached to a wooden "spreader" which is secured to the limb by a broad strip of plaster passing up each side of the leg to above the knee. Counter-extension is made by a perineal band or pad (Fig. 215) attached by strong bandages to the upper end of the splint; the pad should be covered with soft flannel or wash-leather.

In securing the splint to the side of the chest the tendency to its displacement forwards should be counteracted by fixing the bandage to the splint and carrying it round the chest from behind forward. Rotation of the splint must be prevented by supporting it as in Fig. 216, or by fixing a wooden cross-bar

Fig. 216.—Browne's Elastic Catch.

to its lower border. The heel also, by these means, is raised from the bed and painful pressure upon it avoided.

Various modifications of the method of applying the long splint above described are at times of service. Elastic extension from the foot may be obtained by means of the appliance contrived by Buckston Browne (Fig. 216), which consists of a stout india-rubber ring passed over the wooden "spreader" and attached to the splint by a brass catch, such as is used for the cords of window-blinds.

By applying weight-extension to the limb, and raising slightly the foot of the bed, so that counter-extension is made by the weight of the patient's body, the perineal band which is often very irksome may frequently be dispensed with. A wooden "spreader" is fixed to the limb with plaster as above described, and to this the weight-extension is applied, rotation of the long splint being prevented by a wooden cross-bar.

The bandage employed to fix the long splint to the limb may be replaced by a small sheet folded till it reaches from the groin to the malleolus. This is wrapped round the splint so as to get a firm hold of it, and then brought to the limb, passing under it, and secured by strong pins to the part of the limb and the splint.

A knee-splint applied as for disease of the joint (see Disease of

(Vol. ii.), with four short splints surrounding the broken bone, forms an excellent apparatus for a fracture of the femur. The end of the splint be slung to a cradle so as to raise it about six inches from the bed, and motion of the trunk must be prevented by a broad bandage carried over the head and secured to the mattress.

Hodgen, of St. Louis, has introduced the suspension splint for fractures of the femur which is represented in Fig. 217. It consists of a light iron bar bent at a slight angle opposite the knee. The limb is supported in the middle by a series of strips of strong bandage attached to its two bars. A pre-extension apparatus adjusted to the leg in the usual way is carried to the transverse end of the splint which projects beyond the foot. Finally, the splint is slung by cords which pass over a pulley attached to a firm point beyond the foot of the bed. Continuous extension and muscular action are thus obtained. The splint is especially adapted to the treatment

Fig. 217. — Hodgen's Suspension Splint.

of fractures near the upper end of the shaft with much displacement forwards of the upper fragment, and to fractures low down with displacement backwards of the lower fragment.

The starched or plaster bandage may be employed in most cases. In the treatment of fractures of the shaft of the thigh-bone with the starched bandage, the following plan will be found convenient. The limb should be evenly and firmly enveloped in a layer of cotton wadding; a long piece of strong pasteboard, about four inches wide, soaked in starch, must next be applied to the posterior part of the limb, from the nates to the heel. If the patient be very muscular, and the thigh large, this must be strengthened, especially at its upper part, by having strips of bandage pasted upon it. Two narrower strips of pasteboard are now placed, one along each side of the limb, from the hip to the ankle, and another shorter piece on the fore part of the thigh. A double layer of starched bandage should now be applied over the whole, with a strong and well-starched spica. It should be cut up and trimmed on the second or third day, and then re-applied in the usual way. With such an apparatus as this I have treated many fractured thighs, both in adults and in children, without confinement to bed for more than three or four days, but as it is better not to apply the starched bandage before the end of the

second week (Fig. 164). The points to be particularly attended to are, that the hinder pasteboard splint be very strong, at the upper part especially, and that the spica be well and firmly applied, so that the hip and the whole of the pelvis may be immovably fixed.

5. The fracture may be treated by simply relaxing the muscles of the limb. This is effected by laying it upon its outer side, flexing the thigh to nearly a right angle with the body, and the leg upon the thigh, and supporting the limb in this position by an angular wooden or leather splint, extending from the hip to the knee or outer ankle, and by a short inside thigh-splint. The position I have occasionally adopted in fractures about a couple of inches below the trochanters, in which there is a great tendency to the projection outwards of the lower end of the upper fragment, and I have found these cases turn out better in this way than on any other plan of treatment. If there is much shortening a weight-extension apparatus may be applied by means of strapping fixed to the lower part of the thigh.

In fractures of the femur in children, it is often difficult to maintain good position, owing to the restlessness of the patient. In such cases Hamilton

Fig. 218.—Hamilton's Splint.

recommends that a long splint be applied to the sound thigh as well as to the broken one. The two splints are connected at the bottom by a transverse bar (Fig. 218), and some short splints must be put round the thigh to fix the broken bone. I can speak from experience of the very great advantages of this method in young children. The child can be taken up and turned over with the splint without disturbing the fracture in the slightest degree.

Another excellent plan is that recommended by Bryant of applying a back-splint from the heel to the nates and short splints on the sides and front of the thigh, strapping by means of which extension can be made having been previously fixed to the leg. Both limbs are then slung up to a cradle, so as to keep them at right angles to the body. By this means the bandages are kept out of the way of the evacuations passed into the bed, and the weight of the body acts as a constant counter-extending force.

The Treatment of Compound and Comminuted Fracture of the Thigh-bone will vary according as the injury arises from gunshot, or is an accident of civil life. In the former case, for reasons stated at p. 358, amputation should at once be performed if the fracture be below the upper third of the bone. When the upper third is splintered, the result of amputation is so very unsatisfactory that the patient may have a better prospect of recovery if the

limb be treated in splints, and an endeavour made to save it, disarticulation at the hip-joint in such cases being almost invariably fatal.

When a compound fracture of the thigh-bone occurs from one of the common accidents of civil life, even if it be comminuted, the line of practice is not so defined. The course which the Surgeon adopts must be influenced by the extent of injury done to the soft parts, more particularly to the main blood-vessels of the limb. If the integuments and muscles be extensively torn and lacerated, or if there be reason to believe that the femoral vessels have suffered, amputation must be performed. But if the wound be but small, made by the perforation of the bone rather than by the violence which occasioned the fracture, and if the vessels be uninjured, an attempt must be made to save the limb, which should be put up in Thomas's hip-splint, or in the long bracketed splint, and treated with the strictest attention to drainage and to the prevention of decomposition. In cases of compound fracture, where the wound is in the posterior and outer part of the limb, I have found a long thigh-splint, bracketed opposite the seat of injury, the most convenient apparatus, enabling the limb to be kept of a proper length, and the wound to be dressed at the same time.

The treatment of the complication of a *wound of the main artery*, femoral or popliteal, with and by a fracture of the thigh-bone, will vary according as the injury is compound or simple. Such an accident, complicating a compound fracture, would probably be a case for immediate amputation. If the fracture be simple, and a diffused traumatic aneurism form in the ham or lower part of the thigh, we must treat the latter in accordance with the principles laid down at p. 548.

In discussing the treatment of these accidents, in which the question of

Fig. 219.—Diagram to illustrate the Displacement which follows Transverse Fracture of the Femur just above the Condyles. *g*, gastrocnemius; *a.m.*, adductor magnus; *a*, artery; *v*, vein.

amputation of the thigh is raised, I cannot too strongly state my conviction that, unavoidable as it undoubtedly is in some cases, as the only alternative left to the Surgeon, this operation, when practised primarily for compound fractures of the thigh-bone, is one of the most fatal in surgery, and should accordingly not be too hastily resolved upon.

3. FRACTURES IN THE VICINITY OF THE KNEE-JOINT.—The lower end of the thigh-bone may be broken across transversely, immediately above the condyles, and occasionally this may be complicated by a vertical fissure separating the condyles from each other, and extending into the knee-joint. In other cases, the fracture extends through one of the condyles, detaching it

from the shaft of the bone. The readiness with which crepitus can be felt, the line of fracture made out, and the displacement removed by lateral pressure, at once determine the nature of this accident.

When the femur is fractured transversely immediately above the condyles, the lower fragment is powerfully flexed by the gastrocnemius, plantaris, and popliteus muscles, causing its upper extremity to project backwards into the ham, while its lower end of the upper fragment rests on its anterior surface. Thus, although the limb may apparently be extended, the knee-joint is in reality flexed. If a limb in this condition were put up on a long splint and extension made, the displacement would be increased, and non-union of the fracture would very likely result; or, if union did occur, the usefulness of the limb would be most seriously impaired. By putting the limb on a double

inclined plane in a flexed position, the deformity is at once removed, and the fractured ends are brought into apposition; or this result may be obtained by the use of Hodgen's suspension splint. Bryant has recommended in these cases that the tendo Achillis should be divided, and in case the double inclined plane failed to overcome the deformity, this might be of use. The displaced lower fragment in these cases must always come into dangerous proximity to the popliteal artery. Should that vessel be wounded a diffuse traumatic aneurism may rapidly form, and must be treated on the principles laid down on page 548. In some cases though the vessel has escaped an actual wound, gangrene has occurred from pressure on the artery and vein. In others a circumscribed popliteal aneurism has formed at a later period.

Fracture of the lower end of the thigh-bone communicating with an open wound of the knee-joint is usually a case for amputation; but if there be no extensive comminution of the bone or laceration of the soft parts, an attempt may be made to save the limb, free drainage, strict antiseptic precautions, and perfect fixation being essential.

Fig. 220. — Impacted Fracture of Lower End of Thigh-bone.

Impacted Fracture of the Lower End of the Femur.—In these cases the shaft is always driven into the lower fragment. I have had several such cases under my care. In one, the upper fragment, which was very oblique,

was firmly driven into the cancellous structure of the lower one (Fig. 220). In another case, the condyles of both thigh-bones were splintered into a number of fragments, amongst which the shafts were impacted. Excellent union, however, took place, the skin having been uninjured. The diagnosis is not always easy, as unnatural mobility and crepitus may both be wanting, and in many cases, either from a fissure extending downwards or from the bruising at the time of the accident, effusion occurs into the knee-joint, which still further conceals the nature of the injury. The most characteristic feature in these cases is the shortening, and later on, as the swelling subsides, the deformity at the seat of fracture may be clearly recognised.

Separation of the Lower Epiphysis of the Femur is not an uncommon accident in children. The wide surfaces are seldom completely separated, and the nature of the injury is further obscured by effusion into the joint; but if

can usually be recognised by seizing the shaft of the femur in one hand and the knee in the other, when lateral movement will be recognised, accompanied by the soft crepitus characteristic of a separated epiphysis. The treatment consists simply in supporting the limb for a few days on a back splint, till the swelling has subsided, when a starched bandage or plaster of Paris splint may be applied. Union usually takes place by bone, and is followed by some shortening from interference with growth.

The **Period of Union of Fractures of the Shaft and Lower end of the Femur** is between seven and eight weeks in the adult, at the end of which time the patient may dispense with artificial support. It is, however, always about three months before full use of the limb is regained. In children under ten, union is usually firm at the end of the fifth week.

Fractures in the Knee-joint.—It occasionally happens that a small fragment of one of the condyles of the femur may be chipped off by a violent blow, and become loose in the cavity of the joint. After the inflammation and effusion have subsided, the fragment may be recognised as a loose body in the joint. (See Diseases of Joints: Loose Bodies.)

In violent blows on the upper part of the tibia, or in forcible and extreme flexion of the knee, it sometimes happens that the bony attachment of one of

Figs. 221, 222.—Fracture of Condyles from fall on the Bent Knees.

The crucial ligaments is torn up. In the case from which Figs. 221 and 222 were taken, the patient fell from a great height on the bent knees. In one knee, the anterior crucial ligament had torn up the part of the tibia to which it was attached. In the other, the posterior crucial ligament had torn out a piece of the femur, and the bone was fissured a long way up between the condyles. In the case from which Fig. 223 was taken, the anterior crucial ligament was torn from its attachment, bringing with it a scale of bone from the tibia. These injuries cannot be diagnosed during life. The treatment would be that of a sprain of the knee, with effusion of blood into the joint.

FRACTURE OF THE PATELLA may be the result of direct violence, when the bone is often comminuted, or even broken longitudinally, being split, and the joint being injured. But most frequently it occurs as the consequence of the sudden action of the extensor muscles of the thigh in the attempt a person makes to save himself from falling when he suddenly slips backwards. The knee being semi-flexed, the patella rests on the femur only in its transverse axis, and is readily snapped across, much in the same way as one breaks a stick across some resisting object. All fractures of the patella from muscular action are transverse (Fig. 224). The patient does not break his patella in these cases by falling upon it, but he falls because the patella has been broken by the violent action of the extensors of the thigh in his

efforts to save himself. In consequence of these fractures being occasioned by muscular action, they are more frequent in men, especially about the middle period of life, less common in women, and extremely rare in children. I have once, however, had under my care a child under ten years of age who had a transverse fracture of the patella. It not unfrequently happens, when one patella has been fractured, that the unsteadiness of gait causes the opposite one to be broken by muscular action in an effort to avoid a fall. The same patella may be broken more than once; in the cases that I have seen, the second fracture has always occurred in the upper fragment, a little above the line of the original fracture.

The *Signs* of this fracture are very evident. When it is transverse, and has been produced by muscular action, the fibrous expansion from the vasti, over the

Fig. 224. Tibial Attachment of Anterior Crucial Ligament torn up.

Fig. 225. Diagram of position of fragments in fracture of patella. Eversion of Upper Fragment.

bone, is torn; and the separation between the fragments (Figs. 224, 225), which is much increased by bending the knee (Fig. 226), and the inability to stand or to raise the injured limb, indicate what has happened. When it has been produced by direct violence, the muscles being at rest, there is little or no separation, even though the fracture be transverse, as the fragments are held together by the uniform expansion from the extensor muscles. In such cases, and when it is longitudinal or comminuted, the crepitus and mobility of the fragments point it out. Immediately on the occurrence of a fracture of the patella, the knee-joint becomes distended by effused blood, and later by inflammatory exudation. The swelling assumes the ordinary form of the distended synovial membrane. It usually subsides after a few days' rest.

Mode of Union.—When the patella is fractured transversely by muscular action, it rarely, if ever, unites by bone, except as the result of some operative procedure, although cases have been recorded in which after simple treatment the union has been so close that there was strong reason to believe it was osseous. The failure of bony union is due—first, to the wide separation of the fragments by the action of the muscles; secondly, to the distension of the

fluid that prevents their early approximation; and thirdly, to the of the torn fibrous expansion from the vasti which hang down between fragments. Lastly, in the normal state, when the limb is extended, only a portion of the under surface of the patella is in direct contact with the tibia. When the bone is broken, the upper and lower borders sink down on the bone in such a way that even if the fragments can be made to meet posteriorly a gap is left in front. In fractures by direct violence, the expansion covering the bone not being torn, the fragments remain in close apposition, and osseous union readily occurs. In the majority of cases of transverse fracture, the fragments remain separated by an interval varying from one-fourth of an inch to an inch: but in some instances the gap is much greater, amounting even to four or five inches. When the separation does not exceed an inch and a half, the gap is usually filled up by ligamentous tissue, uniting the fragments firmly. In some of the cases, however, in which the separation between the fragments does not exceed this distance, and in most of those in which it extends beyond it, W. Adams has found that the fracture is not

Fig. 250. — Fracture of Patella. Separation between Fragments increased by bending the knee.

by any newly-formed fibrous tissue, but that the fragments are bound together simply by the thickened fascia which passes over the patella, with the bursa patellæ incorporated. Adams finds that the aponeurotic tissue thus uniting the fragments may be arranged in different ways. It may be adherent to the anterior periosteal surface of both fragments: connecting aponeurosis may be reflected over, and be adherent to, both fractured surfaces: or, lastly, (and this is the most frequent arrangement,) connecting aponeurosis may pass from the periosteal surface of the upper fragment to the fractured surface of the lower one, to which it becomes firmly united. In the majority of cases, when united by aponeurotic tissue, the gap opens somewhat towards the skin, coming more nearly in contact posteriorly. Thus it would appear that a patella fractured transversely may be united in two ways: most frequently by the intervention of thickened aponeurotic tissue, and next, by a ligamentous or fibrous union. Of 31 specimens in the London museums, examined by Adams, it was found that in 15 aponeurotic union had taken place, in 12 ligamentous union, and in the remainder the kind of union could not be determined. The aponeurotic union leaves a weakened limb and an unprotected joint: for, in consequence of the separation of the fragments, and the folding in of the fascia, the tibia can be thrust in between the articular surfaces of the knee.

Treatment.—The first step in the treatment of fractured patella is to get the fluid distending the joint: for until this is done it is impossible in any case to bring the fragments into close apposition. Under the influence of heat and the application of evaporating lotions, the fluid will usually be absorbed under a week, and in most cases it will have sufficiently diminished

to allow the fragments to be brought together a day or so before this. A much more efficient mode of getting rid of the fluid and allowing immediate apposition of the fragments is aspiration of the joint. This mode of treatment was adopted in 1872 by Dubrueil, but a case of suppuration of the joint followed by death raised a prejudice against it. The accident in this case was probably due to inoculation of the joint with septic matter by means of a dirty needle. In the hands of Volkmann, Max Schede, and Heath, who have strongly recommended this treatment, no evil consequences have ever followed.

Fig. 227. Stellate Fracture of the Patella.

Fig. 228. Aposynovial Union of a Fractured Patella. Side view.

Fig. 229. Fracture of tibia united by anastomosing vessels.

In order to prevent accidents, the needle must be soaked for ten minutes in 1 in 20 solution of carbolic acid before being used.

When the fluid has been removed or absorbed, the fragments must in some way be kept in sufficiently close apposition for firm ligamentous union to take place. The means adopted to effect this are numerous, and may be classified thus:—1, Position; 2, Special Splints or Apparatus; 3, the plaster of Paris Bandage; and 4, Operative Measures.

1. **Position.**—The upper fragment, which is retracted by the extensor muscles, must be drawn down so as to be approximated to the lower end, which is fixed by the ligamentum patellæ. In order to do this, the leg must be fully extended and the thigh flexed at the hip to relax the rectus femoris. This may be done by placing the patient in a semi-recumbent position and elevating the leg considerably. Whatever apparatus may be subsequently applied, the position of the limb must also be attended to.

2. **Special Splints and Apparatus.**—The simplest mode of treatment is the application of a back splint with a foot-piece. It must extend upwards to the fold of the nates, and be fixed by bandages, leaving the knee exposed. Two rectangular pieces of gutta-percha measuring about two inches long above downwards, and at least one-third of the circumference of the joint in width, are then moulded to the knee, a deep semilunar notch being cut out of each, so that they may accurately fit the upper and lower borders of the

broken bone. These are applied above and below the patella, and approximated and held in position by broad strips of plaster long enough to embrace the limb and the back splint to which they must be fixed. They are applied obliquely in such a way as to steady the lower fragment and to draw the upper downwards towards it. Care must be taken that the pieces of gutta-percha do not press on the upper and lower portions of the patella, lest the fragments be tilted, so that though they are in contact posteriorly they are separated by a considerable interval in front. If gutta-percha be not at hand, pads of lint cut to the same form must be applied beneath the straps. A figure-of-8 bandage may be applied round the limb and splint together. In the place of the gutta-percha and straps of plaster, an apparatus consisting of two broad bands of leather, buckled above and below the knee and united by longitudinal straps, which can be shortened at pleasure, has been employed.

H. O. Thomas, of Liverpool, recommended a plan of treatment which has given excellent results, and has the great advantage of not confining the patient to bed for more than a few days. A Thomas's bed knee-splint (see Diseases of the Knee-Joint), which need not accurately fit the patient provided it be of sufficient length, should at once be applied. The leg is to be retained in position by the usual extension apparatus of adhesive plaster, the ends of the strips being fixed round the bottom of the splint. "To the bandages which secure the extension-plaster round the leg is sewn a piece of elastic webbing with adhesive material spread upon half its length: this being thus fixed below is stretched over the fractured patella and attached by adhesion to the skin of the thigh above the upper fragment of the patella, which it thus constantly draws gently down and exercises also very slight surface pressure over both fragments, pressing them into the space between the condyles of the femur and head of the tibia." The bandages are now applied over the thigh and leg, and a support arranged, either of leather or adhesive plaster, behind the popliteal space, sufficiently tight to hinder any backward strain on the knee-joint. As soon as it can be made, a walking "caliper" knee-splint with a boot must be fitted to the patient; after which he can leave his bed and move about during the remainder of the treatment.

Fig. 250. — Thomas's Knee-splint, applied for Fractured Patella.

3. **Plaster of Paris and Starched Bandage.**—The immediate application of a plaster of Paris bandage after aspiration of the joint has been strongly advocated by Christopher Heath, who has obtained excellent results by this mode of treatment. I have frequently employed the starched bandage without aspiration of the joint, and have in this way obtained very close union without confining the patient to bed after the third day. A back splint of pasteboard is required to fix the knee, and a good pad of lint with a figure-of-8 bandage should be applied above and below the fracture. The action of the pad is much increased by drawing it down and fixing it by two broad strips of plaster.

With any of the foregoing modes of treatment the apparatus must be applied for at least eight weeks, and after its removal some rigid appliance, such as a firm leather splint or a Thomas's caliper splint, must be fitted to the limb and worn for a further period of some weeks or months. If this precaution be not

taken, the union, which at first appeared very close, will gradually yield and in the course of a few months the fragment may be separated by several inches. Thomas maintains that the common cause of failure is insufficient duration of the treatment. He advises that the knee should not be flexed for nine months, and that the patient during the whole of this time should wear a caliper knee-splint. The stiffness that necessarily results from such prolonged rest will, he asserts, always pass off spontaneously, and never requires forcible flexion or other violent means to get rid of it.

1. **Operative Procedures.**—The foregoing methods of treatment are rarely, if ever, followed by osseous union in cases of fracture by muscular action. Various operative procedures have therefore been suggested in order to maintain more accurate apposition of the fragments, and thus obtain union by bone. The simplest of these is by the use of the instrument known as "*Malgaigne's hooks*." It consists of a pair of sharp double hooks, which, being fixed into the two fragments, can be drawn together by means of a screw. It undoubtedly is a most efficient means of approximating the fragments, but it does not necessarily ensure bony union. This mode of treatment was at one time almost abandoned, owing to the pain, irritation, and occasional suppuration that followed its use. By ordinary antiseptic measures these can be prevented, and consequently the use of the hooks has been revived by some Surgeons.

A bloodless modification of this treatment has been suggested, in which the hooks are inserted into the pieces of gutta-percha before described (p. 628), instead of into the bone.

Exposing the bone by a longitudinal incision, and uniting the fragments by a wire suture, was suggested by Severini, and was first practised in America by Rhea Barton some sixty years ago. The operation was repeated by Cooper and others, but as two cases out of five terminated fatally, it was very properly abandoned. With the introduction of antiseptic surgery it was again suggested as a mode of treatment by Lister, and was first performed in this country by Cameron, of Glasgow, and

Fig. 231. Wire Suture applied to Fractured Patella (vertical section).

has subsequently been repeated in a large number of cases. Lister recommends that the wire should be cut short and the ends hammered down, the wound being allowed to heal over it (Fig. 231). Passive motion is to be commenced at the end of the second week. In some cases drainage must be provided during the first few days, by a small incision at the most dependent part of the outer side of the joint, through which a tube may be inserted. A great many most excellent results have been obtained by this treatment, recovery being rapid, union taking place either by bone or by very firm fibrous tissue, and the movement of the joint being unimpaired; but on the other hand there have been at least five deaths since the re-introduction of the operation, and in other cases suppuration, resulting in ankylosis, has followed, and in one at least the patient has had to submit to amputation. It must not be forgotten that under ordinary treatment properly carried out excellent

results are obtained without the slightest danger to life. In fact it is remarkable how well the patient can use the limb even when the fragments are separated by as much as an inch. It would not seem to be justifiable therefore to recommend this operation as the ordinary treatment of a simple case of recent fracture of the patella. On the other hand it offers the only chance of cure in those cases in which, owing to imperfect treatment, the separation between the fragments is so great that the limb is practically useless. In 45 cases of this kind collected by Jahagnier in 1884 the operation was successful in 22, in 9 the function of the limb was imperfectly restored, in 1 the operation could not be completed, in 11 ankylosis followed, 10 times after suppuration of the joint, and 3 died of acute septicæmia or pyæmia. In operating on such cases the fractured surfaces must necessarily be freshened before being brought together, adhesions between the upper fragment and the femur must be freely divided, and in some it has been found necessary to make free incisions in the extensors before the fragments could be brought into contact. In compound fractures, whenever it is practicable, the fragments should be united by wire sutures.

To sum up, the operation of opening the joint and suturing the bone is not to be recommended as the ordinary treatment of fracture of the patella; but if the patient be willing to run the risks of the operation for the chance of a more rapid and perfect cure, and if the Surgeon be confident of his ability to prevent suppuration in the joint, it is a perfectly justifiable proceeding. In the case of a useless limb from an old fracture, the patient has the choice of submitting to the operation with its attendant dangers or walking with his limb fixed in some rigid apparatus for the rest of his life. In compound fractures there need be no hesitation in suturing the fragments in all cases.

Kocher of Berne has suggested another operation which in his hands has given very good results. He passes a thick silver wire beneath the fragments, through the knee-joint, by means of a long and strong curved needle fixed on a handle. He then twists the two ends together, protecting the skin over the patella with a pad of lint.

A. E. Barker has used with success the following modification of this method, which according to Gilis has also been employed by Lagneau in France. A puncture is made into the joint with a scalpel immediately below the lower fragment, and as much blood as possible evacuated; a stout pedicle needle is passed from this puncture through the joint behind the fragments and brought out through the skin at a second puncture above the upper one; the needle is threaded with stout silver wire and withdrawn; the unthreaded needle is again passed through the same punctures but in front of the fragments, and after being threaded with the other end of the wire is again withdrawn. The fragments which are thus surrounded by the loop of wire are forcibly drawn together, whilst the ends of the wire are twisted on the lower border of the patella and cut off short. The suture remains permanently.

Mayo Robson aspirates the joint and inserts two steel pins, one through the quadriceps tendon above the upper fragment, and a second through the ligamentum patellæ below the lower fragment. The fragments are then drawn together by stout silk passed in a figure-of-8 around the projecting ends of the pins.

These methods have given excellent results, but are justifiable only if

performed with strict antiseptic precautions, and as means of ordinary treatment are open to the same objections as the open methods.

After-Effects of Fracture of the Patella.—Stiffness of the knee often remains to a very inconvenient degree after the treatment of a fractured patella. It is usually remedied by friction and manipulation. Thomas asserts that it is better left entirely to Nature, and states that he has seen it take two years before useful mobility returned. But should it not yield to these minor means, an apparatus consisting of a thigh-and-leg piece of stiff leather, united by angularly hinged lateral iron rods, and having an india-rubber "accumulator" adapted behind, should be worn. The continued traction of the "accumulator" will gradually flex the knee. But, as the knee becomes bent, the close union that may have appeared to exist between the fragments gradually yields, and they often gape more or less widely, much to the disappointment of both Surgeon and patient, the ligamentous band stretching like a piece of india-rubber. This cannot be helped; there is the alternative between a straight and stiff knee with close union, or a flexible and mobile one with gaping of the fragments. After the knee is flexible, lateral hinged splints may be worn without the elastic strap. The limb on recovery is usually perfectly strong, and good for any exercise except jumping.

In **Simple Comminuted Fractures of the Patella**, the result of direct blows or kicks, the fragments are not much separated, and union takes place readily by bone. In these cases, after the inflammation, which usually is rather acute, has subsided, the starched bandage may be applied, and the knee and fragments thus both kept immovable.

Compound and Comminuted Fractures of the Patella, especially if occasioned by bullet-wounds, and opening the knee-joint, are always most serious injuries. Under strict antiseptic treatment, however, the limb can usually be saved. The wound should, if necessary, be enlarged, and any loose fragments of bone removed; if the size and shape of the fragments admit of it, and if there is any tendency to separation, they should be drilled and united by wire-sutures. The cavity of the joint should then be syringed out with some efficient antiseptic solution. A drainage-tube must then be inserted on the outer side of the joint. This is best done by passing into the wound a pair of sinus-forceps, or the finger, if the opening is large enough, and making it project at the lowest possible point on the outer side of the joint; it may then be cut down upon and the tube passed. The wound must be dressed with some efficient form of antiseptic dressing and absolute rest maintained. A case of this kind in University College Hospital, which was complicated by a fracture of the thigh about the middle on the same side, progressed under carbolic-gauze dressing exactly like a simple fracture. It was caused by a fall of about thirty feet, the patient coming down upon the bent knee. If the Surgeon has not at hand the means of efficiently carrying out this treatment, as must sometimes necessarily be the case in military practice, immediate amputation would be the safest plan to adopt.

Necrosis of the Patella as the result of fracture is rare. In one such case which was under my care at the Hospital, the patient, a middle-aged man, had met with an ordinary transverse fracture of the patella, which united by ligament; two years after the accident, and without any fresh injury, he came to the Hospital, with necrosis of the outer half of the upper fragment, which was completely detached, and lying in a cavity shut off from the joint. I cut

own upon and removed the necrosed fragment, which appeared to constitute about one quarter of the patella. No cause could be assigned for the necrosis, except defective vascular supply to this part of the bone.

FRACTURES OF THE BONES OF THE LEG.—Both bones of the leg are frequently broken simultaneously, the fracture of the fibula being, as a rule, at a higher level than that of the tibia. The fracture is generally situated near the junction of the middle and lower thirds, and the lower fragments are, in the majority of cases, drawn upwards, behind the upper, by the action of the muscles of the calf; so that the edge of the tibia projects under the skin and may perforate it. In certain instances, however, the direction of the fracture is such that the lower fragment rides over the front of the upper. The tibia, though a stronger bone than the fibula, is as frequently fractured, owing to its being less protected from blows by muscles, and receiving more directly all shocks communicated to the foot. The fractures of the upper part of this bone are usually transverse, and are caused by direct violence; those of the lower part are oblique, and are caused by indirect violence. In these cases the obliquity in the tibia is from before upwards and backwards, and this increases the tendency of the lower fragment to slide up behind the upper. The sharp point of

Fig. 232.—Anatomical Preparation to show Displacement of Fragments in Fracture of Leg

the upper being in front is very apt to wound the skin (Fig. 232). When both bones are broken, the usual signs of fracture, such as shortening, increased mobility at the seat of injury, and crepitus, render the diagnosis easy; but when one bone alone is broken, it is not always a very simple matter to determine the existence of the fracture, as the sound bone, acting as a splint, prevents displacement. If it be the tibia alone that has been broken, the fracture may be detected by running the finger along the subcutaneous edge, until it comes to a point that is somewhat irregular, puffy, or tender, where by careful examination some mobility and slight crepitus may be detected. When the fibula alone is broken, the thick layer of the peroneal muscles overlaying its upper two-thirds renders the detection of the fracture difficult. It can usually be detected by pressing the fibula firmly towards the tibia, when the patient will complain of pain at the seat of fracture, and at the same time a click may be felt; by shifting the point of pressure, it will be ascertained that the pain is always at the same spot. In the lower third, the fracture is easily recognized by the same signs that occur in fractured tibia.

The first step in the **Treatment of Simple Uncomplicated Fractures of the Leg** is to place the patient in a comfortable position while the splints are being prepared. This is done by flexing the hip and knee and laying the limb on its outer side with a soft pillow below the knee. In this way the muscles of the calf, which are the chief cause of displacement, are relaxed. In the treatment of the fracture many kinds of apparatus have been used. In the majority of cases where there is but little displacement and swelling, ordinary leg-splints (Cline's, well padded, are extremely convenient), are

readily applied and keep the bones in good apposition. These may be kept on for the first few days till all swelling has subsided, when they may be replaced by the starched or plaster bandages. In fracture of the leg, indeed, the starched bandage, the Bavarian, or Croft's splint, is especially applicable. The starched bandage should be applied as follows. The limb having been well covered with wadding, a strong soaked pasteboard splint, four inches broad, and long enough to extend from above the knee to six or eight inches beyond the heel, should be applied to the back of the leg. The projecting terminal piece is now to be turned up along the sole of the foot, and two lateral strips adapted, one to each side of the limb. Over this the starched bandage, single or double according to the size of the limb, must be tightly applied. After it is dry, about the end of the second day, it must be cut up and re-adjusted, and the patient may then walk on crutches with the limb slung in front of him. *Arnold's splint* is another apparatus frequently used. It consists of a back splint of tuned iron with a foot-piece extending from just above the knee to the foot. Two wooden side splints are then applied and the whole slung in a cradle. *McIntyre's splint* (Fig. 233) may be found of service in the earlier periods, if there be much ecchymosis or extravasation, as it keeps the limb in an easy position, and allows the ready application of evaporating

Fig. 233. — McIntyre's Splint.

lotions. In applying this splint the angle at which the knee is fixed must be that at which the projection of the lower end of the upper fragment of the bone seems least marked. The foot must be covered with a flannel sock, well sewn on, from the heel of which a tape passes by which the foot can be slung up to a screw in the foot-piece. After extension has been made I prefer to pass a few turns of a roller through the extension slits on each side, so as to close the space above the heel, and thus prevent the foot falling backwards if the suspension by the sock and tape should yield. The splint, as originally designed, was screwed to a block, but it will be found to give much more perfect rest if the whole apparatus is swung in a Salter's cradle (Fig. 234). In some cases of fracture of the bones of the leg McIntyre's apparatus is not applicable. This is more particularly the case when the fracture is very oblique, from above downwards, and from before backwards; in these circumstances, the fragments cannot be brought into good position so long as the limb is kept extended and resting on its posterior surface; the bones riding considerably, and one or other of the fractured ends often pressing upon the skin in such a way as to threaten ulceration. In these cases division of the *tendo Achillis* has been recommended, with the view of removing the influence of morbid contraction. This appears to me, however, an unnecessary procedure, and cer-

tainly was not successful in some cases in which I practised it : for although the tendon was exceedingly tense, only temporary benefit resulted, the displacement returning under the influence of the other muscles inserted into the foot. In these cases the bones may usually be brought into good position by flexing the thigh well upon the abdomen, and the leg upon the thigh, and then laying the limb on its outer side on a wooden leg-splint, provided with a proper foot-piece, and keeping it fixed in this position. In most cases the swing-eradle (Fig. 234) will be found a useful and very easy apparatus. In some fractures of the leg in the upper third, the lower end of the upper fragment projects considerably, and cannot be brought into proper position so long as the knee is kept bent ; but if it be extended, so as to relax the extensors of the thigh, the bone is readily brought into good position. In fractures of the leg, as in all injuries of a similar kind, no one plan of treatment should be adopted ex-

Fig. 234.—SALTER'S SWING-ERADLE FOR FRACTURED LEG

clusively, but the means employed should be varied according to the peculiarities of each case.

In the management of fractures of the leg anywhere near the ankle the foot should be carefully kept as nearly as possible at right angles to the leg. If it be allowed to drop so that the toes point downwards, the stiffness that always follows fracture in this region, will fix it in that position for some time after the fracture is united, and until the false position is corrected by forcible flexion and rubbing, the patient cannot use his leg for walking.

Period of Union.—The time at which all artificial support may be dispensed with is, when both bones are broken, 8 weeks ; if the tibia alone is fractured, 7 weeks ; if the fibula alone, 6 weeks.

Complications of Simple Fracture of the Leg.—In addition to the complications common to all fractures, those of the leg are occasionally attended with injury to the main vessels. The consequences of this accident, and its treatment, have already been discussed (see p. 547 *et seq.*). Venous thrombosis occurs more commonly during the treatment of this fracture than in any other (see p. 550).

Compound Fractures of the Tibia are of more frequent occurrence than similar injuries of any other bone in the body. This is owing to the thin covering of soft parts over the anterior and inner aspect of the bone, and to

the fact of the fracture usually being oblique; so that the sharply pointed end of the upper fragment is likely to be thrust through the integument when the lower part of the limb falls backwards as the injured person attempts to rise or is being raised from the ground. The fracture may also, of course, be rendered compound by the same direct violence that breaks the bone. The treatment must be carried out according to the principles set forth on p. 547 *et seq.* Haemorrhage from one of the main vessels is a rare complication and must be treated according to the rules laid down on p. 555.

Fractures in the Vicinity of the Ankle-Joint are among the most common injuries of the bones of the lower extremity. They are usually occasioned by twists of the foot, by slipping off the kerb, by jumping from a height to the ground, or off a carriage in rapid motion. They are usually

associated with severe strain, or even dislocation, of the ankle. Twist of the foot in these cases must not be confounded with dislocation of the ankle. In a twist the foot carries with it the lower fragments of the leg-bones, and the malleolar arch in a more or less perfect state. In a dislocation, the foot is thrown out from under this arch. The twist of the foot is almost invariably outwards, with the inner side downwards and the outer edge turned up, and the sole usually remains in this direction, though not always to the extent that Dupuytren states, and the inner malleolus projects under the skin. Most commonly the toes are turned somewhat outwards, and the heel inwards.

Fig. 287. Displacement of Bone and Foot in Pott's Fracture. (Richard.)

Fractures of the lower ends of the tibia and fibula present four distinct varieties in degree:—

1. The fibula may be broken at its weakest point, two or three inches above the malleolus externus, the deltoid ligament being either stretched or torn.
2. The fibula may be fractured about three inches above the ankle, the tip of the malleolus internus being splintered off as well (Figs. 235, 236). This constitutes the form of injury called **Pott's Fracture**, and is perhaps the most common fracture in this situation. It very frequently becomes compound, the sharp edge of the root of the inner malleolus cutting through the skin as the foot is twisted outwards.
3. The fibula may be fractured about three inches above the ankle, and the lower end of the tibia at the same time may be splintered off in an oblique direction from without, downwards, and inwards (Fig. 237).
4. The internal malleolus may alone be broken off, the fibula remaining sound, but one of the divisions of the external lateral ligament being torn through.

The **Signs** of these fractures vary somewhat according to the bone that is injured. When the fibula alone is broken, there is but slight displacement of the foot, but there are great pain and much swelling, with perhaps indistinct crepitus, and irregularity of outline, at the seat of fracture. When the lower part of the fibula is broken, pain is produced at the fractured part by squeezing

the bones of the leg together at a point distant from the seat of injury. If the tip of the inner malleolus be broken off as well, this may be ascertained by feeling the depression above the detached fragment. In these cases the crepitus is more distinct, and the displacement of the foot is much more marked, the sole being turned somewhat upwards and outwards, and the patient resting upon its inner side. This peculiar twist of the foot with its outer edge turned up, and the inner side down, is, when present, a most characteristic sign of Pott's fracture; but many cases occur in which, although the bones are broken in the same place, the peculiar deformity is absent. In those cases in which the lower end of the tibia is obliquely splintered, as well as the fibula broken, there are not only the ordinary signs of fracture, but eversion of the foot, but the malleoli are widely separated, giving an

Fig. 236. Pott's Fracture

Fig. 237. Fracture of the Lower End of the Tibia and Fibula.

appearance of increase of breadth to the joint; crepitus is readily felt, and a depression can be perceived corresponding to the line of fracture.

The **Treatment** of these cases is always troublesome. In consequence of the swelling and inflammation that usually occur, it is often almost impossible to make out the exact extent and direction of the fracture. The difficulty of treatment is greatly increased by the small size of, and short leverage afforded by, the fragments; and so great is it, that in some cases the displacement cannot be completely overcome by any amount of skill and patience, but a certain degree of deformity results, leaving a weak and painful joint, the mobility of which is seriously impaired.

If the fracture results from direct violence, there will be a good deal of swelling from ecchymosis and inflammatory exudation; this will require to be subdued by the continuous application of cold, and the limb should be laid on a splint. If there be but little swelling, and not much displacement of the foot, the treatment may best be conducted by the immediate application of a starched or plaster bandage. When there is too much swelling for this, and no twist of the foot, perhaps the best treatment is to put the limb up in

lateral leg-splints, with rectangular foot-pieces, and swing it in a cradle. I have found the splint shown in Fig. 238 a very useful appliance in cases of fracture of the bones of the leg, one or both, in their lower third. The apparatus consists of an ordinary leg-splint cut across at the upper part of the lower third, the two pieces being united by a double rack and pinion. The various displacements that are apt to occur with fractures in this situation can thus be counteracted and corrected. It is in cases of fracture of the lower third of the fibula, with displacement outwards, or of both bones low down with tendency to displacement backwards, that this splint will be found most useful. It may be applied to either side of the leg, as seems best to suit

Fig. 238. Rack and Pinion Leg-Splint applied to correct Displacement of foot outward.

the case in question. Whatever apparatus is used, care must be taken to keep the foot at a right angle with the leg. If the toes be allowed to point, it will be found that there is in some cases a tendency for the astragalus to roll forwards, as it were, from under the malleolar arch. In other instances, again, one of the sharp angular fragments connected with the bone may be pressed forwards, and uniting in this position, give rise to permanent deformity. But whatever care be employed, or apparatus applied, it will be found impossible in some cases to replace one of the thin angular fragments, if it become twisted on its axis, and project sharply under the skin.

If the foot be twisted much outwards, as often happens in Pott's fracture,

Fig. 239. Application of Dupuytren's Splint in Pott's Fracture.

Dupuytren's splint may be applied to the inner side of the limb, to counteract the displacement (Fig. 239). In applying the apparatus, three points require attention: 1. The pad should be folded double at the lower end, and as descend below the upper fragment, so as to form a fulcrum, across which the foot may be drawn to the inner side. 2. The bandage should be applied first to the upper part of the splint. It should not be carried above the knee, but terminate just below the flexure of the joint. 3. The knee should be bent, so as to flex the leg on the thigh, and thus relax the muscles of the calf, which, by drawing up the heel, offer a serious obstacle to the maintenance of the foot in a good position. Much stiffness is always left after union has

taken place, the ankle remaining rigid, weak, and useless for a long time. When this fracture occurs in advanced life the mobility of the ankle-joint is rarely, if ever, regained, and lameness is the almost inevitable result, due partly to adhesions in the sheaths of the tendons, partly to some slight displacement of the articular surfaces. In such cases wrenching, followed by passive motion, douches and frictions may do much to restore mobility.

Dupuytren's Fracture owes its name to the Surgeon who first described it in 1816. The injury resembles Pott's fracture in its mode of production, being caused by forcible eversion of the foot. It differs, however, in the fact that wide separation of the tibia and fibula occurs as the result of rupture of the inferior tibio-fibular ligaments, or separation of that part of the lower end of the tibia to which they are attached. The fibula being fractured about three inches from its lower end, the lower fragment with the foot is forcibly driven outwards, so that the articular surface of the astragalus is completely displaced upwards and outwards from the surface of the tibia. This variety of fracture is extremely rare, and Dupuytren described only two examples. In a specimen in the London Hospital Museum the fracture was compound and due to the fall of a heavy weight on the foot.

The *Treatment* must be carried out on the same lines as that of Pott's fracture.

Fracture of the Internal and External Malleolus occasionally takes place, with great displacement of the foot backwards. It most frequently occurs from catching the heel in running down stairs. The displacement backwards is sometimes not very evident, as the malleoli having gone back with the bones of the tarsus, the appearances are very deceptive, and the patient may thus be left with the toes pointed down and an almost useless foot. It is a good rule in every case of fracture near the ankle to look specially for displacement backwards, even if there appear at first sight to be none, as it is not uncommonly overlooked.

Treatment.—This displacement may be treated by the application of the jointed splint above mentioned (Fig. 238). *Syme's anterior splint* may be used. This is a straight splint, long enough to reach from the head of the tibia to below the foot; its lower extremity is cut out into a deep horseshoe-shaped notch, wide enough to take the instep between the two prongs. It must be padded with a double pad, made of two rolls of cotton-wool in calico; these must lie one on each side of the spine of the tibia to protect it from pressure. The splint is then firmly bandaged to the anterior aspect of the leg, and the foot is drawn forward by bandages passing round the prongs and under the heel, the heel being protected by a thick soft pad.

Compound Fracture into the Ankle-joint is necessarily a dangerous accident. In this injury, the edge of the fractured bone cuts through the integument by apparently a clean and simple wound, but the subjacent areolar tissue is often widely torn, and the deep-seated mischief may be far more extensive than the Surgeon would be led to expect from the external appearances. When the wound is made by the sharp edge of the root of the malleolus, as soon as the foot is replaced and the tension on the skin caused by the eversion is relaxed, the opening no longer corresponds to the seat of fracture, and consequently, if decomposition of the discharges takes place and the joint becomes filled with septic matter, there is no efficient means of drainage, and suppuration, with great tension and deep burrowing

of pus, ensues; the ankle-joint is destroyed and secondary amputation often becomes necessary. The injury, however, is usually recovered from with a good and useful limb when the patient is young and of sound constitution, and the dangers of inflammation and suppuration are guarded against by the establishment of good drainage, by the prevention of decomposition, and by perfect rest. As age advances, however, and the constitution becomes broken, less is to be expected from conservative surgery.

In the *Treatment*, the course to be pursued will depend upon the extent of the injury. If the fracture be not much comminuted, the wound in the soft parts clean cut and but moderate in extent, and the large vessels of the foot uninjured, an attempt should be made to save the limb. The wound and the joint must be carefully cleaned with an efficient antiseptic. If the drainage be insufficient the wound may be enlarged in such a way as to provide free exit for the discharges from behind the malleolus; any splintered fragments must be removed and the wound left open to heal by granulation, some form of antiseptic dressing being applied. The limb must be firmly fixed on a splint; as a rule a lateral splint applied to the side opposite the wound will be found the most convenient. If the wound is on the inner side, as it almost always is, the limb must be flexed and laid on its outer side; should it be on the outer side it may be swung in a Salter's cradle.

If there be great comminution of bone, with dislocation of the foot, and perhaps rupture of the posterior tibial artery, in a person at or beyond the middle period of life, amputation should be practised. In a young subject, even such a serious injury as this may be recovered from, if the Surgeon remove loose fragments and saw off the splintered ends of the bone.

If much of the fibula should require removal, Stromeyer recommended that the limb should be amputated instead, lest a useless foot, affected with a kind of valgus, be left. But, in children and young subjects, this inconvenience and deformity may be overcome by mechanical means; and the probability of its occurrence would not, in my opinion, justify amputation.

Fig. 46. Badly set Foot & Fracture of the Fibula.

In badly set fractures near the ankle-joint.

great deformity with much impairment of use of the foot may result. In these cases the inner malleolus will be found to project greatly, the fibula to be curved inwards above its lower third, so as to form a concavity above the external malleolus, and the foot to be turned somewhat outwards (Fig. 240). I have in two such cases succeeded in removing the deformity to a considerable extent, even after so lengthened a period as two years, by dividing the fibula subcutaneously with a narrow-bladed saw at the seat of greatest concavity, forcibly adducting the foot, and then putting up the fracture in a Dupuytren's splint.

FRACTURES OF THE BONES OF THE FOOT almost invariably result from direct violence, and are usually accompanied by bruising and injury of the soft parts; hence much displacement is rare, and, when the fracture is simple,

rest and position alone are necessary. Compound fractures of the tarsal or metatarsal bones, attended with much bruising and laceration, usually require partial removal of the foot, disarticulation at the ankle-joint, or amputation in the lower third of the leg, according to the extent and severity of the injury.

The **Os Calcis** may be broken by direct violence, as when a person jumping from a height alights forcibly on his heel, and thus fractures the bone. In this way the bone may be simply broken across in front of the ligaments without displacement. I have, however, seen both calcanea shattered to pieces, in the case of a lady, who falling from a window on the third storey, alighted on her heels. In some rare cases, by the powerful contraction of the muscles of the calf, the posterior part of the os calcis is torn away from the rest of the bone.

Signs.—When the os calcis is broken through at the posterior part behind the insertion of the lateral ligaments, the detached fragment will be drawn up by the action of the calf muscles. But when the fracture occurs across the body of the bone, no displacement can take place, owing to the lateral and interosseous ligaments keeping the posterior fragment in position.

In the first form of fracture, the pain, swelling, flattening of the heel, and prominence of the malleoli, indicate the nature of the injury, even though crepitus be wanting. In the second variety, the mobility of the fragment, and its projection posteriorly owing to the action of the muscles of the calf, point to the existence of the fracture, which is confirmed by the occurrence of crepitus.

In the *Treatment* of these injuries, keeping the part fixed by means of bandages and splints, with due attention to the relaxation of the muscles attached to the tendo Achillis, by flexing the leg and extending the foot, is all that can be done. In the separation of a small fragment by muscular action, union will probably take place by fibrous tissue, but in other cases by bone.

The **Astragalus** alone is rarely broken. Ten cases of this injury have been collected by Monahan: in nine the fracture occurred from falls from a height on the foot; in one only from direct violence. I have seen two cases of fracture of the astragalus without implication of the other tarsal bones. In one case it was the result of direct violence; a cart-wheel passing over the foot occasioned a fracture of the astragalus through its neck. There was no material displacement, but the line of fracture could readily be felt, and crepitus was very distinctly elicited on flexing and extending the foot. No better treatment can be adopted in such a case than the starched or plaster bandage. In the other case the fracture was the result of indirect violence, the patient, a man about 30 years of age, falling from a height of about eight fards, and alighting on his feet. Here the fracture was evidently occasioned by the malleolar arch being forcibly driven downwards on the foot, so that the astragalus was broken transversely just in front of the surface that articulates with the tibia—the line of fracture running obliquely downwards and backwards, so that the whole of the upper and posterior part of the bone was detached. This large fragment was driven outwards and backwards, so as to lie between the fibula and the tendo Achillis, lacerating the skin to the extent of about one inch longitudinally, and projecting through the opening thus made. The foot presented a singular degree of deformity, which is represented in Fig. 241. The outer malleolus projected greatly: and immediately behind this the displaced fragment could be felt and seen partially protruding through the rent in the skin. The inner

malleolus was depressed; there was a deep hollow below this. The os calcis was apparently turned somewhat towards the inner side of the foot. The sole was arched, the skin much wrinkled, and the great toe forcibly flexed. There was a deep transverse furrow in front of the ankle-joint. Seeing the hopelessness of

Fig. 241.—Comminuted Fracture of Astragalus. Displacement backwards.

reduction, or rather the impossibility of maintaining the displaced fragment in position, I enlarged the opening through which it showed itself, and then, seizing it with strong forceps, twisted it out, dividing the ligamentous connexions. The case was then treated as one of compound dislocation of the ankle-joint. About a month after the accident, the patient died of pyæmia; and it was then found that the anterior portion of the astragalus had been splintered into seven fragments, which were retained in place by the pressure of the surrounding parts. No other bone of the tarsus was injured, nor was the malle-

olar arch fractured. Of this splintering of the anterior fragment, there was no evidence during life; nor was there any reason to suspect it, as there was neither crepitus nor displacement. The extent of the fracture showed the immense force with which the malleolar arch had been driven downwards on the astragalus by the weight of the patient's body.

The only similar case with which I am acquainted is one recorded by Morris. In this the displaced fragment did not occasion a wound of the integument. It was excised owing to the impossibility of reducing it; but caries of the remaining part of the astragalus and other tarsal bones, rendered amputation of the foot necessary.

The other tarsal bones are very rarely fractured, except in crushes or gunshot injuries of the foot. I have seen the **Scaphoid** fractured in the case of a man who fell down the shaft of a lift at an hotel, about 60 feet deep, receiving fatal injuries to the chest and spine. He appeared to have alighted, in the first instance, on the right foot, the os calcis of which was extensively fractured, and the scaphoid broken across without displacement, the astragalus being uninjured.

In all cases of fracture of the tarsal bones, whether simple or compound, with so much displacement as to render reduction difficult and its maintenance impossible, the best course to be pursued is to cut down upon and remove the displaced fragment.

Fracture of the Metatarsal Bones usually occurs from direct violence, as by the passage of the wheel of a cart or railway carriage over the foot, and is then attended with so much laceration and bruising of the soft parts as not unfrequently to render amputation necessary. I have in one instance known the three outer metatarsal bones broken by a person jumping from a height. But most commonly their elasticity saves them, and the ankle-joint gives way in such an accident. There is but little, if any, displacement in these cases; and unless the soft parts be so damaged as to require amputation, the support of a starched or plaster bandage is usually all the treatment that is necessary.

CHAPTER XXII.

DISLOCATIONS.

Dislocation is the more or less sudden and complete displacement of one of the bony structures of a joint from the other. In the ball and socket joints, as the hip and shoulder, the osseous structures are completely separated from one another, the dislocation then being **Complete**. In the hinge-joints, as the elbow and knee, the osseous surfaces commonly remain partially in contact, though displaced from their normal relations to one another: here the dislocation is **Incomplete**. In most dislocations the integuments covering the displaced bones are put greatly on the stretch; but in some they are ruptured, and then the dislocation is **Compound**. Besides these varieties, Surgeons recognize **Spontaneous** dislocation, in which the displacement does not occur from external violence. In other cases again, the dislocation arises from **Congenital** malformation of the joint, in consequence of which the bones cannot remain in proper apposition; and finally, dislocation may take place as a result of disease in the articulation and surrounding tissues. This is termed **Pathological** dislocation.

It is now customary to describe dislocations of the distal bone or the more movable bone; formerly, dislocation of the proximal bone was often spoken of.

CAUSES.—Dislocation is **Predisposed** to by various conditions, amongst which the nature of the joint appears to exercise most influence; ball and socket joints being more liable to dislocation than any of the other articulations, whilst in some of the synchondroses it never occurs. Krönlein states that 61 per cent. of all dislocations occur at the shoulder-joint, 27 per cent. at the elbow, and 2 per cent. at the hip. These statistics have been obtained from the combined records of the in- and out-patient practice of the hospitals in Berlin, whereas those published by Malgaigne and some others have been derived from in-patient practice only, and are consequently very erroneous.

Dislocations are seldom met with in children, in whom separation of the epiphysis from the shaft more readily takes place. When they do occur it is most frequently at the elbow-joint. Krönlein states that out of 400 dislocations treated in the Berlin hospitals, 22 were met with in this situation in children under ten years of age. I have had under my care a child, just one year old, with dislocation of the head of the femur on the os pubis, occasioned by another older child dragging it along the ground by its leg; Kirby and Mudge have both seen dislocations of the femur on the dorsum ilii in children of three and three and a half years old; and Travers has seen the hip dislocated in a boy five years of age. In old people the bones are so brittle, and the ligaments so tough, that violence causes fracture rather than dislocation. Hence it is principally in young and middle-aged subjects that dislocations are met with. This is well illustrated by an analysis of 81 cases of dislocation

of the hip-joint, collected by Hamilton : of these, 15 occurred under 15 years of age, 32 between 15 and 30, 29 between 30 and 45, and 8 between 45 and 85. They are necessarily far more common in men than in women, from the nature of their respective occupations. Thus, according to Hamilton, of 115 dislocations of the hip, only 11 occurred in women.

The articular ends of the bones of the extremities are kept in their proper positions by the arrangement of the osseous and ligamentous structures of the joints, aided by the continuous tension of the muscles ; and considerable external violence may be applied to a limb without dislocating it. If, however, the muscles be taken by surprise, or if they have been weakened by previous injury of any kind, the joint becomes predisposed to dislocation, and may be displaced under the influence of very slight causes : especially if it be one in which the articulating surface is shallow and the ligaments are comparatively weak. In this way the same joint may be repeatedly dislocated. Thus I have seen a man whose humerus had been dislocated between forty and fifty times, owing to a weakened state of the deltoid.

The **Direct Causes of Dislocation** are *external violence* and *muscular action*. *External violence* may act directly upon a joint, forcing or twisting the articular ends asunder, as happens when the foot is displaced by a twist of the ankle, or when the thumb is dislocated backwards by a blow. But more commonly the force acts at a distance from the joint that is displaced, and the head of the bone is thrown out of its socket by "the lever-like movement of the shaft," as happens when the head of the humerus is dislocated by a fall of the hand, or when the head of the femur is dislocated.

Muscular action alone may cause the dislocation of a bone, even though the part be previously in a sound state. Thus, the lower jaw has been dislocated by excessive gaping, and the humerus by making a violent muscular effort. If the joint have already been weakened by previous injury or disease, muscular action is especially apt to occasion its displacement. Congenital dislocations have been supposed to arise from irregular muscular contractions in the fetus, by which the bones are displaced, and the normal development of the joint is interfered with. In dislocations of the ball-and-socket joints, after the head of the bone has been thrown out of its articular cavity, it is often still further displaced by the contraction of the muscles, which continues until they have shortened themselves to their full extent, or until the dislocated bone comes into contact with some osseous prominence that prevents its further displacement.

SIGNS.—The existence of a dislocation is rendered evident by the change in the shape of the joint, and in the relation of the osseous prominences to one another : by the articular end of the displaced bone being felt in a new position ; and by an alteration in the length of the limb, and in the direction of its axis. Besides this, there is impaired motion, both active and passive, of the injured articulation, with pain in and around it. It should, however, be borne in mind that fracture may exist with the dislocation : hence the mobility may be increased. In examining a patient for a supposed dislocation the Surgeon should never fail to compare the injured joint with that of the other side of the body.

EFFECTS.—The effects of dislocation on the structure of a joint are always serious. The bones are occasionally fractured as well as displaced, more particularly in hinge-joints : the cartilages may be injured ; and the ligaments are

at the same time fracturing the second rib, and separating the first from its cartilage. All the ligamentous structures around the end of the bone were torn through, with the exception of the costo-clavicular ligament, which had preserved its attachments unbroken, and had carried away the cartilage of the first rib in the direction of the displaced clavicle. Dislocation backwards has also occurred as a secondary consequence of curvature of the spine.

The *Signs* are those that usually indicate a dislocation of the sternal end of the clavicle—shortening of the shoulder, and deformity about the upper part of the sternum; but, besides these, a special train of symptoms is occasioned by the pressure of the displaced bone upon the trachea, œsophagus, and vessels of the neck. Difficulty in breathing and swallowing, with congestion of the head giving rise even to a semicomatose state, may be produced to such an extent as to necessitate removal of the end of the bone, as happened in a case of gradual dislocation from deformity of the spine related by Astley Cooper, in which the Surgeon was obliged to saw off the dislocated end. In some cases, the end of the bone is thrown upwards as well as backwards; in others, it takes rather a downward direction.

In the *Treatment* of this dislocation, it is easy to effect the reduction of the bone by making a fulcrum of the fist in the axilla, and then bringing the elbow well to the side, at the same time that an assistant puts his knee between the patient's shoulders and pulls them back; but it is difficult to retain the bone in proper position. To attain this object, the figure-of-8 bandage applied to the points of the shoulders, and crossed over a large pad placed in the middle of the back, will give the most efficient support to the part, the elbow being at the same time well fixed to the side and drawn back.

2. The dislocations of the **Outer End of the Clavicle**, or more correctly, the **dislocations of the Acromion** from the clavicle, are more commonly met with than those just described. The most frequent accident of this description is that in which the bone is thrown **upon the Upper Surface of the Acromion, or upon the Anterior Part of the Spine of the Scapula**. It is usually caused by violent falls upon the shoulder, and is not an uncommon accident at football. The prominence formed by the displaced bone upon the upper surface of the acromion, the narrowing of the distance from the mesial line to the point of the shoulder to the extent of from an inch to an inch and a half, the facility of the reduction of the dislocation, and the prominence of the clavicular portion of the trapezius muscle, indicate the nature of the accident (Fig. 245). The *Treatment* is by no means satisfactory. Reduction may easily be effected by raising the shoulder, drawing it backwards, and carrying it outwards by placing a pad or the hand in the axilla and bringing the elbow well to the side. But, notwithstanding the facility of reduction, there is in many cases an unconquerable tendency to the return of the displacement. This is owing partly to the shallowness of the articular surface of the acromion, partly to the tension of the trapezius, by which the acromial end of the bone is drawn upwards, and in a great degree to the mobility of the shoulder. In every movement of the body or neck there will be found to be a tendency to rising upwards of the end of the dislocated bone, and in the majority of cases this will be insurmountable by any mechanical means that can be employed. It is best limited, if not obviated, by a pad and gutta-serena plate laid on the projecting clavicle, and strapped tightly down by a band passing parallel to the arm and under the flexed forearm, this being

retained in position by being attached to a strap passed round the upper axilla. Even if the displacement continue irremediable, a very useful arm will still be left, though somewhat limited in its upward movements.

The outer end of the clavicle has been dislocated **under the Acromion** by the application of direct violence to the end of the bone. This form of displacement is extremely rare; several instances have, however, been recorded. The diagnosis is easily made and the treatment must be conducted in the same way as that of fractured clavicle.

Fig. 245. Dislocation of the Clavicle on the Acromion.

The acromial end of the clavicle is said to have been displaced **underneath the Coracoid Process**; but it is possible that the diagnosis was erroneous, as on anatomical grounds such a displacement seems hardly possible.

Simultaneous Dislocation of both ends of the Clavicle is very rare, only four cases having been recorded.

DISLOCATION OF THE SCAPULA.—Under this name has been described a very remarkable kind of displacement of the *Lower Angle and Dorsal Border* of the scapula which is occasionally met with, in consequence of which it projects at a considerable angle from the trunk, giving a winged appearance to the back. This displacement has been attributed to the bone slipping away from under the latissimus dorsi muscle; but it is probable that, in the majority of cases at least, it has really been due to paralysis of the serratus magnus. Paralysis of the muscle is easily recognized: the projection of the scapula is most marked when the arm is put forwards at right angles to the trunk; if both arms are put in this position it will be found that the patient can push the sound arm forwards about two inches further than the other, the scapular movement being wanting on the paralysed side; in some cases there has been difficulty in raising the arm above the head; expansion of the chest is less perfect on the affected side, and if the patient is thin it can be seen that the digitations of the muscle are feebly marked. In a case of this kind recorded by G. V. Poore, in which the paralysis followed chronic neuritis of the brachial plexus, the result of a strain, the patient gradually recovered under electrical treatment. I have seen some benefit derived in such cases from the external application of strychnine on a blistered surface, and afterwards from support by means of a properly constructed apparatus.

DISLOCATIONS OF THE SHOULDER-JOINT occur far more frequently than those of any other articulation. The reason of this is to be found in the shallowness of the glenoid cavity, the large size and rounded shape of the head of the humerus, and the weakness of the ligaments; but, above all, in the extent and force of the movements to which the joint is subjected. These displacements indeed would be much more frequent even than they are, were it not for the protection afforded to the joint by the osseous and ligamentous arch formed by the coracoid process and acromion with their ligaments, the great strength of the capsular muscles and their close connection with the joint, and the support given by the tendon of the long head of the biceps; but the principal obstacle to dislocation is the mobility of the scapula, enabling all movements communicated to the hand and arm to react upon that bone.

The **Signs** of dislocation of the shoulder-joint are sufficiently obvious, varying, however, according to the nature of the injury. In all cases there are seven common signs, viz.:—1, flattening of the shoulder: 2, hollow under the acromion: 3, apparent projection of this process, with hollow tension of the deltoid: 4, presence of the head of the bone in an abnormal situation: 5, rigidity: 6, inability to place the hand on the opposite shoulder while the elbow is made to touch the front of the chest: and 7, pain about the shoulder.

The shoulder-joint is susceptible of *four* principal dislocations. Of these, according to Astley Cooper, three are complete, and the fourth partial. I think, however, that on examination it will be found that the so-called *partial* dislocation is in reality a complete one. The directions in which the head of the humerus may be thrown are:—1, *inwards and slightly downwards* beneath the

DISLOCATIONS OF THE HEAD OF THE HUMERUS.

Fig. 246. Subcoracoid. Fig. 247. Subclavicular. Fig. 248. Subspinous. Fig. 249. Subglenoid.

coracoid process—*Subcoracoid* (Fig. 246); 2, *forwards and inwards* beneath the clavicle—*Subclavicular* (Fig. 247); 3, *backwards and downwards* under the spine of the scapula—*Subspinous* (Fig. 248); 4, *downwards and slightly inwards* under the glenoid cavity—*Subglenoid* (Fig. 249). In three recorded cases the head of the bone has been dislocated *upwards and forwards*—*Supracoracoid*.

1. **Subcoracoid Dislocation.**—In the case of *incomplete* dislocation reported by Astley Cooper, the head of the bone was found to be thrown out of the glenoid cavity, lying under the coracoid process upon the anterior part of the neck of the scapula (Fig. 246): the capsular muscles were not torn, but the long head of the biceps had been ruptured. The description given by Astley Cooper, and the illustrative plate in his work on *Dislocations*, appear to point to a form of injury of the shoulder-joint which has been specially described by the French surgeons as a variety of the dislocation downwards: that form of displacement, indeed, which by Boyer has been described as the dislocation "inwards," by Malgaigne as the "subcoracoid" luxation, and by Velpeau as the "subscapular" dislocation—in which the head of the humerus is placed in front of the neck of the scapula, and underneath the subscapular muscle. In this dislocation the head of the bone, instead of being thrown, as in the subglenoid, downwards and slightly inwards, is thrown inwards either directly or slightly downwards as well. Why Astley Cooper described this as a *partial* dislocation, I do not understand; for not only was there rupture of the capsule and of the long tendon of the biceps, but the woodcut at page 401

measured by the effects produced by anesthetizing the patient. So much of the resistance as is thus overcome is due to muscular contraction. All that which continues after this is due to purely mechanical causes connected with the arrangement of the osseous and ligamentous structures of the joint, or with the injury inflicted on them. The resistance offered by the muscles is of several different kinds, and is dependent on different causes. The influence exercised by the patient's will, and the tonic contraction or passive force exerted by the shortened and displaced muscles, undoubtedly often offer great obstacles to reduction. But more serious than these by far is the reflex or spasmodic action, which the patient is unable to control, and which can be overcome only by force, by faintness, or by the paralyzing influence of anesthetics. The longer the dislocation is left unreduced, the more powerful does the resisting force become; being less at the moment of the accident and immediately afterwards than at any subsequent period. Hence reduction should be attempted as soon as possible after the occurrence of the accident; and, if the patient be seen at once, the bone may sometimes be replaced without much difficulty by the unaided efforts of the Surgeon. Thus Liston reduced a dislocated hip by his own endeavours immediately after the accident occurred. If a few hours have elapsed, the muscular tension becomes so great that special measures must be adopted in order to diminish it; and if some weeks or months have been allowed to pass by, the dislocation may have become irreducible, partly owing to permanent secondary shortening of the muscles, which it is impossible to overcome, but chiefly to the matting together of the surrounding tissues, and the formation of adhesions about the head of the bone. The muscular resistance is greatest when an attempt is made at reduction by forcible traction in the direction of the longitudinal axis of the limb, and parallel to the course of the muscles.

In the reduction of a recent dislocation, advantage may sometimes be taken of the occurrence of faintness, or of the patient's attention being distracted to other matters, when the muscles are, as it were, taken by surprise, and the bone readily slips into its place. Such aids as these, however, cannot be depended upon; and muscular relaxation should be induced by the administration of chloroform or ether. By means of these agents, the muscles of the strongest man may be rendered so perfectly flaccid in a few minutes as to offer no opposition whatever to reduction. In no department of practical surgery has the administration of anæsthetic agents been attended with more advantageous results than in this.

2. The reduction of dislocations is also impeded by the mechanical resistance arising from the *anatomical structure of the joint and its ligaments*. The observations of Bigelow, Busch, and others have proved that this impediment to reduction is of more importance than was formerly supposed. Bigelow has shown by dissection of dislocations of the hip, produced in the dead body, that the characteristic attitude of the limb and the difficulty of reduction are due to the tension of the ruptured parts of the capsule and its accessory bands consequent upon the abnormal position of the head of the bone, and thus it is not until these are relaxed, by placing the limb in the proper position, that reduction can be accomplished. Busch has shown that the same is true of the shoulder-joint, the characteristic position of the chief forms of dislocation being maintained when the whole of the soft parts have been removed except the ligaments. If the ligaments are more extensively torn, the limb falls into

the tendon of the subscapularis torn across, together with the internal portion of the capsular ligament; the supraspinatus and the long head of the biceps being stretched, but not ruptured.

When the head of the bone is dislocated below the spine of the scapula, it can be felt and seen there, more especially when the arm is rotated. The axis of the limb is altered, being directed upwards and backwards; the elbow is raised from the side, to which it cannot be approximated, and is carried forwards. There is little or no alteration in the length of the limb, but such as there is is said to be in the direction of lengthening. The accompanying figures, for which I am indebted to Rushton Parker, of Liverpool, show admirably the deformity in this dislocation.

4. In the dislocation **Downwards**, or the **Subglenoid** (Fig. 249), the head of the bone lies in the axilla, resting against the axillary border of the scapula

Fig. 249. Dislocation of the right humerus backwards (Front View).

Fig. 250. Dislocation of the right humerus backwards (Back View).

below the glenoid cavity, and lodged between the subscapular muscle and the long head of the triceps. The tendon of the subscapularis is commonly torn near its insertion into the lesser tuberosity of the humerus, and the capsular ligament is largely lacerated. The supraspinatus may also be torn through, or a portion of the great tuberosity of the humerus detached, and the rest of the capsular muscles put greatly on the stretch. The axillary artery and plexus of nerves are compressed and stretched by the dislocated head of the bone, so that severe pain is commonly experienced in the hand and arm, often accompanied by numbness of the fingers. The compression of the artery is so great that the circulation through the limb may be completely arrested. This I saw well illustrated in a case of subglenoid dislocation complicated with a wound of the forearm, dividing the radial and ulnar arteries. As long as the dislocation remained unreduced, no hæmorrhage took place; but when the head of the bone was replaced, the injured arteries bled freely.

The head of the bone can usually be readily felt in the axilla, at its anterior and under part; the arm is lengthened to the extent of about an inch, and the forearm is usually somewhat bent. The elbow is separated from the trunk

cation is often readily reduced ; but if it does not yield at once, the direction should be changed, while the traction is kept up, to that which relaxes to the fullest extent the untorn ligaments or bands of the capsule. This will in most cases correspond to the position of the limb at the time of the accident. The head of the bone is thus made to pass along the same track which it has torn for itself in being dislocated, and thus is replaced without the infliction of any additional violence on the surrounding tissues.

The question whether the extending force should be applied to the bone that is actually displaced, or to the further end of the limb, has been much discussed, and appears to have received more attention than it deserves. It is true that, by applying the extending force to the displaced bone itself, the

Fig. 242. Close-fitch.

Surgeon has greater command over its movements, with less chance of injury to the intervening bones ; whilst, by applying the extending force to the lower part of the extremity, he has the advantage of a longer lever for the reduction of the head of the bone. This lever, however, it must be remembered, is in many cases a broken one ; and it cannot be made to act if the bone has to be replaced in the direction of flexion of the joints that exist in its course. For this reason, we find that some dislocations are best reduced by applying traction to the bone itself that is displaced, as in luxations of the femur and of the bones of the forearm : whilst, in other cases, as in the dislocations of the humerus, most advantage is gained by applying the extending force to the end of the limb. But I fear upon these points as of comparatively little consequence ; believing that, when the patient is not anesthetized, the muscles of the limb themselves effect the reduction, without the necessity

of the Surgeon employing any very powerful lever-like action of the bone, and that, when the patient is paralyzed by chloroform, the bone is in most cases readily replaced by the simple movements impressed directly upon it, or even upon its articular end, by the hands of the Surgeon.

The force required in effecting the reduction of recent dislocations is often very considerable. So great is the resistance offered, that in some cases the dislocated bone has given way. I am acquainted with cases in which the humerus and the neck of the femur have been broken in attempting the reduction of *recent* dislocations. This accident does not always appear to have been the result of any unskilful employment of force, but in some cases seems to have occurred from natural weakness of bone. We know that "spontaneous" fractures take place from muscular action, often of a very slight kind ; and we can easily understand that, if a bone that would be liable to such ready fracture happened to be dislocated, it would almost of necessity give way under the influence of the force required to replace it.

Manipulation of the limb—that is, impressing upon it certain movements of extension and flexion, of adduction, abduction, and rotation—is, whenever possible, the best mode of reducing a dislocation. The movements impressed

when it is stretched across the chest. As this is an unusual position for any injury to be received in, this dislocation is proportionately rare. An obstacle to this displacement may also be found in the greater strength of the outer portion of the capsule of the joint, as compared with the inner.

Relative Frequency.—Astley Cooper states that the dislocation "into the axilla" is the most frequent form of accident. This opinion is confirmed by most English Surgeons. But Malgaigne, and more recently Flower, have expressed the opinion that the subcoracoid is the most common form. Flower found that of forty-one specimens in the London museums, thirty-one were undoubtedly *subcoracoid*, and that of fifty recent cases of which he had cognizance, forty-four were of this form. Next in order of frequency comes the *subglenoid*, and then the *subclavicular*, which is rare. I believe the subclavicular to be an exaggerated degree of the subcoracoid: the continuance of the same force which has thrown the head of the bone to the inner side of the coracoid process carrying it upwards and inwards under the clavicle. The displacement of the head of the bone under the spine of the scapula is so rare that Astley Cooper met with only two cases of it.

Diagnosis of Injuries about the Shoulder.—In all cases of injury to the shoulder the patient should be stripped so as to show both shoulders in order that the two sides may be compared. Little can be learnt from the history, as different forms of injury may arise from apparently similar accidents. The attitude of the patient is often characteristic: in all dislocations the elbow is separated from the body and the patient leans towards the injured side, so as to allow the limb to hang perpendicularly in its new axis: in fractures the elbow is close to the side and the arm hangs powerless. In fractured clavicle the patient inclines the head to the injured side and supports the weight of the arm by holding the elbow in the other hand. The power of moving the arm remains to some extent in all dislocations, in impacted fractures of the neck of the humerus, and in fractures of the clavicle between the ligaments; but it is entirely lost in unimpacted fractures of the neck of the humerus and in fractures of the clavicle about the middle, or is accompanied by so much pain that the patient cannot be persuaded to attempt it. Having ascertained this much, the Surgeon should stand behind the patient and place his hands over his shoulders in such a way that the tips of the fore-fingers rest on the sterno-clavicular articulation and the thumbs on the spines of the scapulae. By comparing the two sterno-clavicular articulations he will at once recognize any dislocation or fracture of the sternal end of the clavicle. He then moves his fingers outwards along the clavicles until he finds the prominence that always marks the acromio-clavicular articulation on each side. In doing this he will recognize any fracture of the clavicle, and by comparing the acromio-clavicular articulations would detect any dislocation of that joint. The only injury that would escape detection in this way might be the fracture of the clavicle between the corneo-clavicular ligaments. Tenderness would, however, be found which might draw attention to the seat of injury as the fingers passed over it. The fingers are now to be passed round the acromion, carefully comparing it with that on the injured side, by which a fracture of its tip will be detected. At the posterior part of the acromion process near its root is always a small tubercle of bone, which is called the acromial angle. It serves to guide the Surgeon in placing his hands symmetrically on the shoulders, and is also an excellent point from which

partly on the kind of joint that has been dislocated, partly on the particular variety of dislocation that has occurred. Thus, as a general rule, greater freedom of movement and greater utility of limb will be found in old-standing dislocations of ball-and-socket than of hinge joints. But in ball-and-socket joints some dislocations will, if left unreduced, be attended with less evil consequences to the patient than others. Thus, in the *subglenoid* dislocation of the shoulder and the dislocation backwards below the obturator tendon or "*sciatic*" of the hip, the limb will recover itself to a greater extent than in the other forms affecting these joints.

Treatment.—In cases of very old and irremediable unreduced dislocation, much may be done by means of regularly conducted passive movements to increase the mobility of the part, and by means of friction and warm douches to relieve the painful stiffness. In cases not so old, but in which some time has elapsed since the occurrence of the dislocation, two questions always present themselves to the Surgeon:—1. Is it possible to replace the dislocated bone? 2. Is it desirable or prudent to attempt reduction?

The possibility of reducing the dislocation will depend partly upon the joint that is dislocated and the nature and extent of the dislocation, but chiefly on the length of time during which the bone has been out of place. Dislocations of the ball-and-socket joints generally can be reduced at a much later period than those of the hinge joints; those of the shoulder can be reduced after a longer lapse of time than those of the hip. The *subglenoid* dislocation of the shoulder and that of the hip on the *dorsum ilii* are capable of reduction at a later period than the other luxations of the same joints.

The *latest period* at which reduction is possible has been variously estimated by different Surgeons. Astley Cooper gives three months for the shoulder and eight weeks for the hip. As a general statement, this was no doubt tolerably correct at the time when it was made, although reduction had been effected at later periods than those given by Cooper. Thus Breschet reduced a dislocation of the hip at the 78th day, and Travers at the fifth month. But we may not go far beyond this as the limit of *possible* reduction. Brodhurst has reduced the shoulder on the 175th day; Smith (U.S.) in one case at the same month, in another at ten months and a half; Sedillot one at a year; Luckmann of Cincinnati, a dislocation of the femur on the *dorsum ilii*, at six months. Dupierris of Havana, one at over six months, in a boy, and this without chloroform; and R. W. Smith, after nine months had elapsed.

The **obstacles to the reduction of old-standing dislocations** are rather pathological than physiological and anatomical as in the case of recent displacements. They are of several distinct kinds:—1. The powerful tonic contraction of the shortened and displaced muscles; 2. the organic changes that have taken place in the muscles partly from the contraction of the cicatricial tissue formed in the repair of the lacerations which occurred at the time of the injury, and partly from the shortening that has taken place to adapt the muscles to the altered relation of the head of the bone; 3. adhesions that form between the lacerated capsule and the muscles and the displaced head of the bone; 4. lastly, as a more remote effect, pathological changes in the articulating surfaces themselves, by which their shape becomes altered and the socket shallowed, contracted, and perhaps ultimately obliterated.

In order to overcome these obstacles a considerable amount of force must be

used, as adhesions and contractions have to be stretched and torn asunder. This is effected by the multiplying pulleys and by manipulation under chloroform. In employing the necessary force, care must be taken to protect the skin from abrasion, or even laceration, by the use of wet flannel bandages or wash-leather. The force exerted by the pulleys must be considerable; but it should be accompanied by free rotatory manipulations and movements of the head of the bone, so as to loosen it from its adhesions; and reduction will usually be effected in this way rather than by forcible traction alone.

Anæsthesia is of inestimable service in these cases; and it is by its means that the Surgeon has been enabled to extend materially the limit of possible reduction. But, in the reduction of old dislocations, anæsthetics do not give exactly the same kind of help as in those of recent date. In a recent dislocation one great obstacle is muscular contraction; and, by relaxing this, anæsthetics enable the Surgeon to replace the bone at once without difficulty. In old dislocations the obstacles, as has just been stated, consist in various pathological changes that have taken place around and in the displaced bones. These conditions cannot be influenced by anæsthesia; and hence, except as a means of producing insensibility to pain and preventing instinctive or voluntary muscular resistance, chloroform will not aid the Surgeon.

It must be borne in mind that the reduction of old dislocations is a work not only of very considerable difficulty, but also of danger. If several months have elapsed, the obstacles arising from the pathological changes already mentioned will usually be so obstinate as to render the reduction impossible without the employment of a dangerous amount of force; and in many cases they will prevent reduction, whatever force be employed.

The **Accidents** that may occur during attempts to reduce old dislocations, whether successful or not, are the following:—1. Laceration of the skin by the constriction and pressure of the bands to which the pulleys are attached. 2. Laceration of muscles: thus the pectoral has been torn through in attempting reduction of old dislocation of the shoulder. 3. The development of inflammation and suppuration around the dislocation, by the violence to which the soft parts have been subjected. From this cause death has several times resulted in attempts at reducing old hip dislocations. 4. Extensive extravasation of blood from the rupture of small vessels in the lacerated soft parts, giving rise to wide-spread ecchymosis. 5. Laceration of one of the larger veins. A patient of Froberg's died from this cause, after rupture of the axillary vein in an attempt to reduce an old dislocation of the shoulder. 6. Laceration of an artery, with subcutaneous arterial extravasation. This serious accident has happened at least twenty times in attempted reduction of old dislocations of the shoulder. The brachial artery has also been torn in attempted reduction of a dislocated elbow. 7. Laceration of neighbouring nerves. These of the axillary plexus have been torn in attempted reduction of dislocation of the shoulder, and the median in that of the elbow. Flaubert has recorded a case in which the four lower nerves entering into the brachial plexus were torn away from the cord. The patient, a woman 70 years of age, died eighteen days afterwards, with paralysis of both arms and of the leg on the same side as the injury. 8. Fracture of the dislocated bone. This serious accident has usually happened when the Surgeon, after the employment

of extension, has attempted to put in force transverse movements of the bone, or has used the bone as a lever; it has given way, usually high up near the head, at other times in the shaft. It is probable that in most cases this has been predisposed to by the bone having become weakened by want of use. It has occurred several times in the humerus, and at least twelve times in the femur, in attempts at reducing old dislocations of these bones. In most of the recorded cases the bone has readily united, and the condition of the patient has not been materially, if at all, influenced for the worse, except that reduction of the dislocation has necessarily been rendered impossible. 9. Neighbouring bones, such as the ribs and the glenoid cavity, have been fractured in the endeavour to reduce dislocation of the shoulder, and the acetabulum in attempted reduction of a luxated hip. 10. The limb has actually been torn off. This remarkable accident happened to Guérin of Paris, in attempting the reduction, without pulleys but merely by the traction of four assistants, of a dislocation of the shoulder of three months' standing, in a woman 63 years of age, the limb being suddenly torn off at the elbow. The patient died on the twelfth day; and on examination, the bones were found porous, and the muscular and other soft structures pulpy, the limb having evidently lost its natural strength and elasticity.

The occurrence of these various accidents and injuries, in the attempted reduction of old dislocations, cannot always be justly attributed to the employment of an improper amount of force by the Surgeon. The liability to them must rather be looked upon as a necessary accompaniment of attempts at putting back into its place a bone which has been dislocated, and left unreduced for many weeks or months. During this period the bone usually contracts adhesions of a very dense kind to the parts amongst which it lies; and, as it cannot be replaced in its articular cavity until these adhesions have been torn or broken through, it is easy to understand how, in the attempt to do this, neighbouring soft parts, vessels, or nerves may give way, or the bone itself may yield to the force that must be applied to it in order to lift it out of its new bed.

The liability to the occurrence of these accidents should make the Surgeon very cautious how he recommends an attempt to reduce old-standing dislocations. If after a time the new joint have become tolerably mobile and be not painful, it may be better to leave the bone unreduced, rather than expose the patient to great risk, with a slender prospect of eventual success. If the unreduced dislocation give rise to stiffness and pain, much may be done by passive motion, frictions, and douches, to improve the patient's condition.

The **Subcutaneous Section** of muscles, tendons, and bands of adhesions in the neighbourhood of the dislocated joint, was proposed by Dieffenbach as a means of facilitating reduction in old-standing cases; and he has related an instance in which, by these means, a shoulder that had been dislocated for two years was reduced. In many cases in which this plan has been tried, the success has not been commensurate with the expectations founded on it, and in other instances, of which I have seen two or three, the operation has been followed by sloughing and other serious evils, while it has not been attended with any benefit in facilitating reduction. Lister and others have successfully reduced old dislocations of the shoulder by exposing the head of the humerus and dividing the structures which prevented its replacement.

Compound Dislocation is one of the most serious injuries to which a limb

can be subjected. Not only is there such extensive laceration of the soft parts that cover and enter into the formation of the joint as to give rise to the most severe forms of traumatic arthritis, but the bones are often fractured, and the main vessels of the limb perhaps greatly stretched or torn.

The *Treatment* of a compound dislocation must be conducted on the same principles that guide the Surgeon in the management of a wounded joint, viz., rest, drainage, and the prevention of decomposition. Owing to the rupture of the ligaments and muscular attachments, there is usually no difficulty in the reduction; but the danger consists in the destructive inflammation that so frequently follows in the joint. This, as was before pointed out, is due chiefly to the accumulation of decomposing discharges in the cavity: but in the case of a compound dislocation, it is aggravated by the severe bruising and laceration of the surrounding structures. Consequently extensive inflammation and suppuration with sloughing may follow the injury. In all cases it is better not to make any attempt to close the wound by suture, as this would only interfere with the drainage, and union by the first intention is practically impossible. Cleaning the wound and dressing it must be conducted on the principles laid down in the chapter on wounds of joints (p. 513). If the joint be a large one, the line of practice will vary according to circumstances other than the mere dislocation. Thus, if it be in the upper extremity, the patient being healthy, and the soft parts not very extensively contused or torn, the bones may be replaced, after the joint has been properly cleaned with carbolic acid lotion (1 in 20), or some other antiseptic solution, and may then be dressed by one of the antiseptic methods already described. Dry cold may be applied over the dressing if possible. The limb must be placed on a splint to ensure rest for about two weeks, after which, if all goes well, passive motion may be commenced with care. Should suppuration take place, passive motion would only ensure the destruction of the joint; the limb must then be firmly fixed on a splint in the hope of obtaining ankylosis. If there be fracture conjoined with the dislocation, resection should be practised, as was successfully done by Hey in several cases of injury of the elbow of this description; but if the soft parts be greatly injured as well, and especially if the blood vessels and nerves of the limb have suffered, amputation must be performed. In the lower extremity, amputation is more frequently necessary; in the knee, almost invariably so. Yet there are exceptions to this rule; thus, White had a case of compound dislocation of the knee-joint in a boy, nine years of age, at the Westminster Hospital, in which he saved the limb by sawing off the condyles of the femur and reducing the bone. In compound dislocations of the ankle and the astragalus, an attempt should generally be made to save the limb, in the way that will be more specially pointed out when we come to treat of these injuries.

After recovery from compound dislocation, the joint will often remain permanently stiffened; hence attention to position during the treatment is essential. In many cases, however, very good motion is ultimately obtained, though the stiffness may continue for some length of time.

COMPLICATIONS.—Fracture of the Shaft of one of the Long Bones with Dislocation of its Head considerably increases the difficulty of reduction. In these circumstances, it has been recommended to let the fracture consolidate first, and then to attempt the reduction. But to do this is only to defer and increase the difficulties. At least seven or eight weeks must elapse

before the fracture will be sufficiently firmly united to bear the traction requisite to reduce so old a dislocation; and then there will be a great chance of rupture of the callus, and certainly extreme difficulty in the reduction. It therefore appears to me much better, under all circumstances, to endeavour to reduce the dislocation at once, and afterwards to treat the fracture in the usual way. In reducing a dislocation complicated with fracture of the shaft of the displaced bone, the fracture must first be put up very firmly indeed, with wooden splints completely encasing the limb. The patient must then be put fully under the influence of an anæsthetic, which is essential in these cases: when the muscles are completely relaxed, the reduction may be effected in the usual way. If manipulation fails and extension becomes necessary, the extending means should be applied upon the splints, so that there may be no dragging upon the fracture. In this way I have reduced, without any difficulty, a dislocation of the head of the humerus into the axilla, complicated with comminuted fracture of the shaft of the bone, in a remarkably muscular man; and about the same time I had under my care at the Hospital a case of dislocated elbow, with fracture of the shaft of the humerus, that was reduced with ease in the same way. The difficulty in reduction is necessarily increased by the proximity of the fracture to the dislocated joint, and when the epiphysis is broken off from the shaft and dislocated, the difficulty may be great; but it is not insuperable. Some years since, I assisted H. Smith and Dunn in the reduction of a dislocation of the humerus with fracture of the surgical neck of the bone, the displaced head lying to the inner side of the coracoid process. In this case the patient, a young man who had sustained the injury by a fall in an epileptic fit, was put under chloroform, and when he was fully anæsthetized the displaced head of the bone was easily replaced: the patient recovering with an excellent arm.

When a **Simple Fracture extends into the Articular End of the Bone**, as in some dislocations about the elbow and ankle, there is no material increase in the danger of the case or in the difficulty of its management.

In **Compound Dislocation with Fracture of the Articular Ends**, removal of splinters, and partial resection or amputation will be required, according to the seat and extent of injury.

SPONTANEOUS DISLOCATIONS may occur either suddenly or gradually, and may arise from a variety of causes.

Spontaneous dislocation, if the term can properly be applied to such cases, is often met with as the result of disease of the articulation. In all *dactylitis inflammation of joints*, as in tuberculous disease or acute arthritis following a wound, the ligaments become softened, the cartilages are destroyed, and the bones entering into the articulation altered in shape by ulceration: in these circumstances the articular surfaces readily become displaced under the influence of slight muscular action. To this class Volkmann has given the name of *Dislocation from Destruction*. In chronic rheumatic arthritis, especially of the smaller joints, and in the joint affections met with in locomotor ataxy, it sometimes happens that the articular surfaces are gradually forced out of their normal relations by the pressure of osseous outgrowths, springing from the bones close to the margin of the cartilages. These are classed by Volkmann as *Dislocations from Deformity*. In another form, which was specially studied and described by Stanley, the affection is due to a paralytic condition of the muscles surrounding the capsule. In these

Paralytic Dislocations, which are most common in the hip and shoulder, the head of the bone slips out without any very marked sign of disease about the joint, and certainly without any previous destruction of it. In another class, to which Volkmann has given the name of *Dislocations from Distension*, the capsule is stretched and weakened by effusion of fluid within it. These are occasionally the result of acute suppuration within the joint, the capsule becoming softened and giving way at its weakest point, and the head of the bone escaping through the aperture. In these circumstances there would be high fever and intense pain, relieved when the capsule gives way. In other cases the fluid that distends the joint is serous in character; these may be acute, but are more commonly chronic. The ligaments then become gradually stretched till they are no longer capable of maintaining the articular surfaces in position. Thus Stanley records a case in which the capsule of the hip was found to be five inches in length, and Hutton another in which the round ligament measured four inches. In such extreme cases as these, the dislocation may take place without rupture of the capsule. The symptoms usually noted have been obscure rheumatic or neuralgic pains, lasting for some time, in the joint previous to dislocation. It may, however, occur suddenly, without any pain, the deformity of the limb first attracting attention. Such dislocations occasionally occur during an attack of acute rheumatism or one of the acute specific fevers. The condition is almost confined to the hip, but other joints may be affected, and sometimes more than one. Thus, some time ago there was a case in University College Hospital, in which both shoulders and hips were dislocated simultaneously.

Lastly, there is a variety known as *Recurrent Dislocations*, in which the joint, having been dislocated and reduced, the muscular and ligamentous structures have become so weakened that ever afterwards the bone slips out of place on the application of slight force, or at will on the patient throwing the muscles of the limb into action. These dislocations are most common in the shoulder. They may be due to incomplete repair of the capsule, or to fracture with displacement of the edge of the glenoid cavity in the shoulder, or acetabulum in the hip. Joessel has described a case in which after death the cause was found to be rupture of the supraspinatus and infraspinatus muscles, which had become retracted under the acromion without forming new adhesions to the head.

The **Treatment** of spontaneous dislocations is not very satisfactory. In many reduction cannot be accomplished; while in others it may be effected readily enough, but the bone cannot be fixed in the joint. In a case of spontaneous dislocation of the hip, without any apparent disease of the joint, occurring in a young woman, I readily effected reduction by the pulleys, three weeks after the occurrence of the displacement. The limb was then fixed with the long splint, and maintained at a proper length for two or three weeks; when, in consequence of a severe bronchitic attack, it became necessary to remove the apparatus, and the displacement speedily returned. Whilst convalescent from this attack, the patient fell and fractured the displaced femur in its upper third, thus rendering it impossible to replace the bone. In another case of spontaneous dislocation of the knee, occurring in the same painless manner, the joint could not be replaced, and permanent deformity was left. After reduction in similar cases, a splint or a starched bandage should be worn for a considerable length of time, so as to give the liga-

ments of the joint a chance of recovery. If there be a rheumatic tendency, it should be removed by suitable treatment; and if there be a paralytic condition of the muscles, electricity and cold douches with friction may advantageously be employed.

CONGENITAL DISLOCATIONS are occasionally met with in the hip, shoulder, wrist, and jaw, and have attracted the attention of Surgeons through the labours of Guérin, Smith, Chelius, Robert, and others. These dislocations are allied in cause and nature to other congenital deformities of the limbs, such as club-foot, &c. In them there is usually found arrested or imperfect development of some portions of the osseous articular apparatus. Whether this is primary, thus causing the displacement of the bones, or consecutive upon disuse, occasioned by spasmodic action of one set of muscles or by paralysis of another, dependent on some irritation in the nervous centres, is scarcely worth inquiring here. In some cases it would appear as if faulty position of the foetus in utero, or undue violence during birth, may have occasioned the displacement. These dislocations are probably incurable, as there is always congenital defect of structure in the articular ends of the bones, or of the socket into which they are received.

There is a peculiar form of dislocation which I have once, and only once, met with in a child, 12 years of age, otherwise perfectly healthy. It was a dislocation of the head of the radius backwards, in consequence of want of development of the lower third of the ulna. In this case the radius was nearly two inches longer than the ulna. The want of development in the latter bone prevented the proper growth of the forearm; and the radius consequently, after having become slightly curved, was slowly, but completely, dislocated at its humeral end. All the movements of the bone, however, were perfect.

CHAPTER XXIII.

SPECIAL DISLOCATIONS.

DISLOCATIONS OF THE LOWER JAW.

Dislocations of the Lower Jaw are not common accidents. They occur more frequently in women than in men, and have very seldom been met with at either extreme of life ; but Nélaton and Malgaigne relate cases occurring in edentulous subjects of 68 and 72 years of age, and Astley Cooper has seen the accident in a child, occasioned by another boy thrusting an apple into its mouth. These dislocations are most frequently occasioned by forcible action of the depressor muscles of the jaw—by opening the mouth too widely, as in laughing and gaping, or in attempting to take too large a bite. Occasionally the accident has resulted from blows or kicks upon the chin when the mouth was open, or from violent strain upon the part in tooth-drawing, or in removing stumps with an elevator. The mechanism of the dislocation is simple. When the mouth is opened, the interarticular fibro-cartilage with the condyle glides forwards on to the articular eminence ; if this movement be continued too far, and the external pterygoid muscle contract forcibly, the condyle slips forward over the articular eminence into the zygomatic fossa, the axis of the ramus being directed obliquely backwards, and the dislocation thus being complete. In this way both condyles may be displaced, or only one. Maisonneuve and Otto Weber, by producing dislocation on the dead body, found that the condyle lies in front of the root of the zygoma. The coronoid process rarely reaches the malar bone, but usually lies below it, being completely surrounded by the tendon of the temporal muscle. From original observation, Heath confirms this view of the position of the coronoid process. The interarticular fibro-cartilage is attached to the condyle, and follows its movements. The capsular ligament is stretched, but not ruptured ; the external lateral ligament is tense, and passes from behind forward instead of from before backward ; the internal lateral and stylo-maxillary ligaments also undergo stretching, which is increased by raising the chin. The temporal muscles are stretched, according to Maisonneuve, or partly torn, according to Weber.

When the dislocation is **Bilateral**, as most frequently happens, the signs are as follows : The incisor teeth of the lower jaw are separated from those of the upper by an interval varying from half an inch to an inch and a half. Deglutition and speech are impaired, the labial consonants not being pronounced ; there is dribbling of saliva over the lower lip ; the chin is lengthened, and the lower line of teeth advanced about half an inch beyond those of the upper jaw ; the cheeks are flattened, and there is a depression in front of the meatus auditorius externus. There is also an oblong prominence in the temporal fossa between the eye and the ear. If the dislocation be left

unreduced, the patient slowly regains some power of movement over the jaw : he gradually approximates the lips, and, after a time, may even be enabled to bring the lines of teeth into apposition, especially posteriorly.

In the **Unilateral** dislocation, the axis of the lower jaw is directed towards the side opposite to that on which the displacement exists : and the general signs are the same, but in a less marked degree, as those which are met with when both sides are dislocated. The hollow in front of the meatus on the injured side is, however, well marked, and serves to point out the seat and nature of the displacement, the diagnosis of which is not always readily made : indeed, R. W. Smith states that he has seen attempts at reduction applied to the uninjured side.

Astley Cooper described a **Subluxation** of the jaw, most frequently met with in young and delicate women, in which, in consequence of the relaxation of the ligaments, the head of the bone appears to slip forwards upon the eminentia articularis, whenever the mouth is opened at all widely, as in gasping, laughing, &c. It may usually be ascertained by telling the patient to put out the tongue. The bone hitches, as it were, and prevents the mouth from being shut at once. Most commonly, the natural efforts of the patient are sufficient to return the head of the bone into the glenoid cavity with a cracking noise or even a loud snap.

The **Reduction** of a dislocated jaw is easily effected : it being necessary

Fig. 243. Reduction of Dislocated Jaw

only to push the angle of the bone downwards and backwards, and at the same time to raise the chin ; by so doing the attachment of the temporal muscle to the coronoid process acts as a fulcrum, and the condyle is brought slightly downwards so as to be disengaged from the articular eminence, when the internal pterygoid and masseter muscles will at once draw it into its proper position. The reduction is best effected by the Surgeon, standing before the patient, placing his thumbs, well protected by a thick napkin, or a few turns of a narrow bandage, on the molar teeth on each side, and then depressing the angle of the jaw forcibly, at the same time that he raises the chin by means of his fingers spread out and placed underneath it (Fig. 243). The bone is then returned into its place with so forcible a snap that the thumbs may be severely bitten unless care be taken, or they be well protected. When one

is luxated, the efforts at reduction should be applied to the other only. After the reduction, the four-tailed bandage should be applied in cases of fracture of the jaw ; and for several days the patient

must not be allowed to talk, or to eat any solid food, lest the displacement return, which it always has a great tendency to do. Very old dislocations of this bone may be reduced by the process just described. Thus, Stromeyer replaced one after thirty-five, Donovan one after ninety-eight days, and Pollock after four months.

In the cases of *subluxation*, attention should be paid to the state of the general health. Tonics, more particularly iron, should be administered; and good diet, the cold bath, and open air exercise enjoined. If, as frequently happens, there be some tenderness about the temporo-maxillary articulation, a series of small blisters may be applied over it. It is of great importance to prevent the habit of recurrence of the dislocation. This may usually most conveniently be done by letting the patient wear a small silk cap fitted to the chin and attached by four elastic bands on the top of and behind the head, as in the case of a fractured jaw.

Congenital Dislocation of one Condyle of the Lower Jaw is a remarkable and rare condition, for a knowledge of which we are chiefly indebted to R. W. Smith. In this condition there is a singular distortion of countenance. The osseous and muscular structures on the dislocated side are atrophied, and the teeth of the upper jaw project beyond those of the lower, contrary to what occurs in the accidental dislocation; the mouth can be closed, speech is perfect, and there is no dribbling of saliva. Congenital dislocation of both condyles has not yet been observed.

DISLOCATIONS OF THE UPPER LIMB.

DISLOCATIONS OF THE CLAVICLE.—When we look at the flat character of the sterno-clavicular articulation and the very small and shallow surface on the acromion upon which the outer end of the clavicle is received, and reflect on the violence to which the shoulder is frequently subjected, we might at first imagine that dislocations of the clavicle would be among the most frequent forms of injury in this region. But this is very far from being the case. They are, indeed, rarely met with in comparison with fractures of this bone. This is owing to several causes: amongst these are the presence of the interarticular fibro-cartilage in the sterno-clavicular articulation, the shortness and firmness of the ligaments by which the clavicle is attached to the sternum and acromion, and the fact that any force applied to the bone is usually received in a line which corresponds to its axis, thus causing it to be bent or broken rather than luxated. The mobility of the scapula, also, has a special tendency to prevent dislocations of the outer end of the clavicle, the two bones easily moving together.

Dislocations of the clavicle can be occasioned only by violence applied to the shoulder in such a direction as to drive the bone inwards towards the mesial line. Either the sternal or the acromial end of the clavicle may be dislocated, and the simultaneous displacement of both ends has been observed.

1. The **Sternal End of the Clavicle** may be luxated *forwards, backwards, or upwards*.

In the dislocation **Forwards**, which is the most common form, the end of the bone can be felt in its new position, upon the upper part of the sternum and a little below the natural level. The point of the shoulder is approximated to the mesial line, and the depressions above and below the clavicle are strongly

The forearm is flexed and very slightly supinated. When the coronoid process is not broken off, it is fixed against the posterior surface of the humerus, the forearm being immovably placed in its new position. In the rare cases in which this process is fractured, there is great mobility about the joint, and crepitation may be felt as the arm is drawn forwards.

Dislocation of both bones **Forwards** without fracture of the olecranon is an extremely rare accident, but a few undoubted cases have been recorded. In this injury the elongation of the forearm, the projection of the condyles of the humerus, the presence of the sigmoid notch in front of the arm, and the depression of the posterior surface of this bone, render the diagnosis sufficiently easy. In one case at University College Hospital, the injury was produced by the patient, a man 20 years of age, slipping on the pavement and falling on his elbow. In this instance the elbow was much bent; it could be brought to a right angle, and straightened considerably. The forearm was three quarters of an inch longer than its fellow. The condyles of the humerus were on a level with the olecranon; the tendon of the triceps was very tight, whilst the sigmoid notch and the head of the radius could be plainly felt on the forepart of the arm. In the case recorded in the *Lancet*, 1872, by Date of Cwkerne, the dislocation was forwards and outwards, so that the head of the radius lay outside the external condyle. At the same time, the epiphysis at the inner condyle was separated. When the olecranon is broken off, there is elongation of the forearm with great mobility, but the detached fragment can be felt behind the humerus.

The **Lateral** dislocation of the bones of the forearm is almost invariably incomplete; either the head of the radius hitching against the trochlea, or the ulna coming into contact with the capitellum. Complete lateral dislocation of the bones of the forearm is excessively rare. Nélaton has given a woodcut of a complete luxation outwards.

The ulna or radius alone may be displaced; and in some cases both bones are dislocated, but in opposite directions.

2. **Ulna.**—The only dislocation to which the ulna alone is subject is that in a direction **Backwards**. This displacement may be uncomplicated, but is more frequently associated with more or less dislocation of the head of the radius. When it occurs, it may be recognized by the projection of the olecranon backwards, and by the head of the radius being felt in its normal situation, or nearly so, during the movements of pronation and supination. In some extremely rare cases the coronoid process is fractured at the same time, causing ready disappearance and recurrence of the dislocation, with crepitus.

3. **Radius.**—The radius alone may be dislocated *forwards, backwards, or outwards*. The dislocation **Forwards** is by far the most common. In the many instances of it I have seen, it has resulted from a fall on the palm of the hand, by which the lower end of the radius is driven backwards, whilst the upper end is tilted forwards with the whole force of the leverage of the bone, and in this way, rupturing the orbicular ligament, is thrown against the external condyle. The signs of this displacement are the following: The forearm is slightly flexed, and in a position midway between pronation and supination; any attempt at completing the latter movement occasions great pain, as does also the endeavour to straighten the arm. The elbow can be bent only to a right angle, in consequence of the head of the radius being

suddenly brought up against the lower end of the humerus, against which it strikes with a sudden shock (Figs. 257, 259). On rotating the radius great pain is experienced, and the head of the bone can be felt to roll on the fore part of the humerus, the external condyle of which appears to project unnaturally, with a distinct hollow beneath it where the head of the radius should be. The hand and arm can be fully pronated, but cannot be supinated more than half way. The whole of the outer side of the arm is deformed, being carried somewhat forwards (Fig. 258). The rupture of the orbicular ligament

Fig. 257.—Dislocation of the Radius forwards: Limit of Power of Bending the Arm

Fig. 258.—Dislocation of the Radius forwards: Deformity of the Outer Side of the Arm when extended.

Fig. 259.—Position of the Bones in an old Unreduced Dislocation of the Radius forwards.

in this dislocation makes it very difficult to fix the radius so as to prevent a recurrence of the displacement.

The dislocation of the radius **Backwards** is extremely rare; it may always be recognized by the head of the bone being felt subcutaneously, behind the external condyle; the movements of the elbow, and of the radius especially, being at the same time very limited and painful.

Dislocation of the radius **Outwards** is of more frequent occurrence than the last injury, the head of the bone being thrown on the outer side of the external condyle, where it is felt under the skin, rolling as the hand is moved. The natural motions of the joint are of course greatly interfered with.

Subluxation of the Head of the Radius.—This name has been given to an injury not uncommonly produced in children by the nurse or mother jerking the hand suddenly upwards in an attempt to save the child from falling. The limb is held motionless, with the elbow slightly flexed, and the

elevation of the limb. This mode of reduction was first described by Charles White, of Manchester, in 1770. The patient must be placed upon a low chair or couch, and the arm raised perpendicularly by the side of the head at the same time that gentle traction is made upon it. In many cases so little force is required that no counter-extension is required beyond the weight of the patient's body, or the Surgeon may extend the arm with one hand while he steadies the shoulder with the other placed on the acromion and the outer end of the clavicle. Should more force be necessary, an assistant may steady the shoulder, or the Surgeon may use his foot (Fig. 254). When the bone is felt to slip in, the arm must be brought down to the side, while the head of the bone is held outwards by the hand in the axilla. In this mode of reduction the untorn part of the capsule is relaxed to the greatest

Fig. 255. Reduction of a Dislocated Shoulder-joint by the Head in the Axilla

possible extent, as also is the deltoid, which is one of the most powerful of the muscles concerned in keeping up the displacement. This method is almost painless in most cases, and for this reason should always be tried before resorting to other means.

2. Reduction by the following *manipulation* has been recommended by Kocher in all cases of subcoracoid and subclavicular dislocation:—Seat the patient in a chair, and stand by his side; then flex his elbow to a right angle and press it inwards as far as possible towards the chest; then, holding the elbow in one hand, and using the forearm as a lever, rotate gently and steadily outwards till a distinct sense of resistance is felt; the elbow must now be brought forwards, or in other words the arm must be raised, with a slight inclination inwards, until it is nearly at right angles to the anterior plane of the body, the rotation outwards being maintained; finally, the hand is placed on the opposite shoulder, by which a movement of rotation inwards is impressed on the humerus. This method, which was the result of the examination of dislocations produced on the dead body, is so devised as to relax the tight bands of the capsule and to make the opening ripe. It has, in Kocher's hands, been very successful even with old dislocations: thus, he has success-

fully reduced one at three weeks, two at five weeks, three at seven weeks, four at three months, and two at four months. In one case, an old woman of 70, with an unreduced dislocation eight weeks old, fracture of the arm took place, and reduction became impossible.

3. The reduction of the dislocation *by the heel in the axilla* is a most efficient procedure in ordinary cases. In adopting this plan, the patient is laid on his back upon a low bed or couch, or on the ground; the Surgeon, seating himself on the same side as the dislocated arm, takes the limb by the wrist, and places one foot, covered merely with the stocking, well up into the axilla, so that the heel may press against the lower border of the scapula, and the foot act upon the humerus (Fig. 255).

He then draws the limb steadily downwards, and, when it is disengaged to a sufficient extent, brings the hand across the front of the patient, the foot acting as a fulcrum, by which the head of the bone may be reduced by being pushed upwards and outwards. This mode of reduction is very successful in ordinary dislocations into the axilla, and in those under the clavicle. In the latter, however, it will be necessary to draw the arm more obliquely downwards and backwards, and to press the foot somewhat forwards upon the head of the bone, after it has been disengaged by being brought below the coracoid process.

4. The reduction *by the knee in the axilla* (Fig. 256) is precisely the same in principle as the last, though not by any means so good a plan, the knee being too large, and not following the movements of the humerus so readily as the foot. In effecting the reduction by this means, the patient is seated on a chair; and the

Fig. 256.—Reduction of a Dislocation of the Humerus by the Knee in the Axilla.

Surgeon, standing by his side and resting one foot upon the chair, places his knee in the patient's axilla. He then seizes the patient's arm above the elbow with one hand, and, steadying the acromion with the other, draws the limb well away from the body and then depresses it across the knee: the head of the bone is thus reduced.

If these simpler methods fail, or if the dislocation be of old standing, it may be necessary to have recourse to the *pulleys* in order to effect reduction. In applying these the scapula must be firmly fixed, the counter-extension being made by passing the patient's arm through a slit in the middle of a jack-towel, which should be fixed firmly to a hook or staple in the wall. The extending force may then be applied immediately above the elbow; traction being made slowly and steadily in the direction of the axis of the limb. The head of the bone should be directed to the glenoid cavity by the pressure of the Surgeon's hands, as soon as it has come on a level with it. In this way dislocations of the humerus of many weeks' or even months' standing have

of the last edition of his work shows clearly that the head of the bone had formed a new articular cavity for itself in the subscapular fossa, being apparently thrown completely out of the glenoid cavity.

There are three specimens in the London museums, two at St. Bartholomew's and one at Guy's Hospital, in which complete dislocation inwards of the shoulder has occurred without rupture of the capsule.

There is here less deformity than in the other luxations, the acromion not forming so distinct a projection (Fig. 250). The alteration in length measured from the acromion to the olecranon is never great, and often none can be detected. It may be either in the direction of shortening or lengthen-

ing, but is not enough to be of any diagnostic value. The elbow is generally carried backwards and always slightly away from the side; the head of the bone is placed deeply in the upper and inner part of the axilla, and cannot always be very distinctly felt, owing to its being thickly covered with soft parts, by the coraco-brachialis as well as by the pectorals; rotation of the arm and elevation of the elbow are usually required in order that it may be detected. There may be pain from the pressure of the head of the bone on the nerves or from stretching, and if the vein be pressed on, oedema of the whole limb will occur.

2. In the dislocation **Forwards**, or the **Subclavicular** (Fig. 247), the head of the bone is thrown on the inner side of the coracoid process, lying upon the second and third ribs under the pectoral muscles, and immediately below the clavicle. This dislocation is merely an increased degree of the

preceding one, the head of the bone, which at first lies under the coracoid process, being readily drawn inwards, so as to be placed to the inner side of that process under the clavicle. In these cases the capsular muscles are much stretched or torn. In a case recorded by Curling, the infraspinatus and subscapularis muscles were torn away from the tuberosities of the humerus, and the teres minor partially lacerated; the capsule being completely separated from the neck of the bone, which pressed forcibly upon the axillary vessels and nerves. In three cases which I have had an opportunity of dissecting, the great tuberosity was torn away from the head of the bone, with much laceration of the capsule and extensive extravasation, but without rupture of the external rotator muscles in two instances; whilst in the third the supraspinatus, the infraspinatus, and the teres minor, were all torn across near their insertions. In fact, in these cases it appears to be a question of strength between muscle and bone; either the muscles are torn across, or the great tuberosity is torn away, leaving its attached muscles unruptured.

In this dislocation, the head of the humerus can be felt and seen under the pectoral muscles beneath the clavicle; the arm is shortened, the axis of the limb being directed towards the head of the bone, and the elbow is a good deal separated from the side and thrown back.

3. In the dislocation **Backwards**, or the **Subspinous** (Figs. 251, 252), the head of the humerus lies behind the glenoid cavity, and below the spine of the scapula, beneath the infraspinatus and teres minor muscles. Key found

Fig. 250. Subcoracoid Dislocation of Humerus.

the tendon of the subscapularis torn across, together with the internal portion of the capsular ligament; the supraspinatus and the long head of the biceps being stretched, but not ruptured.

When the head of the bone is dislocated below the spine of the scapula, it can be felt and seen there, more especially when the arm is rotated. The axis of the limb is altered, being directed upwards and backwards; the elbow is raised from the side, to which it cannot be approximated, and is carried forwards. There is little or no alteration in the length of the limb, but such as there is is said to be in the direction of lengthening. The accompanying figures, for which I am indebted to Rushton Parker, of Liverpool, show admirably the deformity in this dislocation.

4. In the dislocation **Downwards**, or the **Subglenoid** (Fig. 249), the head of the bone lies in the axilla, resting against the axillary border of the scapula

Fig. 251. — Dislocation of the right Humerus backwards. (Front View).

Fig. 252. — Dislocation of the right Humerus backwards. (Back View).

below the glenoid cavity, and lodged between the subscapular muscle and the long head of the triceps. The tendon of the subscapularis is commonly torn near its insertion into the lesser tuberosity of the humerus, and the capsular ligament is largely lacerated. The supraspinatus may also be torn through, or a portion of the great tuberosity of the humerus detached, and the rest of the capsular muscles put greatly on the stretch. The axillary artery and plexus of nerves are compressed and stretched by the dislocated head of the bone, so that severe pain is commonly experienced in the hand and arm, often accompanied by numbness of the fingers. The compression of the artery is so great that the circulation through the limb may be completely arrested. This I saw well illustrated in a case of subglenoid dislocation complicated with a wound of the forearm, dividing the radial and ulnar arteries. As long as the dislocation remained unreduced, no hæmorrhage took place; but when the head of the bone was replaced, the injured arteries bled freely.

The head of the bone can usually be readily felt in the axilla, at its anterior and under part; the arm is lengthened to the extent of about an inch, and the forearm is usually somewhat bent. The elbow is separated from the trunk

Fracture of the ribs, by the pressure exercised against the wall of the chest, is supposed to have occurred in some cases.

The *extravasation* of a large quantity of blood into the areolar tissue of the axilla has occasionally occurred, without any evidence of the rupture of one of the main vessels. In these cases the swelling has gradually subsided under ordinary treatment, by rest and evaporating lotions.

More serious by far than this is the *rupture of one of the large blood-vessels* in the axilla. This may happen from the pressure of the Surgeon's heel, as in a case recorded by Hamilton, in which the Surgeon unfortunately forgot to remove his boot : but more often it has occurred from the humerus having become adherent to the vessel, and lacerating it when torn away, as in Lister's case in which the artery was adherent to a fibrous band passing from the coracoid process to the dislocated head of the bone. The instances of laceration of the axillary artery, and subcutaneous arterial extravasation in the axilla, in the reduction of old dislocations, are so numerous—there being at least twenty on record—as to be a warning to the Surgeon not to employ too much force.

In the great majority of these cases, the arterial extravasation appeared immediately after the employment of forcible and long-continued extension. In four instances, the aneurismal tumour did not appear until after the lapse of some time. In Dupuytren's case a dislocation into the axilla of six weeks' standing was reduced in a woman 60 years of age. Two or three months after this, a tumour appeared in the armpit. This was mistaken for an abscess, and opened ; arterial bleeding ensued, and the patient died on the eighth day, from secondary hæmorrhage. In Nela-ton's case the patient, also an old woman, had a subglenoid dislocation which was easily reduced. But an aneurism appeared in the axilla, which, three months after the reduction, compelled that distinguished Surgeon to tie the subclavian. Both these aneurisms were probably circumscribed.

Dupuytren's case was not the only one in which the fatal mistake was committed of opening the aneurism in the axilla ; the same thing was done by Pelletan, who mistook the tumour for an "emphysema" ; the result being of necessity fatal. In cases reported by Verduc, Petit, Platner, and Leudet, the aneurism was allowed to run its course unchecked by efficient surgical treatment, and in every instance proved fatal by the sac giving way, and secondary hæmorrhage ensuing. Charles Bell records a case that occurred at the Newcastle Infirmary, in which the pectoral muscles as well as the artery were torn, and immediate amputation became necessary. In six cases at least the subclavian artery has been ligatured, twice by Gibson, and once by Blackman, Warren, Panas, and Gunther, respectively. Four of them proved fatal by secondary hæmorrhage, and one from suppuration, Warren's being the only case in which recovery took place.

What *Treatment* should be adopted for this distressing accident ? If the aneurism be left to itself, or be treated by inefficient means, it must necessarily prove fatal by its rupture or by sloughing and secondary hæmorrhage. The ligature of the subclavian is not very promising, as a fatal result occurred in five out of the six cases in which it has been tried for diffused aneurism, Nela-ton's case having probably been circumscribed. In these circumstances, it seems to me that it would be wiser to apply to these cases the usual principle of treatment that is adopted in cases of diffused axillary aneurism from other

bases: viz., to compress the subclavian, lay open the sac, turn out coagula, and tie the torn artery at the seat of injury.

In one case, the dislocation being of twenty days' standing and the patient (woman 26 years old, Froberg states that reduction was followed by sudden and extensive tumefaction of the axilla, syncope, and death in an hour and a half. A *post-mortem* examination disclosed *laceration of the axillary vein*. No mention is made of any internal injury to account for death. Rupture of the vein has occurred in at least two other cases.

Injury to the *axillary nerves* during reduction, leading to paralysis of the arm, has also been described. A case of this kind is mentioned by Billroth as having occurred in a patient under his care at Zurich. The dislocation was of nine months' standing, and had been attended with partial paralysis of the arm and some muscular atrophy. The reduction was followed by total paralysis, which Billroth attributes to laceration of the axillary nerves in consequence of their having become adherent to the bone. In the case recorded by Flaubert four of the nerves were torn from their attachments to the cord.

Besides these accidents, other evil consequences have occasionally followed prolonged attempts at reducing old dislocations of the humerus, such as sudden death from *syncope*, and *exhaustion*. Guérin's remarkable case of *emulsion of the limb* at the elbow has been already mentioned (see p. 652).

In the event of the Surgeon being unsuccessful in his attempts at reduction, he must endeavour, by means of frictions and passive motion, to restore, as far as practicable, the utility of the limb. forcible attempts to break down adhesions should, however, be avoided lest the axillary vessels be lacerated.

In cases of old standing, in which symptoms of pressure on the large vessels and nerves are present, Billroth recommends excision of the head of the bone. This has been done successfully by Langenbeck, MacCormac and Sheild, in cases of paralysis from pressure.

DISLOCATIONS OF THE ELBOW are very common. According to Krönlein they form 27 per cent. of all dislocations. They occur with special frequency in children: thus, out of 94 cases of dislocation of both bones backwards collected by Krönlein, 22 occurred in children under 10 years of age, and 44 between the ages of 10 and 20. Dislocations of the elbow are most commonly caused by indirect violence, chiefly falls on the hand complicated by a twist of the joint. In other cases they may be the result of direct violence, in consequence of which much swelling speedily sets in, the signs are obscured, and the diagnosis is rendered proportionately difficult: more especially when a dislocation happens to be complicated with fracture of the articular ends of the bones. In these cases, indeed, it is only by an accurate acquaintance with the normal relations of the osseous points, and by a comparison between those of opposite sides, that the Surgeon can detect the true nature of the injury.

The **Varieties** of dislocation of the elbow-joint are very numerous, either both bones of the forearm or only one being displaced.

1. **Both Bones.**—The most common dislocation is that in which both bones are thrown *Backwards*, without fracture of the coronoid process. In these cases, however, this process may be broken off. This injury is readily recognized by the projection backwards of the olecranon, carrying with it the tendon of the triceps, on each side of which there is a distinct hollow. The humeral end of the humerus can also be felt projecting in front of the elbow.

The forearm is flexed and very slightly supinated. When the coronoid process is not broken off, it is fixed against the posterior surface of the humerus, the forearm being immovably placed in its new position. In the rare cases in which this process is fractured, there is great mobility about the joint, and crepitation may be felt as the arm is drawn forwards.

Dislocation of both bones **Forwards** without fracture of the olecranon is an extremely rare accident, but a few undoubted cases have been recorded. In this injury the elongation of the forearm, the projection of the condyles of the humerus, the presence of the sigmoid notch in front of the arm, and the depression of the posterior surface of this bone, render the diagnosis sufficiently easy. In one case at University College Hospital, the injury was produced by the patient, a man 20 years of age, slipping on the pavement and falling on his elbow. In this instance the elbow was much bent; it could be brought to a right angle, and straightened considerably. The forearm was three quarters of an inch longer than its fellow. The condyles of the humerus were on a level with the olecranon; the tendon of the triceps was very tight, while the sigmoid notch and the head of the radius could be plainly felt on the front part of the arm. In the case recorded in the *Lancet*, 1872, by Date of Crookern, the dislocation was forwards and outwards, so that the head of the radius lay outside the external condyle. At the same time, the epiphysis at the inner condyle was separated. When the olecranon is broken off, there is elongation of the forearm with great mobility, but the detached fragment can be felt behind the humerus.

The **Lateral** dislocation of the bones of the forearm is almost invariably incomplete; either the head of the radius hitching against the trochlea, or the ulna coming into contact with the capitellum. Complete lateral dislocation of the bones of the forearm is excessively rare. Nélaton has given a woodcut of a complete luxation outwards.

The ulna or radius alone may be displaced; and in some cases both bones are dislocated, but in opposite directions.

2. **Ulna.**—The only dislocation to which the ulna alone is subject is that in a direction **Backwards**. This displacement may be uncomplicated, but is more frequently associated with more or less dislocation of the head of the radius. When it occurs, it may be recognized by the projection of the olecranon backwards, and by the head of the radius being felt in its normal situation, or nearly so, during the movements of pronation and supination. In some extremely rare cases the coronoid process is fractured at the same time, causing ready disappearance and recurrence of the dislocation, with crepitus.

3. **Radius.**—The radius alone may be dislocated *forwards, backwards, or outwards*. The dislocation **Forwards** is by far the most common. In the many instances of it I have seen, it has resulted from a fall on the palm of the hand, by which the lower end of the radius is driven backwards, while the upper end is tilted forwards with the whole force of the leverage of the bone, and in this way, rupturing the orbicular ligament, is thrown against the external condyle. The signs of this displacement are the following: The forearm is slightly flexed, and in a position midway between pronation and supination; any attempt at completing the latter movement occasions great pain, as does also the endeavour to straighten the arm. The elbow can be bent only to a right angle, in consequence of the head of the radius being

suddenly brought up against the lower end of the humerus, against which it strikes with a sudden shock (Figs. 257, 259). On rotating the radius great pain is experienced, and the head of the bone can be felt to roll on the fore part of the humerus, the external condyle of which appears to project unnaturally, with a distinct hollow beneath it where the head of the radius should be. The hand and arm can be fully pronated, but cannot be supinated more than half way. The whole of the outer side of the arm is deformed, being carried somewhat forwards (Fig. 258). The rupture of the orbicular ligament

Fig. 257. — Dislocation of the Radius forwards. Limit of Power of Bending the Arm

Fig. 258. — Dislocation of the Radius forwards: Deformity of the Outer Side of the Arm when extended.

Fig. 259. — Position of the Bones in an old Unreduced Dislocation of the Radius forwards.

in this dislocation makes it very difficult to fix the radius so as to prevent a recurrence of the displacement.

The dislocation of the radius **Backwards** is extremely rare: it may always be recognized by the head of the bone being felt subcutaneously, behind the external condyle; the movements of the elbow, and of the radius especially, being at the same time very limited and painful.

Dislocation of the radius **Outwards** is of more frequent occurrence than the last injury, the head of the bone being thrown on the outer side of the external condyle, where it is felt under the skin, rolling as the hand is moved. The natural motions of the joint are of course greatly interfered with.

Subluxation of the Head of the Radius.—This name has been given to an injury not uncommonly produced in children by the nurse or mother jerking the hand suddenly upwards in an attempt to save the child from falling. The limb is held motionless, with the elbow slightly flexed, and the

elevation of the limb. This mode of reduction was first described by Charles White, of Manchester, in 1770. The patient must be placed upon a low chair or couch, and the arm raised perpendicularly by the side of the head at the same time that gentle traction is made upon it. In many cases so little force is required that no counter-extension is required beyond the weight of the patient's body, or the Surgeon may extend the arm with one hand while he steadies the shoulder with the other placed on the acromion and the outer end of the clavicle. Should more force be necessary, an assistant may steady the shoulder, or the Surgeon may use his foot (Fig. 254). When the bone is felt to slip in, the arm must be brought down to the side, while the head of the bone is held outwards by the hand in the axilla. In this mode of reduction the untorn part of the capsule is relaxed to the greatest

Fig. 254. Reduction of a Dislocated Shoulder-joint by the Head in the Axilla.

possible extent, as also is the deltoid, which is one of the most powerful of the muscles concerned in keeping up the displacement. This method is almost painless in most cases, and for this reason should always be tried before resorting to other means.

2. Reduction by the following *manipulation* has been recommended by Kocher in all cases of subcoracoid and subclavicular dislocation:—Seat the patient in a chair, and stand by his side; then flex his elbow to a right angle and press it inwards as far as possible towards the chest; then, holding the elbow in one hand, and using the forearm as a lever, rotate gently and steadily outwards till a distinct sense of resistance is felt; the elbow must now be brought forwards, or in other words the arm must be raised, with a slight inclination inwards, until it is nearly at right angles to the anterior plane of the body, the rotation outwards being maintained; finally, the hand is placed on the opposite shoulder, by which a movement of rotation inward is impressed on the humerus. This method, which was the result of the examination of dislocations produced on the dead body, is so devised as to relax the tight bands of the capsule and to make the opening gape. It has, in Kocher's hands, been very successful even with old dislocations: thus, he has success-

ly reduced one at three weeks, two at five weeks, three at seven weeks, four at three months, and two at four months. In one case, an old woman of 70, with an unreduced dislocation eight weeks old, fracture of the arm took place, and reduction became impossible.

3. The reduction of the dislocation *by the heel in the axilla* is a most efficient procedure in ordinary cases. In adopting this plan, the patient is laid on his back upon a low bed or couch, or on the ground; the Surgeon, sitting himself on the same side as the dislocated arm, takes the limb by the wrist, and places one foot, covered merely with the stocking, well up into the axilla, so that the heel may press against the lower border of the scapula, and the foot act upon the humerus (Fig. 255). He then draws the limb steadily downwards, and, when it is disengaged to a sufficient extent, brings the hand across the front of the patient, the foot acting as a fulcrum, by which the head of the bone may be reduced by being pushed upwards and outwards. This mode of reduction is very successful in ordinary dislocations into the axilla, and in those under the clavicle. In the latter, however, it will be necessary to draw the arm more obliquely downwards and backwards, and to press the foot somewhat forwards upon the head of the bone, after it has been disengaged by being brought below the coracoid process.

4. The reduction *by the knee in the axilla* (Fig. 256) is precisely the same in principle as the last, though not by any means so good a plan, the knee being too large, and not following the movements of the humerus so readily as the foot. In effecting the reduction by this means, the patient is seated on a chair; and the Surgeon, standing by his side and resting one foot upon the chair, places his knee in the patient's axilla. He then seizes the patient's arm above the elbow with one hand, and, steadying the acromion with the other, draws the limb well away from the body and then depresses it across the knee; the head of the bone is thus reduced.

If these simpler methods fail, or if the dislocation be of old standing, it may be necessary to have recourse to the *pulleys* in order to effect reduction. In applying these the scapula must be firmly fixed, the counter-extension being made by passing the patient's arm through a slit in the middle of a jack-towel, which should be fixed firmly to a hook or staple in the wall. The extending force may then be applied immediately above the elbow; traction being made slowly and steadily in the direction of the axis of the limb. The head of the bone should be directed to the glenoid cavity by the pressure of the Surgeon's hands, as soon as it has come on a level with it. In this way dislocations of the humerus of many weeks' or even months' standing have

Fig. 256.—Reduction of a Dislocation of the Humerus by the Knee in the Axilla.

been successfully reduced : but in employing these powerful means, especially under the influence of chloroform, the Surgeon should always bear in mind that, unless care be taken, serious mischief, even laceration of the axillary artery, may result (pp. 651, 652).

After a dislocation of the humerus has been reduced, the limb should be firmly fixed to the side for two weeks. It may then be put in a sling for another fortnight ; and, at the end of a month, passive motion, with friction, may be employed. If inflammation occur about the joint, recourse may be had to leeches and evaporating lotions.

After reduction, there is sometimes a tendency for the head of the bone to be drawn upwards and outwards under and against the acromion, owing, evidently to the deltoid and coraco-brachialis muscles not being counter-balanced in their actions by those that have been separated from the head of the bone.

Compound Dislocation of the Head of the Humerus is a rare accident. I have, however, seen two cases of it, and in two directions : downwards—*Subglenoid*, and inwards—*Subcoracoid*. In both cases reduction was effected, and the patients did well. In such a case, even though the injury be extensive, it is better not to amputate if the axillary vessels and nerves be uninjured. The limb may be saved by reducing the bone at once ; and the wound should be treated according to the rules laid down in the chapter on wounds of joints. If the axillary artery be ruptured, either completely or through its inner and middle coats, obstruction to the arterial circulation of the arm will ensue, and amputation must be performed through the articulation.

Complications.—A *Simple Dislocation of the Head of the Humerus, with Rupture of the Axillary Artery* and the formation of a diffused axillary aneurism, is fortunately rare. The treatment will be discussed when treating of rupture of the artery during attempted reduction of an old dislocation.

A very serious accident, and one apparently difficult to treat, consists in the complication of a *Dislocation of the Humerus with Fracture through the Surgical Neck* of the displaced bone. A case of this kind, to which I was called, is described at page 654.

When the dislocation is complicated with a *Fracture of the Shaft of the Bone*, it should be reduced at once by putting the fracture up very firmly, and then attempting the reduction by one of the usual methods. In the cases in which I have already referred (p. 654), I succeeded without difficulty by means of the heel in the axilla.

Congenital Dislocations of the Shoulder-joint have attracted much attention. R. W. Smith has ascertained, by *post-mortem* examination, the existence of two varieties of this condition—the *Subcoracoid* and *Subacromial*. In these there is wasting of the muscles of the shoulder and arm, the motions of which are extremely limited, whilst those of the scapula are preternaturally great. The condition of the bones is also remarkable. In a case of *congenital subacromial luxation* of both shoulders there was no trace of a glenoid cavity : but a well-formed socket existed on the outer side of the neck of the scapula, receiving the head of the humerus, which was small and distorted. These dislocations, though existing from birth, usually become more marked as age advances, and are necessarily irremediable, in consequence of the malformation of the bones and the wasting of the muscles.

Old Unreduced Dislocations of the Head of the Humerus are not unfrequently met with. In the majority of these cases there is a considerable amount of pain and immobility about the shoulder at first; but after a time the head of the humerus forms a new bed for itself, and the movements of the arm become freer and less painful, so that eventually a limb, useful for all except the overhead movements, results.

In cases of old dislocation of the head of the humerus, the question as to the advisability of attempting reduction always presents itself to the Surgeon. As a general rule this should always be cautiously attempted under chloroform, in accordance with the principles laid down at p. 650, if only a few weeks have elapsed from the time of the accident, and then it will usually be attended with success. Reduction has been effected in many cases at much later periods than this: by Brodhurst, after twenty-five weeks had elapsed; by Smith (U.S.), after six, seven, eight, nine, and ten months; by Malgaigne, after eight months; by Caron du Pillard, after six months; and by Sédillot, after a year. By the use of the subcutaneous division of muscles, &c., Dieffenbach is said to have succeeded in reducing a dislocation of the shoulder after it had existed two years. In many cases, however, at a much earlier period than these, the Surgeon will fail, notwithstanding the most persevering attempts at reduction.

Of the few cases in which operation has been undertaken for the relief of unreduced dislocations of the shoulder, the most successful are two recorded by Lister, in both of which the dislocation was bilateral. The first case was of more than nine weeks' standing. An incision was made from the coracoid process along the interval between the pectoralis major and deltoid; the tendon of the subscapularis was divided and the soft parts were freely separated from the head and inner part of the neck of the bone with a periosteum elevator; reduction was accomplished by manipulation and the use of pulleys, fibrous bands being divided as they were put on the stretch. The result in both shoulders was excellent. In the second case, a similar operation was performed on one side, whilst on the other side reduction was effected by removing with a chisel the articular portion of the dislocated head of the humerus. With strict antiseptic precautions the Surgeon should not hesitate to adopt this method rather than incur the risk of lacerating the axillary artery, which may be firmly adherent to the head of the bone, by forcible attempts at reduction.

The *Accidents* that have occurred in attempts at reducing old-standing dislocations of the head of the humerus are such as may arise either from the employment of an undue amount of force, from the separation of the head of the humerus from the adhesions which it has contracted in its new situation, or from pathological changes in the limb itself. Among the first are laceration and bruising of the skin, subcutaneous areolar tissue, and muscles, with extravasation of blood; amongst the latter are fracture of the humerus, laceration of the axillary vessels and nerves, and avulsion of the limb.

Fracture of the humerus has occurred in the practice of many Surgeons of eminence. The surgical neck of the bone appears usually to have given way; and the accident has not occurred so much from forcible extension, as in carrying the arm across the chest so as to tilt the head of the bone into its place, when the shaft becomes exposed to fracture by pressure in a transverse direction. Such an accident necessarily prevents all further attempts at reduction.

Fracture of the ribs, by the pressure exercised against the wall of the chest, is supposed to have occurred in some cases.

The *extravasation* of a large quantity of blood into the areolar tissue of the axilla has occasionally occurred, without any evidence of the rupture of one of the main vessels. In these cases the swelling has gradually subsided under ordinary treatment, by rest and evaporating lotions.

More serious by far than this is the *rupture of one of the large blood-vessels* in the axilla. This may happen from the pressure of the Surgeon's heel, as in a case recorded by Hamilton, in which the Surgeon unfortunately forgot to remove his boot; but more often it has occurred from the humerus having become adherent to the vessel, and lacerating it when torn away, as in Lister's case in which the artery was adherent to a fibrous band passing from the coracoid process to the dislocated head of the bone. The instances of laceration of the axillary artery, and subcutaneous arterial extravasation in the axilla, in the reduction of old dislocations, are so numerous—there being at least twenty on record—as to be a warning to the Surgeon not to employ too much force.

In the great majority of these cases, the arterial extravasation appeared immediately after the employment of forcible and long-continued extension. In four instances, the aneurismal tumour did not appear until after the lapse of some time. In Dupuytren's case a dislocation into the axilla of six weeks' standing was reduced in a woman 60 years of age. Two or three months after this, a tumour appeared in the armpit. This was mistaken for an abscess, and opened; arterial bleeding ensued, and the patient died on the eighth day, from secondary hæmorrhage. In Nélaton's case the patient, also an old woman, had a subglenoid dislocation which was easily reduced. But an aneurism appeared in the axilla, which, three months after the reduction, compelled that distinguished Surgeon to tie the subclavian. Both these aneurisms were probably circumscribed.

Dupuytren's case was not the only one in which the fatal mistake was committed of opening the aneurism in the axilla; the same thing was done by Pelletan, who mistook the tumour for an "emphysema"; the result being of necessity fatal. In cases reported by Verduc, Petit, Platner, and Lendet, the aneurism was allowed to run its course unchecked by efficient surgical treatment, and in every instance proved fatal by the sac giving way, and secondary hæmorrhage ensuing. Charles Bell records a case that occurred at the Newcastle Infirmary, in which the pectoral muscles as well as the artery were torn, and immediate amputation became necessary. In six cases at least the subclavian artery has been ligatured, twice by Gibson, and once by Blackman, Warren, Panas, and Gunther, respectively. Four of them proved fatal by secondary hæmorrhage, and one from suppuration, Warren's being the only case in which recovery took place.

What *Treatment* should be adopted for this distressing accident? If the aneurism be left to itself, or be treated by inefficient means, it must necessarily prove fatal by its rupture or by sloughing and secondary hæmorrhage. The ligature of the subclavian is not very promising, as a fatal result occurred in five out of the six cases in which it has been tried for diffused aneurism, Nélaton's case having probably been circumscribed. In these circumstances, it appears to me that it would be wiser to apply to these cases the usual principle of treatment that is adopted in cases of diffused axillary aneurism from other

causes; viz., to compress the subclavian, lay open the sac, turn out coagula, and tie the torn artery at the seat of injury.

In one case, the dislocation being of twenty days' standing and the patient a woman 26 years old, Froriep states that reduction was followed by sudden and extensive tumefaction of the axilla, syncope, and death in an hour and a half. A *post-mortem* examination disclosed *laceration of the axillary vein*. No mention is made of any internal injury to account for death. Rupture of the vein has occurred in at least two other cases.

Injury to the *axillary nerves* during reduction, leading to paralysis of the arm, has also been described. A case of this kind is mentioned by Billroth as having occurred in a patient under his care at Zürich. The dislocation was of nine months' standing, and had been attended with partial paralysis of the arm and some muscular atrophy. The reduction was followed by total paralysis, which Billroth attributes to laceration of the axillary nerves in consequence of their having become adherent to the bone. In the case recorded by Flaubert four of the nerves were torn from their attachments to the cord.

Besides these accidents, other evil consequences have occasionally followed prolonged attempts at reducing old dislocations of the humerus, such as sudden death from *syncope*, and *exhaustion*. Guérin's remarkable case of *paralysis of the limb* at the elbow has been already mentioned (see p. 652).

In the event of the Surgeon being unsuccessful in his attempts at reduction, he must endeavour, by means of frictions and passive motion, to restore, as far as practicable, the utility of the limb. Forceful attempts to break down adhesion should, however, be avoided lest the axillary vessels be lacerated.

In cases of old standing, in which symptoms of pressure on the large vessels and nerves are present, Billroth recommends excision of the head of the bone. This has been done successfully by Langenbeck, MacCormac and Sheild, in cases of paralysis from pressure.

DISLOCATIONS OF THE ELBOW are very common. According to Krönlein they form 27 per cent. of all dislocations. They occur with special frequency in children: thus, out of 94 cases of dislocation of both bones backwards collected by Krönlein, 22 occurred in children under 10 years of age, and 44 between the ages of 10 and 20. Dislocations of the elbow are most commonly caused by indirect violence, chiefly falls on the hand complicated by a twist of the joint. In other cases they may be the result of direct violence, in consequence of which much swelling speedily sets in, the signs are obscured, and the diagnosis is rendered proportionately difficult: more especially when the dislocation happens to be complicated with fracture of the articular ends of the bones. In these cases, indeed, it is only by an accurate acquaintance with the normal relations of the osseous points, and by a comparison between those of opposite sides, that the Surgeon can detect the true nature of the injury.

The **Varieties** of dislocation of the elbow-joint are very numerous, either both bones of the forearm or only one being displaced.

1. **Both Bones.**—The most common dislocation is that in which both bones are thrown *Backwards*, without fracture of the coronoid process. In rare cases, however, this process may be broken off. This injury is readily recognized by the projection backwards of the olecranon, carrying with it the tendon of the triceps, on each side of which there is a distinct hollow. The articular end of the humerus can also be felt projecting in front of the elbow.

The forearm is flexed and very slightly supinated. When the coronoid process is not broken off, it is fixed against the posterior surface of the humerus, the forearm being immovably placed in its new position. In the rare cases in which this process is fractured, there is great mobility about the joint, and crepitation may be felt as the arm is drawn forwards.

Dislocation of both bones **Forwards** without fracture of the olecranon is an extremely rare accident, but a few undoubted cases have been recorded. In this injury the elongation of the forearm, the projection of the condyles of the humerus, the presence of the sigmoid notch in front of the arm, and the depression of the posterior surface of this bone, render the diagnosis sufficiently easy. In one case at University College Hospital, the injury was produced by the patient, a man 20 years of age, slipping on the pavement and falling on his elbow. In this instance the elbow was much bent; it could be brought to a right angle, and straightened considerably. The forearm was three quarters of an inch longer than its fellow. The condyles of the humerus were on a level with the olecranon: the tendon of the triceps was very tight, while the sigmoid notch and the head of the radius could be plainly felt on the front part of the arm. In the case recorded in the *Lancet*, 1872, by Date of Cresskerne, the dislocation was forwards and outwards, so that the head of the radius lay outside the external condyle. At the same time, the epiphysis at the inner condyle was separated. When the olecranon is broken off, there is elongation of the forearm with great mobility, but the detached fragment can be felt behind the humerus.

The **Lateral** dislocation of the bones of the forearm is almost invariably incomplete; either the head of the radius hitching against the trochlea, or the ulna coming into contact with the capitellum. Complete lateral dislocation of the bones of the forearm is excessively rare. Nélaton has given a woodcut of a complete luxation outwards.

The ulna or radius alone may be displaced; and in some cases both bones are dislocated, but in opposite directions.

2. **Ulna.**—The only dislocation to which the ulna alone is subject is that in a direction **Backwards**. This displacement may be uncomplicated, but is more frequently associated with more or less dislocation of the head of the radius. When it occurs, it may be recognized by the projection of the olecranon backwards, and by the head of the radius being felt in its normal situation, or nearly so, during the movements of pronation and supination. In some extremely rare cases the coronoid process is fractured at the same time, causing ready disappearance and recurrence of the dislocation, with crepitus.

3. **Radius.**—The radius alone may be dislocated *forwards, backwards, or outwards*. The dislocation **Forwards** is by far the most common. In the many instances of it I have seen, it has resulted from a fall on the palm of the hand, by which the lower end of the radius is driven backwards, while the upper end is tilted forwards with the whole force of the leverage of the bone, and in this way, rupturing the orbicular ligament, is thrown against the external condyle. The signs of this displacement are the following:—The forearm is slightly flexed, and in a position midway between pronation and supination; any attempt at completing the latter movement occasions great pain, as does also the endeavour to straighten the arm. The elbow can be bent only to a right angle, in consequence of the head of the radius being

suddenly brought up against the lower end of the humerus, against which it strikes with a sudden shock (Figs. 257, 259). On rotating the radius great pain is experienced, and the head of the bone can be felt to roll on the fore part of the humerus, the external condyle of which appears to project unnaturally, with a distinct hollow beneath it where the head of the radius should be. The hand and arm can be fully pronated, but cannot be supinated more than half way. The whole of the outer side of the arm is deformed, being carried somewhat forwards (Fig. 258). The rupture of the orbicular ligament

Fig. 257.—Dislocation of the Radius forwards. Limit of Power of Bending the Arm

Fig. 258.—Dislocation of the Radius forwards: Deformity of the Outer Side of the Arm when extended

Fig. 259.—Position of the Bones in an old Unreduced Dislocation of the Radius forwards.

in this dislocation makes it very difficult to fix the radius so as to prevent a recurrence of the displacement.

The dislocation of the radius **Backwards** is extremely rare: it may always be recognized by the head of the bone being felt subcutaneously, behind the external condyle; the movements of the elbow, and of the radius especially, being at the same time very limited and painful.

Dislocation of the radius **Outwards** is of more frequent occurrence than the last injury, the head of the bone being thrown on the outer side of the external condyle, where it is felt under the skin, rolling as the hand is moved. The natural motions of the joint are of course greatly interfered with.

Subluxation of the Head of the Radius.—This name has been given to an injury not uncommonly produced in children by the nurse or mother jerking the hand suddenly upwards in an attempt to save the child from falling. The limb is held motionless, with the elbow slightly flexed, and the

hand in a position midway between pronation and supination. On examination no displacement of the bony points at the elbow can be detected: complete flexion of the elbow is impossible and supination is arrested at the mid-position. Of the many explanations of these symptoms which have been suggested two may be especially mentioned. Some Surgeons have supposed that an incomplete dislocation of the head of the radius forwards occurs, whilst others believe that the radius is drawn away from the capitellum by the sudden extension applied to the forearm and that the return of the bone is prevented by a folding in of the orbicular ligament. The *Treatment* consists in flexing the elbow and strongly supinating the hand, when a click is felt over the head of the radius and the movements of the limb are restored. The elbow should then be fixed for three or four days.

Congenital Dislocation of the Radius is occasionally met with, the head of the bone being displaced in either of the three directions mentioned above. F. C. Abbott has recorded a remarkable series of seven cases of congenital dislocation forwards, occurring in four generations of one family.

The **Radius** and **Ulna** are sometimes displaced in **Opposite Directions**, the ulna being thrown *backwards*, and the radius *forwards*. This injury, of which I have seen two instances, usually results from heavy falls upon the hand, with a wrench of the limb at the same time, as when a person is thrown out of a carriage and alights upon his hands. The deformity is of course great, but is readily recognized by the combination of the characters of the two forms of displacement, provided an examination be made before the swelling, which rapidly sets in, has come on.

Complications.—Dislocations of the elbow-joint are very frequently complicated with fracture of one or other condyle of the humerus, of the olecranon, and—more rarely, as we have already seen in the displacement of the ulna—of the coronoid process. In these complicated injuries an exact diagnosis is often extremely difficult, owing to the laxity and mobility of the parts, and to the great tumefaction that accompanies accidents of this description.

Diagnosis.—For the diagnosis of these various injuries a good knowledge of the relative bearings of the different osseous points is essential, but an accurate comparison of the injured with the sound limb is equally important. To do this the Surgeon should stand in front of the patient, whose arm should be placed in exactly the same position on each side. The Surgeon then grasps the right elbow with his left hand, and the left with his right, in such a way that his forefinger on each side is on the point of the olecranon, his thumb on the outer condyle, and his middle finger on the inner condyle. The relative position of these three points is thus easily ascertained. If they bear their normal relation to one another the case is not one of dislocation of both bones in any direction, but it may in a young subject be a separation of the lower epiphysis of the humerus (see p. 522). The thumb on each side must then be gradually moved down the ridge formed by the outer condyle, and if the radius is displaced a hollow will be felt immediately beneath it, contrasting clearly with the prominence on the uninjured side. An assistant should then pronate and supinate the hands, by which the head of the radius will easily be recognized in whatever position it may be. Many errors in diagnosis of these injuries arise from not carefully comparing the two sides in this way. It not unfrequently happens, however, that the swelling so obscures the bony points that within a few hours of the injury diagnosis is impossible.

The mode of **Reduction** in dislocations of the elbow-joint varies according as the ulna is displaced or not. When the ulna is dislocated, in whatever direction it may be thrown, and whether the radius be displaced at the same time or not, the great obstacle to reduction is the hitching of the processes of the bone against the articular end of the humerus. If either the olecranon or the coronoid process be fractured, this entanglement cannot take place, and the joint then readily slips into its position, though it is very difficult to maintain it there. The reduction of the displaced ulna, when uncomplicated by fracture, may be effected, as Astley Cooper recommended, by bending the arm over the knee. The patient being seated on a chair, the Surgeon rests one foot upon the seat, and, placing the knee in the bend of the injured elbow, grasps the forearm with both hands (Fig. 260); fixing the arm, he presses the knee firmly against the inner aspect of the forearm, so as to disengage the ulna from the lower end of the humerus, and at the same time he bends or pushes the forearm into proper position, into which, indeed, it has a tendency to return owing to the action of its own muscles, as soon as the opposing osseous surfaces are separated.

In a case of backward dislocation of both bones, under the care of W. G. Spencer, of the Westminster Hospital, the protrusion of the end of the humerus through a rent in the anterior ligament rendered reduction without operative interference impossible.

In dislocations of the radius, all that is required is to fix the upper arm, and then, employing extension from the wrist, to straighten the arm well; when, by bending the elbow at right angles, the head of the radius may be pressed into a proper position.

After reduction has been effected, the limb should be put up in an angular splint, the hand being kept semiprone. If the radius have been displaced, a pad may be applied over its head, so as to prevent a return of the displacement, which is very apt to occur when the orbicular ligament is torn. In the case of dislocation of the radius *forwards*, reduction is best maintained by keeping the arm in the flexed position, and thus relaxing the biceps which tends to draw the bone forward when the elbow is extended. The inflammation which usually results must be treated by the application of evaporating lotions. When it has subsided, passive motion may be commenced, and frictions and douches employed, so as to remove the stiffness that is apt to be left about the joint.

In those cases in which the dislocation is complicated with fracture of some part of the articular ends, and in which the diagnosis of the precise nature of the injury, owing to the swelling or other causes, has not been very clearly

Fig. 260 - Dislocation of the Elbow: Reduction.

made out, the joint should be placed in as good a position as possible, by a process of traction, flexion, and moulding, so as to bring the *osseous* points into proper bearing with one another, and angular splints must then be applied. At the end of three weeks passive motion may be commenced, lest permanent rigidity, which is very apt to supervene, come on.

Compound Dislocations of the Elbow are always serious injuries, although by the employment of a rigorous antiseptic treatment their gravity may be much lessened. By these means a useful joint may usually be saved, when the soft parts are not too extensively lacerated, without any operative interference. In other cases the Surgeon may have to decide between resection of the articular ends and amputation of the arm. In this the Surgeon will be guided by the considerations stated at p. 594, in reference to compound fracture of this joint. Recovery with a very useful limb has been recorded even after compound dislocation of the elbow, complicated with rupture of the brachial artery.

Old-standing Dislocations of the Elbow are reduced with much difficulty in all cases in which the ulna is completely displaced: this is owing rather to the interlocking of the irregular articular surfaces and to the formation of adhesions in the torn capsule and around the displaced bones, than to muscular contraction. The tendon of the triceps, and even that of the biceps, have been divided in order to facilitate reduction, but in those cases in which I have done this or seen it done, no good has resulted. As a general rule, I believe that it will be found extremely difficult, even under anæsthesia and with the aid of the pulleys, to reduce an ulna that has been completely dislocated for more than a month, although successful cases of many months' standing have been recorded. When the ulna is only partially dislocated, even though the radius be completely displaced, reduction may be effected without much difficulty at a much later period—it is said, as late as two years after the accident; here, however, the difficulty is not to effect but to maintain the reduction, as the bone has a constant tendency to slip forwards and outwards. Provided a dislocated elbow can be so far reduced as to allow the forearm to be bent at a right angle, a useful arm will be left.

Dislocation of the Lower End of the Radius, or, as it is sometimes termed, **Dislocation of the Lower End of the Ulna**, may take place either in a forward or a backward direction. The signs of the displacement are very evident, the lower end of the ulna forming a sharp projection under the skin. This dislocation has also been met with occasionally as a complication of fracture of the radius either at its lower end or in the shaft. In a case recorded by Godlee the radius was fractured very obliquely at the junction of the lower and middle thirds. The lower end of the ulna was torn away from its attachments and was projecting beneath the skin on the front of the carpus, the flexor carpi ulnaris having slipped completely behind it. The injury was caused by a violent fall backwards, the patient's hands being put out behind him to save himself. It was found impossible to replace the limb in proper position, even under an anæsthetic, and the lower end of the displaced ulna, including the lesser sigmoid cavity, was removed through an incision made over it. After this the fractured radius and the displaced hand were easily restored to their normal position. The patient recovered with a most useful hand. E. M. Moore, of Rochester, New York, has removed the lower end of the ulna

In five cases somewhat similar to the above. In every case recovery took place with practically no impairment of function.

DISLOCATIONS OF THE WRIST are of such rare occurrence that their existence has been denied by Surgeons of great experience. Although there can be no doubt that fractures at the lower end of the radius, more especially when impacted, have often been mistaken for these displacements, yet there can be no question that they do occasionally occur, any doubt upon this point having been cleared up by the dissection of cases by Marjolin and Voillemier. The observations of these Surgeons, together with those previously made by Astley Cooper, tend to show that dislocation of the **Hand and Carpus** from the radius may take place either *backwards* or *forwards*.

These accidents are occasioned either by falls on the palm, or by the hand being forcibly bent forwards. In falls on the palm the hand may be thrown forwards under the bones of the forearm, lying on their palmar aspect. In forcible bending of the hand forwards there may be displacement of it and the carpus backwards on the dorsal aspect of the radius and ulna.

In the **Dislocation of the Hand and Carpus Backwards**—the **Dorsal** displacement—there will be shortening of the limb below the elbow, with a large dorsal prominence occasioned by the carpus overlapping the lower end of the radius, which bone will be felt and seen as a projection on the palmar side. In the other variety of radio-carpal dislocation, the **Hand and Carpus are thrown Forwards** under the radius and ulna on their **Palmar** aspect. This dislocation is illustrated in the accompanying figure taken from a cast sent to me by Cudge of Norwich (Fig. 261). In it the projection of the styloid process of the ulna and the lower end of the radius form a concave line on the dorsal aspect, overlapping the carpus, which lies on the palmar side of the radius.

FIG. 261.—Dislocation of the Hand and Carpus forwards.

The *Diagnosis* of these injuries has to be made from sprains of the wrist, from simple and from impacted fractures of the radius. The great and prominent deformity will at once enable the Surgeon to distinguish a dislocation from a simple sprain. From simple fracture of the lower end of the radius, the peculiar deformity (see p. 599), and the absence of crepitus, will afford ready means of diagnosis. It is from the impacted fracture of the lower end of the radius that it is most difficult to distinguish a dislocation. In the dislocation, however, the general laxity of the wrist-joint, the greater tenderness with which the deformity is removed, the peculiar and abrupt swelling, and the absence of obliquity of the hand towards the radial side, will enable the Surgeon to distinguish the true nature of the injury.

In the *Treatment* of these cases, reduction is readily effected, and must be maintained by the application of antero-posterior splints of sufficient length to take in the hand.

Compound Dislocation of the Wrist, without fracture of the bones of

Dislocation of the Wrist is a rare accident. In one such injury under my care, inflicted by machinery, the hand was thrown forwards, the radius projecting backwards, and the soft structures on the palmar aspect of the joint were so extensively lacerated as to necessitate amputation. The *Treatment* of such a case will depend on the amount of injury done to the soft parts. If these be not very extensively lacerated, an attempt may be made to save the limb; but if they be widely torn through, the arteries and nerves lacerated, and the tendons hanging out, amputation will be required.

Congenital Dislocation of the Wrist may take place either forwards or backwards. The limb is in either case greatly deformed. The bones are shortened and altered in shape, more especially the lower end of the radius. The muscles are also shortened, the extensor tendons forming a sharp angle as they pass over the carpus.

DISLOCATIONS OF SINGLE BONES OF THE CARPUS are by no means frequent. The bone that is most commonly displaced is the **Os Magnum**. This accident is usually caused by falls, in which the hand is violently bent forwards, in consequence of which this bone starts out from its articulations, projecting as a round hard prominence on the back of the wrist opposite to the metacarpal bone of the middle finger. It may readily be reduced by being pressed upon while at the same time the hand is extended. There is, however, a great tendency for the bone to slip out again, leaving considerable weakness of the joint; so much so, that in two cases recorded by Astley Cooper, the patients found it necessary to wear artificial supports.

The **Pisiform Bone** is occasionally dislocated upwards. In a case under my care, it was displaced by an effort to lift a heavy weight, and drawn up the arm to a distance of nearly an inch by the flexor carpi ulnaris.

A case some time ago occurred to me, at the Hospital, in which the **Semilunar Bone** was dislocated. The patient had fallen from a height, injuring his spine, and doubling his right hand under him. On examining the wrist, a small hard projection was felt on its dorsal aspect; this readily disappeared on extending the hand and employing firm pressure, but started up again as soon as the wrist was forcibly flexed. It was evident that the bone belonged to the first row of the carpus; and from its size, position and shape, there could be little doubt that it was the semilunar bone. Tinslie, of Brighton, has related a case in which the semilunar bone was dislocated anteriorly, so that it projected upwards and forwards between the radius and ulnar.

DISLOCATIONS OF THE METACARPAL BONES.—The **Metacarpal Bones** may very rarely be dislocated from the carpus. This accident happens usually to a single metacarpal bone; which, in consequence of some extreme degree of violence, is forced out of its bed and thrown backwards on the carpus. Most frequently, it is the result of injury and shattering of the hand by gun-barrel or powder-flask explosions; and in such cases the metacarpal bone of the **Thumb** commonly suffers, the dislocation being compound, and complicated with extensive laceration of the palm, and possibly with fracture of the bones. Except in such cases dislocation of the metacarpal bone of the thumb is rare, though the articulation between this bone and the trapezium appears at first sight not to be of a character to resist great external violence. This is probably owing in a large measure to the powerful muscles by which the bone is supported in all cases in which the force is applied upon its inner aspect, as it most frequently is, as well as to the little leverage afforded

by so short a bone. Luxation of the metacarpal bone of the thumb has, however, been observed to take place *forwards* as well as *backwards*, the latter being the more common. The *Reduction* is in general easy, extension being made from the thumb by means of a piece of tape applied round the first phalanx.

Next to the metacarpal bone of the thumb, those of the **Index** and **Middle Fingers** are most liable to dislocation backwards: in some cases complete, in others incomplete. I know of no recorded case in which *all* the metacarpal bones have been dislocated from the carpus. The annexed engraving (Fig. 262) from a cast in University College Museum, was taken from a patient in the Hospital, in whom I believe that this accident must have occurred; the hand being thrown forwards and shortened, and the carpal bones forming a

Fig. 262—Dislocation of the Metacarpus, forwards, from the Carpus

Fig. 263—Dislocation, backwards, of the Proximal Phalanx of the Thumb.

rounded and *convex* prominence on the dorsum of the metacarpus. The convex appearance of this corresponds with the outline of the carpal bones, and differs so very remarkably from the concave aspect of the lower end of the radius and ulna, as seen in the radio-carpal dislocation (Fig. 261), that I think there can be little doubt as to the nature of the injury.

The *Treatment* of such cases will be the same as that for ordinary dislocations of the carpal bones; splints of sufficient length to take in the hand being applied, after reduction, in order to maintain the parts in position.

DISLOCATIONS OF THE METACARPO-PHALANGEAL ARTICULATIONS are by no means of common occurrence. They are usually produced by falls on the hand, and are met with at all ages: most commonly in the young adult, but sometimes at an earlier age. I have seen this accident in a child four years old. Most frequently the **Proximal Phalanx of the Thumb** is the bone that is dislocated, being thrown *backwards* on the metacarpal bone (Fig. 263) in such a way that the articular surface of the phalanx rests upon the back of the metacarpal bone immediately above its head (Fig. 264). The signs of the accident are sufficiently evident. In the normal state of the hand, the metacarpop-

phalangeal articulation of the thumb is convex backwards : in this dislocation it becomes convex towards the palmar aspect and angularly concave behind. The head of the metacarpal bone can be felt and seen projecting on the palmar aspect of the thumb. The proximal phalanx stands up as it were upon the back of this bone, but the articular surface of the phalanx cannot be felt, owing to its being in contact with the posterior part of the metacarpal bone just above its neck. The phalangeal articulation is always semiflexed. The

Fig 264. — Dislocation of the Proximal Phalanx of the Thumb

dislocation of the proximal phalanx of the thumb has, owing to the difficulty of its reduction, attracted more attention from Surgeons than it would at first sight appear to deserve. In some cases the dislocation has proved irreducible, notwithstanding the employment of as much force as it was safe to use, and the Surgeon has been obliged to have recourse to operative interference in order to replace the head of the bone. The obstacle to the reduction of this small bone has been attributed to different causes. Thus, Hey supposed that it was owing to the constriction of the neck of the bone between the lateral ligaments of the joint, and Dupuytren entertained a similar opinion. The folding in of the anterior

ligament of the joint, and the interposition of a sesamoid bone between the articulating surfaces, have also been regarded as giving rise to this peculiar difficulty in reduction. The more probable explanation, however, appears to be that the narrow neck of the metacarpal bone becomes constricted by the two tendinous attachments of the short flexor of the thumb, which must be carried back over its broader head, together with the displaced phalanx : the head of the metacarpal bone being grasped between the tendons and the torn capsule of the joint, like a stud between the sides of a button-hole. The observations of Vidal, Malgaigne, and Ballingall point to this as the cause of the great difficulty in reduction that is often met with.

Reduction.—Although, as has been said, great difficulty in reduction is often met with, it would be a great error to suppose that it always exists. On the contrary, very many of these dislocations are most readily reduced by simple traction and manipulation. Should any difficulty be experienced, the following plan will usually succeed. The hand and metacarpal bone being fixed by an assistant, the Surgeon bends back the thumb, so as to bring the phalanx to a right angle with the metacarpal bone on which it is displaced. He now employs traction in the axis of the displaced portion of the thumb, keeping the metacarpal bone well pressed down into the palm. Having thus unlocked the phalangeal articular surface from the back of that bone, he draws it well forwards, and, when it is opposite the head of the metacarpal bone, bends it down into the palm. In this way I have reduced a dislocation of the phalanx backwards between five and six weeks after its occurrence. Simple traction in the straight direction, however forcible, and even when aided by the pulleys, will do little, if any, good in the reduction of this dislocation, as the only effect is to draw the slit in the capsule and the two

heads of the short flexor more tightly round the neck of the bone. Very severe extension has been employed without any effect; and there is a tradition in the surgical profession in London of a thumb having been dragged off in the attempt to reduce this dislocation by pulleys. If the Surgeon fail in reducing the displaced phalanx by manipulation under chloroform, as above described, or by traction, the dislocation should not be left without a further effort to replace the bone; and this may usually be done readily enough by the subcutaneous section of the resisting structures. The Surgeon must bear in mind that the obstacle to reduction is purely mechanical; that muscular contraction has nothing to do with it; and that it is quite as great when the patient is anæsthetized as when he is not. He must therefore enlarge the slit in the capsule, and divide the tense bands formed on each side by the tendinous attachments of the short flexor. This operation is best done by passing a tenotome through the skin in front of the joint, and cutting first on one side, then on the other. The chief resistance will be found on the ulnar side of the thumb, where the tendinous insertion of the adductor pollicis joins that of the short flexor. After these structures have been cut through,

Fig. 265.—Reduction of Dislocation of Thumb.

the phalanx can be placed, and the thumb should be put up securely between splints.

When reduction has been effected, care must be taken to prevent recurrence of the displacement. This is best done by keeping the thumb bent into the palm, and retaining it there by means of a gutta-percha cap moulded over it and bandaged down. If the dislocation be left unreduced, the thumb will to a great extent become useful, but necessarily shortened, and incapable of much flexion.

In *Compound Dislocation* of this joint, the bone may usually be readily replaced, but in some cases it has been found necessary to remove the head of the metacarpal bone.

DISLOCATIONS BETWEEN THE PHALANGES are usually partial or incomplete, and most commonly consist of a twist of the second upon the proximal phalanx.

Complete dislocation of the ungual phalanx, though very rare, is possible. I have seen it in the thumb when, by a fall upon its end, the ungual phalanx has been thrown on to the back of the proximal one, the head of which projected on the palmar aspect. I have also known the ungual phalanx of the little finger dislocated backwards in an attempt to catch a cricket-ball.

Partial dislocation of the middle phalanx, which is a very common accident,

is readily recognized by the deformity it causes (Fig. 266), and is easily reduced by pressure and traction in proper directions. A very convenient

Fig. 266.—Partial Dislocation of the Middle Phalanx of the Middle Finger.

mode of applying traction is by means of the toy called an "Indian puzzle" which grasps the finger more tightly the more it is pulled upon; or the apparatus represented in Fig. 265 may be used. The finger will continue to be stiff and comparatively useless for some length of time, the joint being swollen and tender; the patient can generally bend it, but cannot extend it fully or bear any traction upon it. This condition is especially apt to be troublesome and chronic if the patient be gouty, or if his general health be otherwise deranged, and it requires rest and local counter-irritation, with appropriate constitutional treatment. In *Compound Dislocation* of the phalanges, the bone should be replaced, the finger supported by a gutta-percha splint, and the wound dressed antiseptically. In some cases it is necessary to remove the projecting end of

bone before this can conveniently be done; ankylosis then results, a sufficiently useful finger being left.

DISLOCATIONS OF THE LOWER LIMB.

DISLOCATIONS OF THE PELVIS.—It occasionally happens that, in consequence of severe blows upon or compression of the pelvis, the **Symphysis of the Pubic Bones**, or more frequently the **Sacro-iliac Articulation**, is displaced. Here the nature of the injury is indicated by the deformity that results; and the same treatment is required as in fracture of the pelvis, with which these accidents are commonly associated.

The **Coccyx** is sometimes violently bent, and almost dislocated *forwards*, by falls; or it may be forcibly bent *backwards* during violent parturient efforts. These accidents are apt to be followed by that painful neuralgic affection **Coccydynia**, described at p. 607.

DISLOCATIONS OF THE FEMUR.—Notwithstanding the great depth of the acetabulum, the complete manner in which the head of the thigh-bone is received into its cavity, the firmness of the capsular ligament, and the great strength of the muscles which surround and support the joint, dislocations of the hip are more frequently met with than those of many other joints that appear less perfectly supported. This is doubtless in a great measure owing to the action, on the head of the femur, of the great length of leverage of the thigh-bone itself when external violence is applied to the knee, and of the whole of the lower extremity when the violence is applied to the foot. Dislocation of the hip-joint occurs chiefly in young or middle-aged adults. In very old people, fracture of the neck of the femur will commonly be produced by the same violence that would have displaced the head of the bone at an earlier age. In children dislocation is rare, as the shaft generally gives way. Yet it does happen even at a very early age. Two cases have occurred in my practice: in one the bone was dislocated on the pubic bone, in a child a year and a half old; in the other on the dorsum ilii, in a boy of six.

The different forms of dislocation of the femur were described with great ease and precision by Astley Cooper, according to whom the head is most

commonly thrown **upwards and somewhat backwards**, so as to lodge on the slightly concave surface between the acetabulum and the crista illi, resting in the gluteus minimus, and having the trochanter turned forwards (Fig. 267); or the head may be thrown **downwards** into the foramen ovale, lying upon the obturator externus muscle (Fig. 269); or **forwards and upwards** upon the horizontal branch of the pubic bone under the psoas and iliacus muscles, to the outer side of the femoral vessels (Fig. 270); lastly he described a variety in which the head of the bone was supposed to be thrown **backwards**

DISLOCATIONS OF THE HEAD OF THE THIGH BONE, ACCORDING TO ASTLEY COOPER'S CLASSIFICATION.

Fig. 267 — Upwards and somewhat backwards, upon Crista Illi.

Fig. 270 — Forwards and Upwards on the Pubic Bone

into the great sciatic notch and to rest upon the pyriformis (Fig. 268). It has since been shown, however, that the peculiar features of this form are due not to the head of the bone sinking into the notch, but to the relation of the femur to the obturator internus muscle.

The classification originally given by Astley Cooper has been slightly modified in accordance with the more accurate knowledge we now possess. It has been shown by experiments on the dead body that the most important structure in the mechanism of dislocation of the hip is the **ilio-femoral liga-**

ment. Gann of Chicago, Busch, Von Pitha, and, more recently and fully, Bigelow, have insisted on an exact knowledge of this important ligament as constituting the basis of a correct understanding, not only of the mechanism of the various forms of dislocation of the hip, but also of the proper method to be adopted for their reduction. Bigelow, to whom we are especially indebted for a most lucid exposition of the subject, has shown that the four commonly described dislocations of the hip could be demonstrated in the dead body after the whole of the muscular and ligamentous structures round the joint had been divided except the ilio-femoral ligament and the obturator internus muscle, which suffice to direct the limb into the position peculiar to each dislocation and to fix it there, the muscle being concerned only in the production of the dislocation described by Astley Cooper as "into the sciate notch." The importance of the obturator in this form of dislocation had previously been pointed out by Malgaigne, but his observations seem to have been singularly overlooked. The ilio-femoral ligament is of great strength. Bigelow has found its breaking strain in the dead body to range from 250 to 750 pounds. It is single above where it is attached to the anterior inferior spine of the ilium and divides below into two strong bands, one inserted into the upper and the other into the lower end of the anterior intertrochanteric line, from which fact Bigelow gives it the name of the Y-ligament. The **obturator internus muscle** is also, as pointed out by Bigelow, a structure of great strength, owing to the intermixture of tendinous fibres with its muscular substance. In consequence of this arrangement it becomes practically an accessory ligament to the joint.

The observations of Bigelow have shown that whenever one or both of the branches of the ilio-femoral ligament remain unton the head of the bone falls into certain definite positions giving rise to characteristic signs; when the ligament is completely ruptured the position assumed by the bone is uncertain, being due chiefly to accidental circumstances. He, therefore, divides dislocation into **Regular**, in which one or both branches of the ilio-femoral ligament remain unton; and **Irregular**, in which the whole ligament is ruptured.

For convenience of description, and with a view to practical utility, the regular dislocations may be divided into three chief groups, to which must be added certain exceptional forms which are so rare as only to require mention.

1. **Dorsal Dislocations, or Dislocations Backwards and Upwards.**—Of these there are two varieties: *a*, when the head of the bone passes above the obturator internus (dislocation on to the dorsum ilii); *b*, when the head passes below that muscle (dislocation into the sciatic notch of Astley Cooper) (Figs. 267, 268).

2. **Thyroid Dislocations, or Dislocations Downwards.**—These dislocations present four varieties, of which one only is common—obliquely inwards and downwards on the thyroid foramen (Fig. 269). In addition to this, there are three exceptional forms: *a*, inwards and downwards as far as the perineum; *b*, vertically downwards below the acetabulum; *c*, outwards and downwards as far as the tuberosity of the ischium.

3. **Dislocations Upwards, or Pubic Dislocations.**—Of this form there are two varieties: *a*, when the head of the femur is displaced on to the pubic bone (Fig. 270); *b*, when it lies beneath the anterior inferior spine of the ilium, or the *subspinous dislocation*.

The exceptional forms of dislocation are the following:—

4. The **Anterior Oblique**, in which the head of the bone lies behind the anterior inferior iliac spine.

5. The **Supraspinous**, in which the head of the bone lies above the anterior inferior iliac spine, between it and the superior spine.

6. The **Everted Dorsal Dislocation**, in which the head of the bone lies on the anterior part of the dorsum, behind the anterior inferior iliac spine. In the two last forms the outer branch of the ilio-femoral ligament is ruptured.

The **Mechanism of the Production** of these various dislocations has been much discussed. It is generally recognised that in the thyroid and pubic dislocations the limb is abducted at the time of the injury, and that the head of the bone leaves the capsule in a downward direction, passing through the thinnest part of the capsule, the position it afterwards assumes being due to the direction of the force applied to the abducted limb. Astley Cooper believed that in the dorsal dislocation the limb at the time of the accident is adducted and flexed, and that the head of the bone leaves the acetabulum in a direction directly backwards. Henry Morris, who has investigated this subject both by experiment and by observation of specimens, has come to the conclusion that in all dislocations the head of the bone leaves the capsule in a downward direction, while the limb is *abducted*. He is of opinion that with few exceptions all dislocations are primarily the same, that is to say, downwards, the subsequent position of the bone being determined by the degree of flexion and rotation to which the limb is exposed. Thus the posterior dislocation results from flexion and rotation inwards accompanying the abduction, and the anterior or pubic from rotation outwards and extension accompanying the abduction, while the downward dislocations result from forced abduction alone. That this explanation is true of the great majority of dislocations is highly probable, but there are recorded cases to show that a dorsal dislocation may occur in the way described by Astley Cooper, directly backwards during flexion and adduction.

With regard to the **Relative Frequency** of the various forms of dislocation, Astley Cooper says that of 20 cases of dislocation of the hip, 12 will, on the average, be on the dorsum ilii (above the tendon of the obturator internus of Bigelow), 5 on the sciatic notch (below the tendon of the obturator internus), 2 on the thyroid foramen, and 1 on the pubic bone. Hamilton states that, excluding anomalous cases, of 104 dislocations which he has collected, 55 were on the dorsum ilii, 28 into the sciatic notch (below the tendon of the obturator internus), 13 into the thyroid foramen, and 8 upon the pubes.

In the **Reduction** of dislocations of the hip-joint, two methods may be employed, *extension* or *manipulation*. In extension, forcible traction is made by pulleys or otherwise in the direction of the axis of the limb, overcoming by main force any obstacle arising from muscular contraction or the mechanical resistance of ligaments. In manipulation force is avoided, the Surgeon's object being to relax the ligaments which offer a mechanical obstruction to reduction, and to disentangle the head of the bone from its abnormal position, and by impressing on it various rotatory movements, each adapted to the particular case, to bring it back into the acetabulum. Manipulation is mentioned by Hippocrates. The earliest modern description is by Thomas Anderson, Surgeon, of Leith, in the third volume of "The Medical and Philosophical Com-

mentaries" for 1775. He describes two cases, one of dislocation on the foramen ovale in a man: the other a dislocation of the dorsum ili in a boy. In the first case the pulleys had been used ineffectually several times, when the "laque" slipping, their use was discontinued. Mr. Anderson says: "I was convinced that attempting the reduction in the common method, with the thigh extended, was improper, as the muscles were put upon the stretch, the action of which is perhaps sufficient to overcome any extension we can employ. But by bringing the thigh to near a right angle with the trunk, by which the muscles would be greatly relaxed, I imagined the reduction might more readily take place, and with much less extension. *I raised the thigh to about a right angle with the trunk*, and, with my right hand at the ham, laid hold of the thigh, and made what extension I could. At the same time that I did this, with my left hand at the head and inside of the thigh, I pressed it towards the acetabulum, while my right gave the femur a little circular turn, so as to bring the rotula inwards to its natural situation, and at the second attempt it went in with a snap." In the second case, the reduction was not attempted till the eighteenth day after the accident. The patient was laid across the bed, and the thigh raised so as to form an acute angle with the trunk. In this situation, the knee of the dislocated limb lay considerably over the sound thigh. "Considerable extension was then made; with my left hand I laid hold of the middle of the leg which I brought inwards. By this *the femur made a circular turn*, which directed its head towards the acetabulum, into which it went with a sensible noise" (pp. 426—428).

The method was, however, first distinctly advocated by Nathan Smith, in 1831, and extended by Reid, of Rochester (U.S.A.), in 1851; but it was not until the publication of Bigelow's work that the scientific principles of manipulation were fully laid down. At the present time no Surgeon would resort to extension by means of pulleys in a recent dislocation of the hip without having first attempted reduction by manipulation. In those of *old standing*, extension by means of the pulley is still required, as by manipulation sufficient force cannot be exerted to overcome those secondary causes of resistance that become developed in such cases.

After-Treatment.—The fact of the reduction being accomplished is ascertained by comparing the bony points of the limb with those of the opposite side, and seeing if they correspond. The patient should be kept in bed for three weeks. During the first fortnight the limb is fixed on a long splint after which passive movement is practised.

I shall describe both methods of reduction in connection with each of the principal forms of dislocation of the hip.

1. Dorsal Dislocations, or Dislocation Upwards and Backwards.

Causes.—The dorsal dislocations are occasioned by violence acting upon the limb while flexed and slightly adducted, or according to some authorities, abducted: as when a person is struck on the back with a heavy weight while kneeling, or is thrown forwards, or falls whilst carrying a heavy load upon his shoulders, when the upper and posterior part of the joint receives the whole strain. Thus, in a case under my care in University College Hospital, it was caused by a heavy weight falling from a crane upon a man's back as he was kneeling on one knee and reaching down to put a ticket on the side of a railway-truck. In another case it was caused by the patient's falling between the carriage and platform in a railway station in such a way that he lay on his

side on the footboard with his knee against the platform and his back against the carriage. As the carriage slowly moved, his leg became flexed, and the space being insufficient, the head of the bone was pushed out of the socket. Bigelow states that if the femur is flexed at right angles, and thrust directly backwards with sufficient force, the head will tend to pass between the obturator internus and the pyriformis. At an angle of forty-five degrees it may be thrust upwards and backwards above the pyriformis. Both these displacements would give rise to the symptoms of dislocation upon the dorsum ilii. In extreme flexion, or in cases complicated by forcible inward rotation, the head tends to pass out beneath the tendon of the obturator internus, and we then have the form of dorsal dislocation formerly described as into the sciatic notch.

Pathological Anatomy.—The capsule is ruptured below or more rarely behind, but the ilio-femoral ligament is intact in all dorsal dislocations. The ligamentum teres is mostly torn, but not necessarily in all cases. Dupuytren and Sedillot both mention cases in which this ligament escaped without rupture. In dislocation on the dorsum ilii, the head will be found lying in a variable position on the ilium, above and behind the acetabulum. The trochanter is directed forwards, being held in that position chiefly by the unruptured external band of the ilio-femoral ligament, which is very tense. The muscles are torn to a varying degree in different cases. Astley Cooper found the gemelli, obturators and quadratus, completely torn, and the pectineus slightly torn in one case. Syme found the gluteus maximus extensively torn, with the head of the bone imbedded in it: the gluteus minimus, the pyriformis, and the gemellus superior lacerated; and the head of the femur lying upon the gemelli and the great sciatic nerve. MacCarthy found the deeper fibres of the gluteus maximus torn by the head of the bone, which was lying with its anterior part on the brim of the acetabulum, with the lowermost fibres of the gluteus minimus interposed, and the dimple for the ligamentum teres directed backwards and inwards. The posterior fibres of the gluteus medius were also lacerated, and the pyriformis, obturator internus, and gemelli had been completely torn from their pelvic attachments. The quadratus femoris was uninjured. The capsule had given way posteriorly; in front and above it was intact. Although some fibres of the ligamentum teres had been ruptured, the ligament still resisted all attempts to break it. The ilio-femoral and pubo-femoral bands were uninjured, notwithstanding that the acetabulum had separated into its three component parts, the fracture also traversing the ilio-pectineal eminence. The lowermost fibres of the external oblique muscle of the abdomen, and some fibres of the sartorius, psoas magnus, and iliacus internus muscles were also ruptured. In all these cases it is evident that the bone had passed out above the obturator; in the last this muscle was torn.

In dislocations *below the tendon of the obturator internus* the position assumed by the bone is best explained by the accompanying figures taken from Bigelow's work on the Hip. Fig. 271 shows the normal position of the muscle behind the head and neck of the bone. It is evident that in a state of extreme flexion, or of moderate flexion with forcible internal rotation, the head might be made to pass out beneath the muscle. Immediately after the accident the limb is almost invariably extended either in lifting the patient or in placing him on his back. The ilio-femoral ligament being untorn, and

consequently the neck of the femur being more or less firmly fixed, the head moves upwards as the limb is extended till it comes to lie above the muscle in the position shown in Fig. 272, the obturator internus now lying in front of the neck of the bone and passing over it, thus limiting the displacement upwards. The injury to surrounding muscles is very various. Billard d'Angers found the gluteus maximus and medius lacerated and the gemelli torn, probably from the strain they had been subjected to by the position of the obturator. MacCarthy found the gluteus maximus not torn, but the bursa between it and the vastus externus was ruptured and filled with blood. The sheath of the great sciatic nerve was also distended with blood, and the nerve fibres separated from one another. The posterior fibres of the gluteus minimus were torn and the areolar tissue beneath the muscle filled with blood. The quadratus femoris muscle was torn completely in two, and the uppermost fibres of the abductor magnus, and some fibres of the gemelli and obturator

Fig. 271.—Pelvis and Head of the Femur, with the obturator internus in natural position. (Bigelow.)

Fig. 272.—Pelvis and Head of Femur, showing dislocation below the line of the obturator, with secondary displacement of the head upwards, and secondary position of the obturator internus. (Bigelow.)

internus muscles, were lacerated. The capsule was perfect in front and above, but torn at the most posterior part. The ligamentum teres had been torn off close to the femoral attachment.

The accompanying drawing (Fig. 273) is from a case which was admitted into University College Hospital. The patient died from other injuries a few hours after admission. The dislocation was reduced without the slightest difficulty by manipulation and showed no tendency to slip out again, though the man was very restless before death. The dislocation was easily reproduced after the limb had been dissected and rigor mortis had passed off. A considerable extravasation of blood was found beneath the gluteus maximus. The only muscle torn was the gemellus inferior, the upper border of the quadratus was slightly bruised, and the lower border of the gluteus minimus was also marked by a little extravasated blood, apparently from the pressure of the head of the bone in its abnormal position, and there was extravasated blood in the sheath of the great sciatic nerve. A small fragment had been chipped from the margin of the acetabulum, but was firmly fixed by the capsule.

Symptoms.—If the head of the bone have been displaced *above the obturator and upon the dorsum of the ilium*, the hip will be found to be a good deal distorted, the gluteal region being somewhat prominent, and the upper part of the thigh enlarged, in consequence of the approximation of the muscular attachments, so as to give an appearance of widening to the hip. The head of the bone can be felt in its new situation, more especially on rotating the limb: the trochanter is less prominent than natural, usually lying close against the brim of the acetabulum, and being turned forwards: it lies considerably above "Nélaton's line" drawn from the anterior superior spine of the ilium to the tuberosity of the ischium: there is marked shortening, varying from one to two inches in some cases, perhaps even as much as three

Fig. 72. (From) Dissection below the tension. *a*, *y*, *y*, Gluteus max., medius and minimus; *p*, pectineus; *q*, attachment of capsule; *t*, tensor; *b*, gemelli inferior; *q*, quadratus; *c*, great sciatic nerve; *m*, adductor magnus; *h*, biceps; *ob*, obturator internus; *p*, *e*, gemelli superior.

inches. The amount of shortening will necessarily depend upon the distance to which the head of the bone is thrown *upwards* on the dorsum. The position of the limb is remarkable, being distinctly rotated inwards, with the thigh slightly bent upon the abdomen, and the leg upon the thigh, so that the knee is semi-flexed, and raised from the surface on which the patient is lying. The foot is inverted, so that the ball of the great toe rests on the instep or against the ankle of the sound limb; and the heel is somewhat raised. The axis of the dislocated thigh is directed across the lower third of the sound thigh. The movements of the joint are greatly impaired; abduction and eversion are not practicable, but inversion, adduction, and a certain amount of flexion upon the abdomen, can be practised. When the patient is lying flat, with the knee slightly raised and advanced, the lumbar spine is on

its proper level; but if an attempt be made to straighten the knee, so that the limb lies flat, the lumbar spine will arch forwards.

The slight flexion, the rotation inwards, and the adduction are all due to the position in which the neck of the bone is held by the ilio-femoral ligament: flexion and adduction are easy because by approximating the intertrochanteric line to the anterior inferior iliac spine they relax the ligament.

When the head of the bone has escaped *below the tendon of the obturator* we have the dislocation formerly described as into the sciatic notch, and to which the name "sciatic" is still usually applied. If seen immediately after the accident there may be extreme flexion and adduction, the dislocated limb crossing the sound thigh near the groin, but usually before the Surgeon sees the case the limb has been brought down so that the head has gone up behind the obturator. The symptoms then resemble those of the dislocation on to the dorsum ilii, differing chiefly in degree. The inversion of the knee and foot are, according to Bigelow, more marked, and consequently the trochanter is less prominent than in the dislocation on the ilium. In some cases, however, the inversion is less marked than in others. The shortening is very much less, as it is limited by the obturator internus in its abnormal position, and consequently the trochanter is but little above Nelaton's line: it seldom exceeds an inch and is usually not so much. The position of the limb will depend upon the degree to which the thigh has been extended since the accident. In the erect position the weight of the limb brings it down so that the axis of the thigh may be directed across the sound knee, and the toe of the injured side may rest on those of the opposite toe (Fig. 274). Thus it may closely resemble a dislocation on the dorsum ilii, the most important difference being the small amount of shortening when the head has escaped below the tendon. By violent manipulation or extension the obturator internus may be torn, and the lower dislocation may thus be converted into one on the dorsum ilii.

Fig. 274. — Dislocation below the Tendon. Much Inversion. (Bigelow.)

The *Diagnosis* of this form of dislocation is easy in proportion as the head of the bone lies high on the dorsum ilii. The lower it is placed the more difficult does the detection of the displacement become, and the greater the risk of its being overlooked altogether, or mistaken for a sprain. In ordinary cases of fracture of the neck of the thigh-bone, the eversion of the limb at once shows that the head of the bone is not dislocated on the ilium. The only severe injury of the hip with which the dislocation upwards and backwards can be confounded is the rare case of *fracture of the neck of the thigh-bone, with inversion of the limb*. In this accident, the increased mobility and the existence of crepitus will enable the Surgeon to make the diagnosis. Should the case, however, be one of *impacted extracapsular fracture, with eversion*, then the difficulty of diagnosis is undoubtedly great. A correct conclusion may, however, be arrived at by observing that in the fracture the flattened trochanter is approximated to, and is nearly in a perpendicular line with the anterior superior spine of the ilium; whilst in the dislocation the trochanter is diagonally behind that process of bone, and the head of the thigh-

4. The **Anterior Oblique**, in which the head of the bone lies behind the anterior inferior iliac spine.

5. The **Supraspinous**, in which the head of the bone lies above the anterior inferior iliac spine, between it and the superior spine.

6. The **Everted Dorsal Dislocation**, in which the head of the bone lies on the anterior part of the dorsum, behind the anterior inferior iliac spine. In the two last forms the outer branch of the ilio-femoral ligament is ruptured.

The **Mechanism of the Production** of these various dislocations has been much discussed. It is generally recognised that in the thyroid and pubic dislocations the limb is abducted at the time of the injury, and that the head of the bone leaves the capsule in a downward direction, passing through the thinnest part of the capsule, the position it afterwards assumes being due to the direction of the force applied to the abducted limb. Astley Cooper believed that in the dorsal dislocation the limb at the time of the accident is adducted and flexed, and that the head of the bone leaves the acetabulum in a direction directly backwards. Henry Morris, who has investigated this subject both by experiment and by observation of specimens, has come to the conclusion that in all dislocations the head of the bone leaves the capsule in a downward direction, while the limb is *abducted*. He is of opinion that with few exceptions all dislocations are primarily the same, that is to say, downwards, the subsequent position of the bone being determined by the degree of flexion and rotation to which the limb is exposed. Thus the posterior dislocation results from flexion and rotation inwards accompanying the abduction, and the anterior or pubic from rotation outwards and extension accompanying the abduction, while the downward dislocations result from forced abduction alone. That this explanation is true of the great majority of dislocations is highly probable, but there are recorded cases to show that a dorsal dislocation may occur in the way described by Astley Cooper, directly backwards during flexion and adduction.

With regard to the **Relative Frequency** of the various forms of dislocation, Astley Cooper says that of 20 cases of dislocation of the hip, 12 will, on the average, be on the dorsum ilii (above the tendon of the obturator internus of Bigelow), 5 on the sciatic notch (below the tendon of the obturator internus), 2 on the thyroid foramen, and 1 on the pubic bone. Hamilton states that, excluding anomalous cases, of 104 dislocations which he has collected, 55 were on the dorsum ilii, 28 into the sciatic notch (below the tendon of the obturator internus), 13 into the thyroid foramen, and 8 upon the pubes.

In the **Reduction** of dislocations of the hip-joint, two methods may be employed, *extension or manipulation*. In extension, forcible traction is made by pulleys or otherwise in the direction of the axis of the limb, overcoming by main force any obstacle arising from muscular contraction or the mechanical resistance of ligaments. In manipulation force is avoided, the Surgeon's object being to relax the ligaments which offer a mechanical obstruction to reduction, and to disentangle the head of the bone from its abnormal position, and by impressing on it various rotatory movements, each adapted to the particular case, to bring it back into the acetabulum. Manipulation is mentioned by Hippocrates. The earliest modern description is by Thomas Anderson, Surgeon, of Leith, in the third volume of "The Medical and Philosophical Com-

mentaries" for 1775. He describes two cases, one of dislocation on the foramen ovale in a man: the other a dislocation of the dorsum illi in a boy. In the first case the pulleys had been used ineffectually several times, when the "lacque" slipping, their use was discontinued. Mr. Anderson says: "I was convinced that attempting the reduction in the common method, with the thigh extended, was improper, as the muscles were put upon the stretch, the action of which is perhaps sufficient to overcome any extension we can employ. But by bringing the thigh to near a right angle with the trunk, by which the muscles would be greatly relaxed, I imagined the reduction might more readily take place, and with much less extension. *I raised the thigh to about a right angle with the trunk*, and, with my right hand at the ham, laid hold of the thigh, and made what extension I could. At the same time that I did this, with my left hand at the head and inside of the thigh, I pressed it towards the acetabulum, while my right gave the femur *a little circular turn*, so as to bring the rotula inwards to its natural situation, and at the second attempt it went in with a snap." In the second case, the reduction was not attempted till the eighteenth day after the accident. The patient was laid across the bed, and *the thigh raised so as to form an acute angle with the trunk*. In this situation, the knee of the dislocated limb lay considerably over the sound thigh. "Considerable extension was then made; with my left hand I laid hold of the middle of the leg which I brought inwards. By this *the femur made a circular turn*, which directed its head towards the acetabulum, into which it went with a sensible noise" (pp. 426—428).

The method was, however, first distinctly advocated by Nathan Smith, in 1831, and extended by Reid, of Rochester (U.S.A.), in 1851; but it was not until the publication of Bigelow's work that the scientific principles of manipulation were fully laid down. At the present time no Surgeon would resort to extension by means of pulleys in a *recent* dislocation of the hip without having first attempted reduction by manipulation. In those of *old standing*, extension by means of the pulley is still required, as by manipulation sufficient force cannot be exerted to overcome those secondary causes of resistance that become developed in such cases.

After-Treatment.—The fact of the reduction being accomplished is ascertained by comparing the bony points of the limb with those of the opposite side, and seeing if they correspond. The patient should be kept in bed for three weeks. During the first fortnight the limb is fixed on a long splint, after which passive movement is practised.

I shall describe both methods of reduction in connection with each of the principal forms of dislocation of the hip.

1. **Dorsal Dislocations, or Dislocation Upwards and Backwards.**—

Causes.—The dorsal dislocations are occasioned by violence acting upon the limb while flexed and slightly adducted, or according to some authorities, abducted: as when a person is struck on the back with a heavy weight whilst kneeling, or is thrown forwards, or falls whilst carrying a heavy load upon his shoulders, when the upper and posterior part of the joint receives the whole strain. Thus, in a case under my care in University College Hospital, it was caused by a heavy weight falling from a crane upon a man's back as he was kneeling on one knee and reaching down to put a ticket on the side of a railway-truck. In another case it was caused by the patient's falling between the carriage and platform in a railway station in such a way that he lay on his

side on the footboard with his knee against the platform and his back against the carriage. As the carriage slowly moved, his leg became flexed, and the space being insufficient, the head of the bone was pushed out of the socket. Bigelow states that if the femur is flexed at right angles, and thrust directly backwards with sufficient force, the head will tend to pass between the obturator internus and the pyriformis. At an angle of forty-five degrees it may be thrust upwards and backwards above the pyriformis. Both these displacements would give rise to the symptoms of dislocation upon the dorsum ilii. In extreme flexion, or in cases complicated by forcible inward rotation, the head tends to pass out beneath the tendon of the obturator internus, and we then have the form of dorsal dislocation formerly described as into the sciatic notch.

Pathological Anatomy.—The capsule is ruptured below or more rarely behind, but the ilio-femoral ligament is intact in all dorsal dislocations. The ligamentum teres is mostly torn, but not necessarily in all cases. Dupuytren and Sédillot both mention cases in which this ligament escaped without rupture. In dislocation on the dorsum ilii, the head will be found lying in a variable position on the ilium, above and behind the acetabulum. The trochanter is directed forwards, being held in that position chiefly by the unruptured external band of the ilio-femoral ligament, which is very tense. The muscles are torn to a varying degree in different cases. Astley Cooper found the gemelli, obturators and quadratus, completely torn, and the pectineus slightly torn in one case. Syme found the gluteus maximus extensively torn, with the head of the bone imbedded in it; the gluteus minimus, the pyriformis, and the gemellus superior lacerated; and the head of the femur lying upon the gemelli and the great sciatic nerve. MacCarthy found the deeper fibres of the gluteus maximus torn by the head of the bone, which was lying with its anterior part on the brim of the acetabulum, with the lowermost fibres of the gluteus minimus interposed, and the dimple for the ligamentum teres directed backwards and inwards. The posterior fibres of the gluteus medius were also lacerated, and the pyriformis, obturator internus, and gemelli had been completely torn from their pelvic attachments. The quadratus femoris was uninjured. The capsule had given way posteriorly; in front and above it was intact. Although some fibres of the ligamentum teres had been ruptured, the ligament still resisted all attempts to break it. The ilio-femoral and pubo-femoral bands were uninjured, notwithstanding that the acetabulum had separated into its three component parts, the fracture also traversing the ilio-pectineal eminence. The lowermost fibres of the external oblique muscle of the abdomen, and some fibres of the sartorius, psoas magnus, and iliacus internus muscles were also ruptured. In all these cases it is evident that the bone had passed out above the obturator; in the last this muscle was torn.

In dislocations *below the tendon of the obturator internus* the position assumed by the bone is best explained by the accompanying figures taken from Bigelow's work on the Hip. Fig. 271 shows the normal position of the muscle behind the head and neck of the bone. It is evident that in a state of extreme flexion, or of moderate flexion with forcible internal rotation, the head might be made to pass out beneath the muscle. Immediately after the accident the limb is almost invariably extended either in lifting the patient or in placing him on his back. The ilio-femoral ligament being untorn, and

consequently the neck of the femur being more or less firmly fixed, the head moves upwards as the limb is extended till it comes to lie above the muscle in the position shown in Fig. 272, the obturator internus now lying in front of the neck of the bone and passing over it, thus limiting the displacement upwards. The injury to surrounding muscles is very various. Billard d'Angers found the gluteus maximus and medius lacerated and the gemelli torn, probably from the strain they had been subjected to by the position of the obturator. MacCarthy found the gluteus maximus not torn, but the bursa between it and the vastus externus was ruptured and filled with blood. The sheath of the great sciatic nerve was also distended with blood, and the nerve fibres separated from one another. The posterior fibres of the gluteus minimus were torn and the areolar tissue beneath the muscle filled with blood. The quadratus femoris muscle was torn completely in two, and the uppermost fibres of the abductor magnus, and some fibres of the gemelli and obturator

Fig. 271. Pelvis and Head of the Femur with obturator internus in natural position. (Bigelow.)

Fig. 272. Pelvis and Head of Femur showing dislocation below the tendon of the obturator, with secondary displacement of the head upwards, and abnormal position of the obturator internus. (Bigelow.)

internus muscles, were lacerated. The capsule was perfect in front and above, but torn at the most posterior part. The ligamentum teres had been torn off close to the femoral attachment.

The accompanying drawing (Fig. 273) is from a case which was admitted into University College Hospital. The patient died from other injuries a few hours after admission. The dislocation was reduced without the slightest difficulty by manipulation and showed no tendency to slip out again, though the man was very restless before death. The dislocation was easily reproduced after the limb had been dissected and rigor mortis had passed off. A considerable extravasation of blood was found beneath the gluteus maximus. The only muscle torn was the gemellus inferior, the upper border of the quadratus was slightly bruised, and the lower border of the gluteus minimus was also marked by a little extravasated blood, apparently from the pressure of the head of the bone in its abnormal position, and there was extravasated blood in the sheath of the great sciatic nerve. A small fragment had been chipped from the margin of the acetabulum, but was firmly fixed by the capsule.

Symptoms.—If the head of the bone have been displaced *above the obturator and upon the dorsum of the ilium*, the hip will be found to be a good deal distorted, the gluteal region being somewhat prominent, and the upper part of the thigh enlarged, in consequence of the approximation of the muscular attachments, so as to give an appearance of widening to the hip. The head of the bone can be felt in its new situation, more especially on rotating the limb; the trochanter is less prominent than natural, usually lying close against the brim of the acetabulum, and being turned forwards; it lies considerably above "Nelaton's line" drawn from the anterior superior spine of the ilium to the tuberosity of the ischium; there is marked shortening, varying from one to two inches in some cases, perhaps even as much as three

FIG. 273. Dorsal Dislocation below the tendon. *g, g', g''*, Gluteus max., medius, and minimus; *p*, pyramiformis; *a*, attachment of capsule; *t*, trochanter; *ge i*, gemellus inferior; *q*, quadratus; *n*, great sciatic nerve; *ad*, adductor magnus; *b*, biceps; *ob*, obturator internus; *ge a*, gemellus superior.

inches. The amount of shortening will necessarily depend upon the distance to which the head of the bone is thrown *upwards* on the dorsum. The position of the limb is remarkable, being distinctly rotated inwards, with the thigh slightly bent upon the abdomen, and the leg upon the thigh, so that the knee is semi-flexed, and raised from the surface on which the patient is lying. The foot is inverted, so that the ball of the great toe rests on the instep or against the ankle of the sound limb; and the heel is somewhat raised. The axis of the dislocated thigh is directed across the lower third of the sound thigh. The movements of the joint are greatly impaired; abduction and eversion are not practicable, but inversion, adduction, and a certain amount of flexion upon the abdomen, can be practised. When the patient is lying flat, with the knee slightly raised and advanced, the lumbar spine is on

its proper level; but if an attempt be made to straighten the knee, so that the limb lies flat, the lumbar spine will arch forwards.

The slight flexion, the rotation inwards, and the adduction are all due to the position in which the neck of the bone is held by the ilio-femoral ligament: flexion and adduction are easy because by approximating the intertrochanteric line to the anterior inferior iliac spine they relax the ligament.

When the head of the bone has escaped *below the tendon of the obturator* we have the dislocation formerly described as into the sciatic notch, and to which the name "sciatic" is still usually applied. If seen immediately after the accident there may be extreme flexion and adduction, the dislocated limb crossing the sound thigh near the groin, but usually before the Surgeon sees the case the limb has been brought down so that the head has gone up behind the obturator. The symptoms then resemble those of the dislocation on to the dorsum ilii, differing chiefly in degree. The inversion of the knee and

Fig. 274. — Dislocation below the Tendon. Much inversion. (Bigelow.)

foot are, according to Bigelow, more marked, and consequently the trochanter is less prominent than in the dislocation on the ilium. In some cases, however, the inversion is less marked than in others. The shortening is very much less, as it is limited by the obturator internus in its abnormal position, and consequently the trochanter is but little above Nélaton's line: it seldom exceeds an inch and is usually not so much. The position of the limb will depend upon the degree to which the thigh has been extended since the accident. In the erect position the weight of the limb brings it down so that the axis of the thigh may be directed across the sound knee, and the toes of the injured side may rest on those of the opposite foot (Fig. 274). Thus it may closely resemble a dislocation on the dorsum ilii, the most important difference being the small amount of shortening when the head has escaped below the tendon. By violent manipulation or extension the obturator internus may be torn, and the lower dislocation may thus be converted into one on the dorsum ilii.

The *Diagnosis* of this form of dislocation is easy in proportion as the head of the bone lies high on the dorsum ilii. The lower it is placed the more difficult does the detection of the displacement become, and the greater the risk of its being overlooked altogether, or mistaken for a sprain. In ordinary cases of fracture of the neck of the thigh-bone, the eversion of the limb at once shows that the head of the bone is not dislocated on the ilium. The only severe injury of the hip with which the dislocation upwards and backwards can be confounded is the rare case of *fracture of the neck of the thigh-bone, with inversion of the limb*. In this accident, the increased mobility and the existence of crepitus will enable the Surgeon to make the diagnosis. Should the case, however, be one of *impacted extracapsular fracture, with inversion*, then the difficulty of diagnosis is undoubtedly great. A correct conclusion may, however, be arrived at by observing that in the fracture the flattened trochanter is approximated to, and is nearly in a perpendicular line with, the anterior superior spine of the ilium; whilst in the dislocation the trochanter is diagonally behind that process of bone, and the head of the thigh-

it can be felt in its new situation by deep manipulation of the gluteal region.

Reduction of Dorsal Dislocation by Manipulation.—The patient must

FIG. 275. Reduction of a Dorsal Dislocation of the Hip by Traction.

FIG. 276. Reduction of a Dislocation by Rotation. The Thigh is flexed, slightly adducted and rotated inwardly, as in the first stage of reduction of a dorsal dislocation.

laid upon his back on a mattress on the floor and fully anesthetized, the physician standing on the injured side. There are two chief ways in which reduction may be effected, viz., by *traction* and by *rotation*.

Traction is thus performed :—

Flex the thigh upon the abdomen, bending the limb at the knee to a right angle (Fig. 275). The flexion relaxes the ilio-femoral ligament, and the relaxation may be further increased by slight adduction; then rotate very slightly inwards; that is to say, move the foot away from the middle line while the knee is held steady. This disengages the head from behind the socket; slight traction in the line of the femur will then usually bring the bone into position; if more force is required the Surgeon may place his foot,

Fig. 277. Dorsal Dislocation. Reduction by Rotation. The limb has been flexed and abducted, and it remains only to rotate it outwards, and so to render the outer branch of the Y-ligament tense. (Bigelow.)

covered only with a stocking, on the anterior superior spinous process, to steady the pelvis while he raises the bent knee. In the great majority of cases reduction will easily be effected by this plan.

Rotation is thus performed :—The Surgeon, standing on the injured side, grasps the ankle with one hand and the leg below the knee in the other as in Fig. 276. He then steadily flexes the thigh upon the abdomen, so that the head of the bone is lifted out from behind the acetabulum and the ilio-femoral ligament relaxed. At the same time that the thigh is flexed it is better to keep it slightly adducted. The limb must now be slowly abducted, and finally rotated outwards by

bringing the foot of the injured side over the sound leg. By this manoeuvre the head is made to revolve around the great trochanter, which is fixed by the outer branch of the Y-ligament, and to rise into its articular cavity (Fig. 277). Finally the limb is brought down parallel to the other. Bigelow has summarised the movements necessary to effect reduction this way in the following words, "*Lift up, bend out, roll out.*"

Reduction by Extension. according to Astley Cooper's method, is effected in the following manner. The patient, having been put under the influence of chloroform, is laid on his back upon a strong table. One staple should then be fixed in the floor near the head of the bed at the side corresponding to that of the dislocated limb, while another staple is placed in the wall at the foot, above the level of the body, in a direct line with the axis of the limb and about twelve feet from the other. The counter-extending force must then be made by a jack-towel or a padded leather belt passed between the injured thigh and the perineum, and fixed to the staple in the floor. The pulleys must now be attached to proper straps, or to a towel fixed with a clove-hitch knot immediately above the knee, at one end; the other extremity being attached to the staple in the wall, which should be so situated as to be continuous with the axis of the lower part of the limb. The knee being then slightly bent and rotated inwards, traction is applied slowly and steadily until the head of the bone has approached the acetabulum, when the Surgeon rotates the limb outwards so that the head may slip into its socket (Fig. 278). This method is seldom, if ever, required in recent or

locations. Should it be necessary, as in an old dislocation, it would be better to flex the thigh more than is shown in the figure after the bone had been brought down as far as possible by extension in the axis of the limb.

Reduction of the Dislocation below the Tendon of the Obturator is effected by the same processes of manipulation as in the other form of the dorsal dislocation. The first method, that of *traction*, is usually at once

Fig. 278. — Reduction of the sciatic Dislocation by Extension.

successful. Astley Cooper found great difficulty in the reduction of this dislocation, and he, Lisfranc and other Surgeons, have failed to reduce it by extension. They believed that the difficulty arose from the head of the bone sinking into the great sciatic notch. The fallacy of this view and the part played by the obturator internus in resisting reduction by extension in the axis of the limb has already been pointed out. Should *extension* be necessary, it must be made with the thigh flexed at a right angle to the trunk.

In either of these dislocations, if difficulty arise in raising the bone over the edge of the acetabulum, recourse may be had to the plan recommended by Astley Cooper, of lifting the head of the bone over the edge of the acetabulum by means of a round towel placed under the upper part of the thigh and over the shoulders of an assistant, who, first stooping and at the same time resting his foot on the patient's pelvis, should then raise his shoulders and draw the bone towards its socket.

Fig. 279. Dislocation Downwards and Outwards towards the Tuberosity below Tendon. (Bigelow.)

Dislocation downwards and outwards towards the tuberosity of the ischium is described by

Bigelow as closely allied to the dorsal dislocation below the tendon. It arises from *causes* similar to those giving rise to a dorsal dislocation, applied when the thigh is fully flexed on the abdomen. The head of the bone bursts out through the capsule and passes below the tendon of the obturator internus, rupturing the gemellus inferior and the quadratus, and comes to lie close to the tuberosity of the ischium. It can be felt in this situation; there is extreme flexion and adduction and rotation inwards (Fig. 279). On extending the limb, the neck of the bone remaining fixed by the dio-femoral ligament, the head passes upwards behind the tendon of the obturator internus, and the dislocation is thus converted into an ordinary "dorsal below the tendon."

Dislocations of the head of the femur directly backwards with fracture of the brim of the acetabulum may occur when a heavy weight falls on the back of a person who is kneeling. In this case the pelvis is drawn down violently on the femur, which is fixed against the ground at its lower end. The impact of the blow drives the posterior part of the brim of the acetabulum against the head of the femur, and this is thrust through the capsule at its posterior part. It is, perhaps, rather the pelvis that is thrust forwards than the femur backwards, but the result is the displacement of the head of the bone, which is lodged directly behind the cotyloid cavity.

2. Dislocations Downwards or Thyroid Dislocations.—*Causes.*—The dislocation appears to be occasioned by the limb being suddenly and violently abducted, as by falls with the legs widely separated; in consequence of which the head of the bone is tilted against the inner side of the capsule, and, rupturing this, is thrown on the thyroid foramen.

Pathological Anatomy.—The head of the bone escapes by a laceration of

Fig. 280. Thyroid Dislocation. (Bigelow.)

Fig. 281. Reduction by Manipulation in Femur Dislocation. Rotation and Circumduction Inwards of Head of Femur. (Bigelow.)

the inner side of the capsule where it is thin and membranous. The ilio-femoral ligament is un torn, and holds the root of the neck up while the head descends, and passes somewhat inwards, consequently the femur is flexed and abducted. The round ligament is torn. The pectineus and adductor brevis muscles have been found to be lacerated in this injury.

Symptoms.—The hip is flattened, and the prominence of the trochanter completely absent, or indeed replaced by a depression. The limb is lengthened by about two inches, advanced before the other, and considerably abducted (Fig. 280). The knee is bent and incapable of extension; the foot usually points forwards, but is sometimes slightly everted and widely separated from its fellow. When the patient stands, the body is bent forwards, partly to accommodate the pelvis to the flexed position of the limb dependent on the ilio-femoral ligament, and partly on account of the tension of the psoas and iliacus muscles; in a thin person the bone may be felt in its new situation.

When he lies on his back the knee is much raised, the thigh being flexed according to Bigelow to an angle of 35° .

Reduction by Manipulation may be done by rotation or traction as follows. *Traction* may be done thus: the Surgeon flexes the limb and abducts it, and then placing his foot upon the side of the pelvis, pulls or jerks the thigh in the direction in which the head is required to go to reach the socket. If more force is required a towel may be put round the lower part of the thigh. In *rotation* the limb, having been flexed on the abdomen so as to bring it into a perpendicular position, must be slightly abducted so as to disengage the head of the bone. The thigh is then to be strongly rotated inwards and adducted, the knee being carried towards the floor (Fig. 281).

Reduction by Extension is done as follows:—The patient is laid on his back; a counter-extending girth, or towel, is then placed round the pelvis and fixed firmly to a staple next to the sound side of the patient. A padded

Fig. 282.—Reduction of Dislocation into Thyroid Foramen by Extension.

girth is then to be placed between the perinaeum and the upper part of the dislocated thigh. From this, extension is made by means of the tourniquet or the pulleys, which are fixed to a staple at a little distance from the injured side of the patient. Extension having then been made to such a degree as to elevate the head of the bone from the depression in which it lies, the Surgeon passes his hand behind the sound leg, and, seizing the ankle of the injured limb, presses it backwards and draws it towards the mesial line, taking care to keep the knee straight, and thus throwing the head of the bone into the acetabulum by the action of a long lever (Fig. 282).

The following are more rare forms of dislocation downwards:—

The head of the thigh-bone may be thrown **directly downwards**, so as to rest on the lower margin of the acetabulum, between the sciatic notch and the thyroid foramen. Two cases of this injury have been recorded by Gurney at Camberne, and one by Luke. In it there is less eversion of the limb than

in the thyroid dislocation (Fig. 283). Bigelow has pointed out that the head of the bone, when thrown below the lower margin of the acetabulum, may be further displaced; either backwards on the dorsum ilii, or forwards to the thyroid foramen. In extreme flexion, however, the head may pass down as far as the *tuberosity or the ascending ramus of the ischium*; in the latter case the limb is everted, in the latter inverted, and in all cases flexed. The head of the bone may pass also **into the perineum**, so as to be felt in its abnormal situation behind the scrotum. It has been known to compress the urethra, and thus give rise to retention of urine. The thigh is extremely abducted and stands out at a right angle with the body; and the toes may be

Fig. 283. Dislocation directly downwards. (Bigelow.)

Fig. 284. Dislocation downwards and towards perineum. (Bigelow.)

either inverted or everted—which is ascribed by Bigelow to the want of firm bearing for the trochanter in the perineum (Fig. 284).

In the **Reduction by Manipulation** of these two rare forms of dislocation downwards, the thigh is to be bent and its head guided towards the socket. During this, the dislocation is sometimes converted into one of the thyroid or dorsal variety. In the dislocations downwards, vertical traction and slight inward rotation may be used; in the dislocations downwards and outwards, traction upwards and inwards, with abduction and rotation outwards; in the displacement downwards and inwards, traction upwards and outwards.

Probably allied to these forms of dislocation is that in which the head of the bone has been found thrown **downwards and backwards towards the lesser sciatic notch**. In these cases there is considerable shortening, but the position of the limb appears to vary. In an instance that occurred to Keate, the limb was abducted and the toes turned outwards. In a case reported by Wornald, the limb was turned inwards. Although the limb is described as shortened in these cases, Warren has related a case in which it was elongated.

Dislocation Upwards or Pubic Dislocation.—The cause of the dislocation is either direct violence applied to the back of the thigh while the limb is abducted; or it arises from the patient making a false step in walking, and suddenly throwing his body backwards in order to avoid a fall, twisting and displacing the limb.

Pathological Anatomy.—The capsule is lacerated at its inner aspect, the ilio-femoral ligament remaining entire and causing rotation of the limb outwards; the obturator internus is tense and holds the limb backwards, being the

chief agent in preventing flexion : the gemelli are stretched or torn, and the quadratus femoris has also been found to be ruptured. In one case related by Astley Cooper, Poupart's ligament was torn up, and in another the pectineus and adductors were torn ; but whether this was done by the dislocation or by the direct injury that occasioned it is uncertain.

Symptoms.—The dislocation upwards **on the Pubic Bone** presents very unequivocal signs. The hip is flattened ; the head of the bone can be distinctly felt lying in its new situation above Poupart's ligament, to the outer side of the femoral vessels, where it may be made to roll by rotating the limb. The thigh and knee are slightly flexed, rotated outwards, and abducted ; the

Fig. 285. Pubic Dislocation (Bigelow.)

Fig. 286. Pubic Dislocation. Head of Femur (from suspended by Y ligament.) (Bigelow.)

limb, which is separated from its fellow, is shortened to the extent of an inch (Figs. 285, 286).

The **Reduction by Manipulation** can be effected by traction and rotation, or by rotation alone. The former is effected by drawing the limb downwards, and at the same time raising it up so as to flex it gradually on the abdomen as the head of the femur becomes disengaged from its position. It may then be rotated inwards, and the head of the bone thus directed towards the acetabulum.

By *rotation*.—Bigelow recommends it to be thus accomplished : semi-flex the thigh so as to relax the ilio-femoral ligament and to bring the head down from the pubes ; then abduct and rotate inwards to disengage it completely ; lastly, while rotating inwards and drawing on the thigh, carry the knee inwards and downwards to its place by the side of its fellow.

With regard to the **Reduction by Extension**, Astley Cooper advises that the patient should lie upon his back with his legs widely separated ; and that, counter-extension being then made by a girth carried between the perineum and the injured thigh, and fixed to a staple in front of and above the body, the pulleys should be fixed upon the lower part of the thigh, and the

extension made downwards and backwards. After this has been continued for a sufficient time, an assistant lifts the head of the bone by means of a towel over the brim of the acetabulum (Fig. 287).

Fig. 287. Reduction of Pubic Dislocation by Extension.

The head of the thigh-bone may also be thrown **under the anterior inferior spinous process**, constituting the **Subspinous Dislocation** of Bigelow. There is shortening of the limb, which is everted, but less abducted

or advanced than in the dislocation on the pubes. The head of the bone can be felt in its new situation. One peculiarity of this dislocation is that in some of the recorded cases the patient has been able to walk immediately after the accident. Bigelow explains this by the position of the Y-ligament over the upper part of the neck of the femur (Fig. 288). Reduction of the dislocation is accomplished in the same way as in the pubic form.

Fig. 288. Subspinous Dislocation. The Y-ligament is stretched across the Neck of the Bone, which lies beneath it. (Bigelow.)

increased circumduction across the symphysis, with a little eversion if necessary to dislodge the head of the bone. By inward rotation, the head of the bone is thrown on the dorsum.

In the true *supraspinous dislocation*, the outer branch of the Y-ligament is ruptured; the limb is shortened and everted. In a case related by Cummins, the limb was shortened three inches. Reduction may be effected by circumduction inwards and eversion, by which the dislocation is rendered dorsal, and may then be reduced as already directed.

Everted Dorsal Dislocation may occur when, in dislocation on the dorsum, the outer branch of the Y-ligament is broken; the integrity of this portion being necessary for the inversion of the limb.

Irregular Dislocations of the head of the thigh-bone occur when the Y-ligament is wholly ruptured. The displacement may take place in any of the above-described directions; but the characters are inconstant.

Reduction of old Dislocations of the Hip-Joint is attended not only with great difficulty, but with no small amount of danger. The probability of effecting reduction rapidly decreases with the length of time that the bone has been left unreduced, and more rapidly in some dislocations than in others. Thus it is easier to reduce an old dislocation on the dorsum ili than one below the tendon of the obturator internus. Dislocation of the head of the thigh-bone on the dorsum of the ilium may usually be reduced without any great difficulty, up to the end of the first fortnight. After that time the difficulty increases considerably; and, although reduction has frequently been effected in these cases up to the sixth or eighth week, yet it has also not unfrequently failed, notwithstanding repeated attempts. After two months have elapsed, the reduction is a work not only of great uncertainty, but also of no slight danger from risk of suppuration in the soft parts, or fracture of the femur. But cases have been reported, and are referred to at p. 650, in which these dislocations have been reduced at a much later period, even as late as six or nine months. The method of manipulation should be employed with complete anaesthesia, and if this fail extension must be tried. In a case recently in University College Hospital under the care of Christopher Heath, a dorsal dislocation was successfully reduced by manipulation on the 106th day. The success which has followed operative interference in the reduction of old dislocations of the shoulder would seem to warrant the application of the same treatment in the case of the hip, should manipulation and extension fail. If the bone be left permanently unreduced, it will in time acquire considerable mobility, more particularly in the lower dorsal dislocation, the patient walking readily with a shortened but otherwise useful limb. Should the limb be useless from great adduction and flexion, relief might be given by subcutaneous section of the neck, which would restore parallelism of the limb. In the case of a thyrioid dislocation which had been unreduced for twenty months, W. MacCormic restored the utility of the limb by excising the head of the bone.

In the attempt to reduce old dislocations of the hip-joint the soft parts have been extensively lacerated in some cases; in others fatal inflammation around the joint has ensued; and, in twelve cases with which I am acquainted, the thigh-bone was fractured. This accident has happened to Surgeons of the highest eminence. In most of these cases the bone gave way at its neck or below the trochanters; the dislocation was of course left unreduced, but the patients recovered without difficulty, the fracture being treated in the usual way. The cause of the fracture appears usually to have been the employment of force in a transverse or rotatory manner, after extension had been kept up for some considerable time. There is no proof that undue violence was used in any of these cases. It is probable that in some the femur had become atrophied and weakened by disuse of the limb, thus readily snapping.

The Complication of Fracture of the Femur with Dislocation of the Hip-Joint occasions a very serious state of things that may baffle the efforts

of the most skilful Surgeon. The line of practice to be adopted must depend in a great measure on the seat of fracture. If this be below the middle of the thigh, the limb should be put up tightly in splints, and an attempt made under chloroform to reduce the dislocation in the ordinary way, by manipulation or by pulleys applied over the splints. If the fracture be high up, near or at the neck, the patient should be put under chloroform, and an attempt should then be made by pressure on the dislocated head and manipulation to replace it. It is possible that this might be effected, as in similar injuries of the humerus, with comparatively little trouble. Should reduction in this way not be practicable, we may adopt the plan successfully employed by Budley, who, in a lad of eighteen, with dislocation on the dorsum ili and fracture of the displaced bone, allowed union of the fracture to take place, and then, at the end of five weeks, effected reduction.

Simultaneous Dislocation of both Hips, in different directions, or of one hip with fracture of the opposite thigh-bone, has been met with in some rare instances.

Spontaneous Dislocation from distension of the joint is almost exclusively met with in the hip. In most cases it has occurred in children during an attack of acute rheumatism or typhoid fever. The patient having necessarily been confined to bed, and usually very ill, the accident has frequently been overlooked until he tried to walk some two or three weeks, or perhaps longer, after the dislocation occurred. In all recorded cases the head of the bone has been displaced backwards and upwards. The treatment of these cases is to attempt to reduce the dislocation by the ordinary means. If these fail, a very useful limb will usually be obtained by passive motion and the application of a weight-extension apparatus at night. If this fails, and the limb remains much adducted and useless, after a year or two the position of the limb may be greatly improved by excising the head of the bone, an operation which has been performed with excellent results by Rawdon of Liverpool, and Adams of London. There seems no reason, however, to adopt this somewhat severe proceeding till it is quite evident that a useful limb cannot be obtained without it. In a case of this kind in University College Hospital, a large extravasation of blood followed the attempted reduction, which finally suppurated. The incision to evacuate the pus exposed the head of the bone, which was accordingly removed, and the patient, a girl aged about twelve, made an excellent recovery with a useful limb, upon which she could bear the whole weight of her body.

Congenital Dislocation of the hip is by no means rare; it occurs most frequently in girls, and may affect either one hip or both. The dislocation is almost invariably on the dorsum ili, though other varieties have been met with. When it is double, the deformity, being symmetrical, is seldom recognized till the child begins to walk. The signs of the affection are in most cases clearly marked. The situation of the heads of the bones behind their natural position causes the pelvis when the patient is erect to be tilted forwards, carrying with it the last lumbar vertebra; to compensate for this there is a curve backwards in the upper lumbar and lower dorsal vertebrae. Thus the lumbar spine forms a very extreme curve, with its convexity forwards (lordosis); the trochanter is approximated to the anterior superior spine of the ilium, and the head of the bone may be seen on the dorsum ili; the thigh seems shortened and is more or less adducted, and the toes may be straight or

directed inwards; the patient walks fairly well, but with a peculiar rolling or "waddling" gait.

Treatment.—If the patient walks well, nothing is needed, beyond in some cases the use of a properly constructed support. This should consist of a padded metal belt encircling the pelvis between the trochanter and the iliac crest, and having a moulded leather cap to fit the upper end of the femur; from this a steel rod passes up to the armpit and carries a crutch by which part of the weight of the body is transmitted to the displaced bone. Adams, following the original suggestion of Pravaz, has endeavoured to reduce the upward displacement of the femur by prolonged extension applied in the recumbent position; whilst Barwell has divided the adductor and other muscles with the same object. Hoffa and König have endeavoured to construct a cotyloid cavity by turning down flaps of periosteum and bone from the surface of the ilium. It seems, however, that these and other severe measures which have been recommended, are unnecessary in the majority of cases. When, however, the displacement is such as seriously to interfere with the power of walking, extension, with perhaps the division of muscles, may be practised with advantage.

DISLOCATIONS OF THE PATELLA are not frequently met with. They may, however, occur in four directions, viz., *outwards, inwards, edgewise or vertically, and upwards.*

1. The dislocation **Outwards** is the most common variety of the accident; the bone being thrown upon the outer side of the external condyle of the femur, with its axis directed somewhat backwards and downwards, so that the inner margin is directed forwards. The knee is flattened in front, and is broader than usual; the patella can be felt in its new situation, and the muscles which form the quadriceps extensor are rendered tense, more especially the vastus internus; the leg is sometimes extended, but more frequently the knee is slightly flexed. This accident usually happens from sudden muscular contraction, especially in persons who are knock-kneed. In some cases it has been occasioned by direct violence driving the bone out of its position. Most frequently, the patella is only partially displaced outwards, with some rotation of the bone in the same direction.

Holthouse has recorded a case of *congenital* dislocation of the patella outwards, in a boy aged seven. The right patella was so displaced that its inner articular facet rested on the outer condyle, and when the knee was flexed the dislocation became complete. There was no inclination inwards of either knee. The mother alleged that the condition had existed from birth, and that at first both knees were affected. The boy could run and jump as well as other children.

2. The dislocation **Inwards** is very rare; Malgaigne could find record of only one case of the kind.

In these lateral dislocations, *Reduction* may be effected by laying the patient on his back, bending the thigh on the abdomen, and raising the leg so as to relax the extensor muscles. The Surgeon then, by pressing down that edge of the patella which is furthest from the middle of the joint, raises the other edge, which, being tilted over the condyles, is immediately drawn into position by the action of the extensors.

In a case, recently in University College Hospital, of dislocation of the patella outwards associated with genu valgum, Macewen's operation for the

cure of the latter did not relieve the dislocation. The displacement of the patella was stated to be congenital, and there was an imperfect development of the external condyle of the femur and of the trochlear surface. A perfect cure was obtained by Bilton Pollard as follows:—The vastus externus was divided through an external incision, the trochlear surface was enlarged and deepened with a chisel, and finally through an incision on the inner side a portion of the capsule of the joint was excised. After the operation the patella kept in its proper position even during complete flexion of the knee.

3. A remarkable form of dislocation of the patella is that in which this bone becomes twisted upon its axis in such a way that it is placed **Vertically**, one of its edges being fixed between the condyles, and the other projecting under the skin, and pushing this forwards into a distinct tumour. Streubel, who has collected 120 cases of dislocation of the patella, states that one-sixth of these were vertical, and in about two-thirds of these the outer edge was forwards. In some cases the bone has been turned almost completely round, the posterior articular surface becoming partly anterior. The signs of the dislocation are evident, manual examination indicating the vertical displacement of the patella, with a deep depression on each side. The limb is completely extended, flexion being impossible.

This dislocation has most generally arisen from sharp blows or severe falls upon one edge of the patella, whilst the limb has been semiflexed, in consequence of which the bone appears to have been semi-rotated and fixed in its new position. Violent muscular contraction, however, conjoined with a twist of the leg, but without any blow, has been known to produce it in some cases.

The **Reduction** of this displacement has sometimes been very difficult; in other cases it has been readily effected; whilst in two or three instances it has been found to be quite impracticable, in spite of attempts, by means of elevators and the section of the muscles or of the ligamentum patellæ, to replace the bone. The cause of this difficulty of reduction is not very clear; it is certainly much greater than can be explained by simple muscular contraction, and may not improbably be owing to the aponeurotic structures which cover the bone becoming twisted or entangled under it, or, as Mahzume supposes, to the superior angle of the bone being wedged in the *subcondylar* space. Forcible flexion of the knee under an anæsthetic followed by sudden extension, while the projecting edge of the bone is forced into its place, appears to have answered better than any other method of treatment, and will probably seldom fail. If this do not succeed, reduction may perhaps be effected by the patient making a sudden and violent muscular effort at extension of the limb, or attempting to walk. In other cases the bone has been readily replaced by bending the leg, and rotating it on the axis of the tibia, at the same time that the patella is pressed into position.

In no case in which subcutaneous section of the tendon of the quadriceps extensor and of the ligamentum patellæ has been practised does it appear to have facilitated reduction, and in one the patient died of septic inflammation of the knee-joint. Should all other measures fail, the Surgeon may expose the bone with strict antiseptic precautions and endeavour to replace it by the use of an elevator and the division of resisting structures.

4. Dislocation of the patella **Upwards** can occur only in consequence of the rupture of its ligament. This accident, which is always accompanied by

effusion into the joint, requires the same treatment as a fractured

DISLOCATIONS OF THE KNEE.—This joint, owing to the breadth of its articular surfaces, and the great strength of its ligaments, is seldom dislocated. If such an accident happens, it usually arises from falls from a great height, or by the patient jumping from a carriage in motion. The tibia may be dislocated in four directions: *to either side, forwards or backwards.* Besides complete displacements, the joint is subject to a partial luxation, dependent upon dislocation of one or both semilunar cartilages.

The **Lateral** dislocations of the tibia are the most common. They are *incomplete*, and are usually accompanied by a certain degree of rotation of the limb outwards. These displacements may be either **External** or **Internal**. In the first, the outer condyle of the femur rests upon the inner articular surface of the tibia; in the other, the inner condyle is placed upon the outer articular surface. In either case, the knee is slightly flexed; there is a marked sulcus in the situation of the ligamentum patellæ, and the deformity of the joint at once indicates the nature of the displacement.

In these cases *Reduction* is always easy; indeed, it is occasionally effected by the unaided efforts of the patient or by a bystander. It may be accomplished by flexing the thigh upon the abdomen, then extending the leg, and, at the same time, rotating the leg at the knee.

The dislocation **Backwards** may be *complete* or *incomplete*. When it is complete, the posterior ligament of the joint and the posterior crucial ligament are torn, the muscles of the ham are stretched, the limb is shortened to the extent of an inch and a half or two inches, and is semiflexed; the head of the tibia can be felt in the ham, and there is a deep transverse depression in front of the joint immediately below the patella.

The dislocation of the tibia **Forwards** is of more frequent occurrence than the last. In it, the lower end of the femur projects into the ham, compressing the vessels occasionally to such an extent as to arrest the circulation through the leg, lacerating the ligaments, and stretching the muscles in the situation. The tibia projects forwards, its head forming a considerable prominence on the anterior part of the knee, with a deep depression immediately above the patella, which is rendered more evident by the relaxation of the extensors of the thigh; the leg is usually rotated somewhat inwards or outwards, and there is shortening to the extent of about two inches.

These antero-posterior dislocations are very commonly incomplete. When incomplete, they present the same symptoms, but in a less marked degree, than which characterize the complete displacements.

The *Treatment* of these dislocations, extension should be made from the knee, whilst the thigh is fixed in a semiflexed position. When the leg has been drawn down sufficiently, proper manipulation will bring the bones into position; splints must then be applied and the joint kept at rest for two or three weeks, at the end of which time passive motion may be commenced.

Complications.—Dislocations of the knee-joint are more liable to serious complications than those of any other articulation. Not only are the ligaments and the muscles injured, but stretching, and perhaps laceration, of the arterial vessels, followed by gangrene of the limb, may occur; or the injury may be followed by destructive inflammation of the joint.

Compound Dislocation of the Knee-joint is one of the most serious

injuries to which the limbs are liable: the external wound being usually large, ragged, and accompanied by the protrusion of the condyles of the femur, with much laceration of the soft structures in the vicinity of the joint. These injuries, as a general rule, call imperatively for amputation: but cases have occurred in which the limb has been saved. Hence, if the patient be young, if the great vessels do not appear to have been seriously injured, and if the wound in the soft parts at the same time be not very extensive, nor much bruised, an attempt may be made to save the limb. In a case of this kind in a boy, A. White sawed off the end of the femur which protruded through the ham, and succeeded in saving the limb.

Congenital Dislocations of the Knee have occasionally been met with, with displacement of the tibia forwards. Cases of this kind have been recorded by Hilton, Guérin, Barwell, and Godlee. In some it was complicated by absence of the patella. In Barwell's case flexion was extremely limited, but by pushing the tibia backwards it could be carried to a considerable angle, and by fixing it in this position with a plaster of Paris bandage, the dislocation was completely cured at the end of six weeks.

Subluxation of the Knee, Displacement of a Semilunar Cartilage, or as it was termed by Hey "internal derangement of the knee-joint," is a common and very troublesome accident. It usually occurs whilst the knee is slightly flexed and the leg rotated inwards or outwards. Thus it may happen in rising from a kneeling position or in kicking a football (the limb affected being that upon which the patient is standing), or by striking the toe against a stone in walking. The patient is seized suddenly with acute and sickening pain in the knee, often so severe as to cause nausea or faintness. He may fall, but is conscious of having injured the knee before falling. On examination the limb will be found semiflexed and incapable of complete extension, any attempt to straighten it fully being attended with severe pain. In many cases a distinct fulness can be recognized on one side of the ligamentum patellæ in the hollow between the tibia and the femur, and there is tenderness at the same spot. In the course of a short time in most cases the joint becomes distended by inflammatory effusion.

This accident has been the subject of much investigation from the time it was first described by Hey. It has long been recognized that it is due to a displacement of one of the semilunar cartilages. The internal cartilage is far more commonly displaced than the external, although considering the firm attachments of the internal cartilage, the wide separation of its extremities and its considerable size, it might appear probable that the opposite would be the case. From anatomical considerations, Scott Lang is of opinion that the internal cartilage is displaced during flexion with rotation outwards, and the outer by flexion with rotation inwards. As the former is infinitely the more common movement, this would explain the comparative rarity of displacement of the outer cartilage. Usually the anterior extremity of the cartilage is partially displaced and loosened, but more rarely the dislocation is complete.

In a case of this kind found in the dissecting-room and recorded by Godlee, the external cartilage was completely torn away from its attachment to the capsule of the joint, and occupied a vertical position in the intercondylar fossa. Occasionally the cartilage is torn as well as displaced, and a portion may even be completely detached.

Reduction.—This can usually be effected by flexing the joint at the same time that a strain is put upon the knee in such a direction as would tend to separate the condyle of the femur from the tibia on the affected side. A movement of rotation should then be given, outwards if the external cartilage is displaced, and inwards if the inner, and at the same time the limb may be suddenly straightened. This may sometimes be done when the muscles are off their guard, the patient's attention being directed elsewhere, but more commonly an anæsthetic is required. The evidence of complete reduction consists in the restoration of the power of extending the articulation. The synovitis that usually follows this injury requires to be treated by fomentations and rest on a splint. The cartilage is not fixed again as firmly as it was before the accident, and in the great majority of cases recurrence of the displacement takes place at intervals. The best means of preventing this is to support the knee either with an elastic knee-cap or a flannel bandage firmly applied. Should reduction prove impossible, or should the displacement return immediately when the patient uses his limb again, it is useless to try to fix the cartilage by prolonged rest. The patient should begin to use his leg freely as soon as the synovitis has subsided, and after a time the displaced cartilage seems to accommodate itself to its new position, and may give no further trouble. In some cases, however, the patient is seriously crippled by the frequent recurrence of the dislocation and the synovitis which follows. Under these circumstances the joint may be opened and the cartilage stitched down, or, if this be impossible, the displaced portion may be excised. Most successful results have followed this treatment in the hands of Annandale, H. W. Allingham and others, but no Surgeon is justified in undertaking the operation, unless it be done with full antiseptic precautions.

Rupture of the Posterior Crucial Ligament is an accident that occasionally occurs as the result of a violent blow on the anterior aspect of the head of the tibia, such as may be received in a railway accident when the patient is thrown forwards against the opposite seat. The symptoms are at first effusion of blood and synovia into the injured joint. When this is absorbed, it will be found that the knee is weak, giving way slightly when flexed in walking. When the patient is seated with the knee flexed to a right angle, and the foot firmly planted on the ground, if the tibia be grasped at its upper end and moved backwards and forwards, it will be found to be capable of a slight displacement backwards into the ham. The *Treatment* consists in supporting the knee with a properly fitted apparatus.

The **Head of the Fibula** has occasionally, though very rarely, been displaced by direct violence. Boyer and Sanson have each recorded a case of this kind. One such case has occurred in my own practice. It happened in a gentleman about 28 years of age, who, in descending an Alpine slope covered with snow, fell with one leg bent forcibly under him, so that he came down, as it were, in a sitting posture. The head of the fibula was thrown back off the articulating surface, and remained permanently in its new situation. The limb was somewhat weakened, so that the patient could not jump, but otherwise he suffered no inconvenience. The tendon of the biceps was very tense; and when I saw the case, some time after the accident, its traction effectually prevented all attempts at reduction.

DISLOCATIONS OF THE ANKLE occur in consequence of displacement of the astragalus from the bones of the leg, whilst it continues to preserve its normal

connection with the rest of the foot. These dislocations are almost invariably connected with fracture of the lower end of the fibula, or of the inner malleolus. In fact, on looking at the arched cavity into which the astragalus is received, it is evident that this bone can scarcely be displaced laterally without fracture of one side of this arch. In considering these dislocations we must, in accordance with the general nomenclature of similar accidents, in which the distal part is always said to be displaced from the proximal, look upon the foot as being dislocated from the leg, and not consider the tibia as being displaced upon the foot. It is necessary to explain this, inasmuch as a good deal of ambiguity occurs in surgical writings from the same accident being described differently, according to the view taken of the part displaced. Thus, Astley Cooper speaks of the tibia as being dislocated at the ankle; whilst Boyer and others, regarding the foot as the part displaced, have described the same injury in directly opposite terms.

Dislocations of the foot from the bones of the leg may take place in four directions viz., *to either side, backwards, or forwards*. In all cases, the injury appears to be occasioned either by the foot being twisted under the patient in jumping or running; or else by its being suddenly arrested by coming into contact with the ground whilst the body is carried forwards. The lateral dislocations when simple are almost invariably incomplete, although rare cases have been recorded in which they were complete. Compound lateral dislocations, the result of extreme violence, are not uncommonly complete. The simple antero-posterior dislocations are more commonly complete.

The incomplete dislocation **Outwards** is of most frequent occurrence. The inner malleolus projects forcibly against the skin. The deltoid ligament is either ruptured, or the lower end of the inner malleolus broken off; there is a depression above the outer ankle corresponding to a fracture of the fibula; and the sole of the foot is turned upwards and outwards, the inner side touching the ground, whilst the outer edge is turned up. It is, in fact, merely a severe case of Pott's fracture (Fig. 235).

In the dislocation **Inwards**, which is a rare accident, the lower end of the tibia is splintered off in an oblique manner from within outwards, whilst the external lateral ligament is ruptured or the fibula broken. The outer edge of the sole rests against the ground, and the inner side is turned up. The astragalus is thus rotated on its longitudinal axis in such a way that the inner articular surface is in contact with the lower end of the tibia.

The *Reduction* of these lateral displacements is readily effected by traction on the foot, while the leg is flexed at the knee in order to relax the muscles of the calf; leg splints with lateral foot-pieces must then be put on, or Dupuytren's splint may be applied on the side opposite to that to which the foot is displaced.

In the dislocation of the foot **Backwards**, the deltoid ligament is ruptured, the fibula probably broken in the usual situation, and the tibia rests on the scaphoid and cuneiform bones; the foot consequently appears shortened, the heel rendered more projecting, and the toes pointing downwards.

Partial dislocation in this direction may occur without fracture, as the following case will show. A boy, aged about 14, wrestling with another felt his left foot give way and fell. He was unable to stand, and was at once brought to University College Hospital. Two hours afterwards there was no swelling about the ankle. The sole looked directly downwards, but the foot

was twisted outwards on the vertical axis of the astragalus for about 15° . The lower end of the tibia formed a distinct projection, most marked on the outer side. Beneath this was a corresponding hollow. The heel was thrown slightly backwards. Measured with a pair of calipers the distance from the tendo Achillis to the instep was increased by half an inch. The great toe was over-extended by the stretching of the extensor tendon and could not be flexed. The movements of the ankle were very limited. There was no fracture of either bone. Reduction was easily effected under chloroform.

The dislocation **Forwards**, in which the foot is lengthened, and the tibia rests upon the upper and posterior surface of the os calcis, behind the astragalus, is an accident of extreme rarity.

In the *Treatment* of these antero-posterior displacements of the ankle, traction of the foot in a proper direction, the leg being fixed and flexed upon the thigh, will readily effect replacement. Sometimes subcutaneous division of the tendo Achillis is necessary. The limb should afterwards be put up in a plaster of Paris or starched bandage for at least three weeks.

Compound Dislocations of the Ankle-joint are serious and by no means unfrequent accidents, the displacement occurring in the same direction and from the same causes as the simple forms of the injury.

In the *Treatment* of compound dislocations of the ankle an attempt should be made to save the limb in all cases in which the main vessels are sound, the soft parts not too extensively torn or the bones too widely splintered. Some efficient antiseptic method must be adopted and a successful result will usually be obtained. The limb should be firmly fixed to a single splint with a rectangular footpiece applied to the side opposite to the wound. If the bones are projecting and comminuted it may be necessary to remove the splinters, and possibly to saw off the malleoli in order to obtain a flat surface to rest on the astragalus, as was originally recommended by Hey. If antiseptic treatment is not available an attempt may still be made to save the limb if the soft parts be not too extensively injured. Astley Cooper, who was a strong advocate of conservative treatment in these cases, advised that the wound should be closed by means of a piece of lint soaked in the blood flowing from the wound. Should suppuration occur, the pus usually burrows widely beneath the muscles of the calf and secondary amputation may be necessary.

DISLOCATIONS OF THE ASTRAGALUS.—The astragalus is occasionally displaced from its connection with the bones of the leg above, and with those of the tarsus below, being thrown either *forwards* or *backwards*. These dislocations invariably happen from falls upon or twists of the foot; more particularly when it is extended upon the leg. When the foot is in this position, the lower end of the tibia either breaks off on the application of sufficient violence, or the head of the astragalus is forced out of the cavity of the scaphoid and its bed on the os calcis; the particular kind of displacement that occurs depending upon the direction in which the force is acting and in which the foot is twisted. Dislocation of the astragalus differs from dislocation of the foot in this, that when the foot is dislocated, the astragalus, though thrown out from under the malleolar arch, preserves its connections with the rest of the tarsus; whilst these are always broken through when the astragalus is the bone dislocated, even though it have not completely escaped from between the malleoli.

In the dislocation **Forwards**, the head of the bone may be thrown either

outwards or *inwards*, very seldom directly to the front : but I do not think there is any evidence to show that complete lateral dislocation of this bone can occur irrespective of displacement forwards : the so-called *lateral* dislocations being displacements of the bone forwards, with twists to one or the other side. The dislocation *forwards*, with lateral inclination, may be either *complete* or *incomplete*. When it is *complete*, the bone is thrown out of its bed on the calcaneum, and separated from its connections with the malleolar arch above and the scaphoid anteriorly, being forced in front of the tarsus, and lying upon the scaphoid and cuneiform bones. When the dislocation is *incomplete*, the head is separated from the scaphoid, and is thrown up on it, or on the external cuneiform or cuboid bones, the body of the astragalus maintaining its connections with the malleolar arch and os calcis. I agree with those who describe the displacement *forwards* and *outwards* as more common than that *forwards* and *inwards*.

In either case the displaced bone forms a distinct tumour upon the instep in the outline of which the form of the astragalus can be distinctly made out. Over this, the skin is so tightly drawn as often to appear to be on the point of bursting. When the bone is thrown somewhat inwards, the foot is turned outwards, and the internal malleolus projects distinctly. When the astragalus is thrown *outwards*, displacement of the foot inwards, with great projection of the lower end of the fibula, takes place. In some cases, fracture of the neck of the astragalus is combined with these dislocations : and not uncommonly the luxation is compound from the first, or speedily becomes so if left unreduced. in consequence of the sloughing of the skin which covers the anterior surface of the bone, the exposed portion of which undergoes necrosis.

The dislocation **Backwards**, into the hollow between the tendo Achillis and the tibia, is rare, there being, according to Hamilton, but twenty recorded cases. This form is, I believe, always complete, and in the majority of cases there is displacement of the bone *inwards*, as well as *backwards*.

Treatment.—The reduction of the dislocation *forwards*, whether attended with lateral displacement or not, varies greatly in facility ; in some instances being effected with the greatest possible ease, in others being attended with almost insurmountable difficulties. This difference depends, I think, on whether the dislocation is complete or not. When the astragalus is not completely thrown from under the arch formed by the bones of the leg, a portion of it being still entangled between their articular surfaces and that of the calcaneum, it may usually be readily reduced by relaxing the muscles of the calf, and pushing the bone back into its proper position. But when the astragalus is completely dislocated, the upper surface of the calcaneum is drawn up under the arch of the malleoli by all the strength of the muscles that pass from the leg to be inserted into the foot. In these circumstances, in order that reduction may take place, it is necessary first of all to separate the articular surfaces to such an extent as to admit of the astragalus being pushed back into its socket ; this is almost impossible, owing to the great perpendicular thickness of this bone, to the extent to which it is consequently necessary to draw down the foot, and to the little purchase that can be obtained on it. In such cases, reduction has been greatly facilitated by the division of the tendo Achillis, by which ample operation the whole strain of the muscles of the calf is taken off.

If reduction be still impracticable, and the bone continue irreducible on the dorsum of the foot, what should be done ? Two courses present them-

selves to the Surgeon : either at once to cut down upon the astragalus and to remove it ; or to put the limb at rest on a splint, and to wait the result. In some rare cases, the displaced astragalus has given rise to comparatively little inconvenience : but this can seldom be expected. If the dislocation have been in the direction forwards, the skin will usually slough and the displaced bone then will necrose and must be removed. In former times it was considered safer to leave the bone as long as possible before removal in the hope that the space between the tibia and the os calcis might have closed behind the displaced astragalus before it had to be taken away and that the operation would thus be reduced to a simple superficial incision. In the present day, with efficient antiseptic treatment, there is no fear of any trouble following immediate removal. If, therefore, the means for carrying out the treatment are at hand, the bone should at once be dissected out and the case treated like one of excision of the astragalus for disease.

In luxation *backwards*, the bone has not hitherto to my knowledge been reduced, except in one case which occurred in University College Hospital, in which the tibia and fibula were also fractured. It is by no means improbable that subcutaneous division of the tendo Achillis may in future

Fig. 289. - Dissection of Foot in Compound Dislocation of Astragalus outwards.

enable the Surgeon to effect reduction. The result is, however, satisfactory, even though the bone be not reduced, the patient recovering with a useful foot. If the dislocation be left unreduced, the soft parts covering the bone may slough, as happened in a case recorded by R. C. Williams of Dublin, in which the bone was consequently extracted.

In **Compound Dislocation of the Astragalus** (Fig. 289), the rule of practice must depend upon the extent of injury. If the integuments have merely been rent in consequence of the outward pressure of the displaced bone an attempt must be made to reduce the dislocation by the aid, if necessary, of the division of the tendo Achillis ; and, if this be effected, to close the wound by the first intention. If the bone be comminuted as well as dislocated, the proper practice will be to remove the loosened fragments, and to dress the wound antiseptically, allowing it to heal by granulation. If the bone be irreducible, it should at once be dissected out. If together with the dislocation of the astragalus, the foot be extensively crushed, amputation may be required either at the ankle-joint or at some convenient part of the leg.

SUBASTRAGALAR DISLOCATION.—In this injury, which is produced by causes similar to those occasioning dislocation of the astragalus, the calcaneum and

scaphoid, carrying with them the rest of the foot, are dislocated from the astragalus, which is left *in situ* under the malleolar arch. The displacement is most commonly in a direction *backwards*, with an inclination inwards or outwards. In these cases the nature of the injury is recognized by the backward displacement of the heel, whilst the astragalus retains its normal relations to the malleoli. The *Treatment* consists in flexion of the leg and attempts at reduction by extension applied to the foot in a direction forwards. If moderate extension fail, division of the tendo Achillis, and if necessary of other tendons, may be practised, on the same principle as in dislocation of the astragalus.

DISLOCATIONS OF THE OTHER TARSAI BONES are of extremely rare occurrence. Most of these bones, however, have been found luxated at times.

The **Calcaneum** has been dislocated laterally from its connection with the cuboid in consequence of falls from a height, the sufferer alighting upon his heel. Chelius mentions a case in which this bone was dislocated by the effort of drawing off a tight boot. *Reduction* seems to be readily effected by relaxing the muscles, and pressing the bone back into its proper position.

The **Scaphoid** and **Cuboid Bones** have been dislocated upwards, in consequence of a person jumping from a height and alighting upon the ball of the foot. In these instances the limb is shortened and curiously distorted, the toes pointing downwards, and the arch of the instep being increased so as to resemble closely enough the deformity of club-foot. *Reduction* may be effected by drawing and pressing the parts into position.

The **Internal Cuneiform Bone** has occasionally been found to be dislocated. Astley Cooper mentions an instance of the kind. If reduction be not effected by pressing the bone into its position, no great evil appears to result to the patient, the motions of the limb not being seriously interfered with.

Sometimes the tarsal joints are extensively torn open without any one bone being distinctly dislocated. I have seen this accident in the case of a young man who caught his foot between the spokes of a revolving wheel: the foot was violently bent and twisted, and all the tarsal joints more or less torn open, so as to necessitate amputation.

DISLOCATION OF THE METATARSAL BONES, though excessively rare from the manner in which they are locked into the tarsus, and retained by short and strong ligaments, yet occasionally occurs. Instances are recorded by Dupuytren and Smith; Liston mentions a case of luxation of the metatarsal bone of the great toe from direct violence; and Tuffnell records a case of luxation downwards and backwards of the inner three metatarsal bones, in a man whose horse fell and rolled over him. Two cases have occurred in my practice, in one of which, by the pressure of a "turn-table" on a railway, the *outer* three metatarsal bones were dislocated downwards. In the other, in consequence of a horse falling and rolling on its rider, there was a compound dislocation of the first, with a simple dislocation of the fourth, metatarsal bone. The question of amputation will always present itself in these cases, and must be determined on general principles, by the age of the patient, and the extent of injury to the soft parts.

Luxations of the *Phalanges of the Toes* but rarely happen, and present nothing special in nature or treatment.

INJURIES OF REGIONS.

CHAPTER XXIV.

INJURIES OF THE HEAD.

INJURIES of the Head are among the most important subjects that can engage the Surgeon's attention. Their importance is derived not so much from the injury of the scalp and skull, as from the implication of the brain in many cases directly, and in others indirectly and remotely. In consequence of this, it is of the first moment in practice to study these injuries as a whole, with special regard to the affections of the encephalon that are produced by them, and from which they derive the greater part of their interest.

INJURIES OF THE SCALP.

CONTUSIONS OF THE SCALP are of common occurrence, and present some peculiarities. However severe the contusion may be, the scalp seldom sloughs. This is owing to the great vascularity and consequent vitality of the integuments. In many cases, the contusion is followed by considerable extravasation of blood, raising up the scalp into a soft semi-fluctuating tumour. It occasionally happens, that this extravasation gives rise to the supposition that fracture exists, owing to the edge of the contusion feeling hard, whilst the centre is soft, causing an apparent depression of the subjacent bone. In some cases, indeed, this deceptive feeling will occur without any considerable extravasation of blood, the depressed centre being due to the compression of the scalp by the blow that has been inflicted upon it. This I have seen occasionally in children, in whom the scalp is soft. The difficulty of distinguishing between such an extravasation and a depression of bone is often so great as to mislead the most experienced Surgeons. Usually it can be effected by feeling the smooth bone at the bottom of the soft central depression. If seen soon after the accident the raised edge can usually be made to melt away under the finger by firm pressure, till the solid bone can be clearly felt beneath, at the same level as that in the centre of the swelling. But in case of doubt, if symptoms of compression of the brain are present, it will be safer to make an incision, and examine directly the state of the bone itself.

The **Treatment** of contusion of the scalp is very simple; the continuous application of evaporating lotions being usually sufficient for the removal of all effusion. As a rule no attempt should be made to remove the blood by puncturing the swelling, but if the amount is considerable, and more especially if it coagulates at the circumference, leaving a collection of fluid in the centre,

this may be removed by means of the aspirator. Contusions of the scalp in young women have been followed by severe neuralgic pains in the part struck which are extremely rebellious to treatment; but in two cases which I have seen, after lasting for a long time, they gradually disappeared. In such cases, incisions down to the bone are said to have been beneficial.

CEPHALHÆMATOMA.—It occasionally happens that bloody tumours of the scalp form in newly-born children, either from contusion of the head in consequence of the pressure to which it is subjected in its passage; or from bruising by obstetric instruments. These tumours, which are often large and fluctuating, are termed **cephalhæmatomata**. They may occur in two situations, either *between the aponeurotic structures of the scalp and the periosteum*, or *between this membrane and the bone*.

The **Subaponeurotic Cephalhæmatoma** is by far the most common variety. It usually forms a large, soft, fluctuating tumour, situated upon one of the parietal eminences, and having a somewhat indurated circumference. The tumour will usually subside in a few days under the use of a simple evaporating lotion.

The **Subperiosteal or Subpericranial Cephalhæmatoma** is an injury of somewhat rare occurrence. It appears as a fluctuating tumour, almost invariably seated on one parietal bone, most commonly the right, without decoloration of the scalp, but with a hard elevated circle around it, and a soft depressed centre, almost giving the sensation of a hole in the cranium. Pressure, however, gives rise to no cerebral symptoms, and enables the Surgeon to feel the bone at the bottom of the depression. These tumours are usually small, seldom more than two inches in diameter, and it occasionally happens that they are multiple. It is worthy of note, however, that each tumour is always confined to a separate bone, never passing beyond the sutures, where the adhesions between the periosteum and the bone are strongest. This affection is most frequently met with in children born in first confinements, and owing to the greater size of the head it is more common in boys than in girls; according to Bouchard, in the proportion of thirty-four to nine.

Pathology.—In this affection the periosteum is separated from the bone by an extravasation of blood, and both are covered with decolorised clot, but are otherwise healthy; the fluid in the centre is the serum from the coagulated blood. The hard circle surrounding the depression is formed by a deposit of osseous tissue in the angle formed by the raised periosteum and the bone beneath. This deposit is effected in such a way that, on a transverse section being made, the inner wall is found nearly perpendicular, whilst the outer slopes down upon the cranium, thus giving a crateriform appearance to the margin of the tumour.

Treatment.—In the majority of cases the blood is slowly absorbed and no treatment is required. If, however, absorption do not occur, aspiration will usually effect a cure. If it fails, the swelling must be punctured and a fine drainage-tube inserted with proper antiseptic precautions. If suppuration occurs, there is some risk of necrosis of the bone and intracranial mischief.

WOUNDS OF THE SCALP are often followed by serious consequences. They are divided into three classes—first, those not penetrating to the pericranial aponeurosis; secondly, those opening up the loose areolar tissue beneath that membrane without exposing the bone; and thirdly, those extending through the periosteum and denuding the bone. Scalp wounds are very common as

the result of drunken brawls or accidents amongst the lowest classes, and the heads on which they are inflicted are very often grimed with dirt and crusted with grease, while the patients are often broken down by dissipation and improper feeding. It is not surprising, therefore, that unless great care is taken in the treatment, erysipelas and other diffuse inflammations are very prone to follow these injuries. If these disturbing causes are absent scalp wounds usually heal with remarkable ease, even though the part be much bruised and lacerated, and sloughing rarely occurs, as the supply of blood is abundant and the vitality of the tissues high.

The *Complications* which may follow wounds of the scalp vary with the degree of the injury. In the first class, in which the pericranial aponeurosis is not wounded, no complications occur beyond those common to all similar injuries. In the second class, in which the pericranial aponeurosis is wounded, diffuse suppuration beneath that membrane is very prone to occur if strict asepsis be not maintained.

The pericranial aponeurosis or tendon of the occipito-frontalis muscle is firmly attached to the fat and fascia superficial to it, whilst it is very loosely connected with the parts underneath. This arrangement is often of great service in protecting the skull from fracture, especially when the head is caught between two solid bodies, as, for example, the wheel of a cart and the ground; the scalp is then torn off and the head slips away, thus escaping further injury. In suppuration occurring under the tendon of the occipito-frontalis, the pus gravitates to the most dependent parts until arrested by the attachments of the aponeurosis. These attachments are as follows:—Posteriorly, the fleshy bellies and tendon are attached to the superior curved line of the occipital bone, and to the mastoid process along the line of insertion of the sterno-mastoid. Laterally, the aponeurosis is thin, gives origin to the attollens and attrahens aurem, and in front of the ear runs down, superficial to the temporal fascia, to be attached, like it, to the zygoma; pus gravitating in this direction, therefore, forms a bag of fluid just above the zygoma, never extending into the cheek. In front, the fleshy fibres of the muscle are blended with those of the corrugator supercilii and the orbicularis palpebrarum, while in the middle line they are continued down over the nose into those of the pyramidalis nasi; the pus under this part will therefore collect in the upper eyelids, and in a pouch over the root of the nose.

When the wound is too tightly closed, either by sutures or by a pad of lint allowed to stick to it by the dried blood, the serous fluid, necessarily effused in the first few hours, forces its way into the loose areolar tissue beneath the pericranial aponeurosis. If the wound be small the fluid is usually absorbed, and healing takes place without trouble. Frequently, however, it distends the lymph-spaces and decomposes, and thus starts a spreading inflammation which may affect the whole of the subaponeurotic areolar tissue. This septic cellulitis commences usually about the third day after the injury, and terminates, as such inflammations generally do, in diffuse suppuration and sloughing of the cellular tissue. The scalp itself never sloughs, nor is the bone exposed by destruction of its periosteum. There is a general puffy swelling of the scalp and diffused redness, often extending over the face, and it is probable that this state of things has often been confounded with erysipelas, and has given rise to the idea that stitches in the scalp cause that disease. This condition is frequently fatal, especially in old people, unless

actively and efficiently treated; death occurring either from septic poisoning, pyæmia, or exhaustion.

It is important to make the diagnosis between erysipelas of the scalp and diffuse suppuration beneath the pericranial aponeurosis, as the treatment of the two conditions is very different. In *erysipelas* there is a characteristic invasion (see Chap. XXXII.); the redness and swelling, when they appear on the face, can be seen to have a sharply defined margin, and they spread to extend beyond the limits of the pericranial aponeurosis, reaching to the cheeks or mouth, and very commonly involving the pinna of the ear. The lymphatic glands at the upper part of the neck are swollen and tender. In *diffuse cellulitis beneath the aponeurosis*, the swelling does not go beyond the limits of that membrane; the blush that may extend beyond is of small extent, and has a diffused margin; the pinna of the ear is not affected, and the lymphatic glands are not swollen.

In the first and second classes of scalp wounds there is no special tendency to cerebral complications of any kind when the brain is not injured by the same violence that inflicts the wound.

In the third class of scalp wounds in which the bone is exposed, and perhaps denuded for some extent, healing as a rule takes place readily enough if drainage is maintained and asepsis secured. Should a part of the injured scalp be torn away or slough, and a portion of the skull be exposed, exfoliation of the outer table, though probable, does not necessarily occur; for in many cases granulations will spring up on the exposed bone, which still receives vascular supply from the diploë, and thus healing will take place.

If decomposition of the discharges and suppuration occur in a wound laying bare the bone, the patient is exposed to various dangers beyond diffuse suppuration beneath the aponeurosis. The bare bone, being bathed in septic pus, is not unlikely to necrose. Should this happen, the dead portion separates in most cases without further evil consequences, but until this has taken place the patient can never be considered out of danger. The complications to which he is liable are caused by the septic matter penetrating the dead outer table and affecting deeper parts. In this way a diffuse septic inflammation may be set up in the diploë (septic osteomyelitis), and should this happen death from septicæmia or pyæmia is almost inevitable. After death in such a case, on chiselling away the outer table, the diploë will be found to be soaked in offensive pus, and the large veins that lie in it will be seen to contain softening thrombi, portions of which have been washed on into the blood-stream and given rise to abscesses in the lungs or other viscera. All forms of pyæmia and septicæmia are met with in these cases, and the symptoms differ in no respect from those which occur in blood-poisoning from other wounds. (See Chapter XXXIII.) The older writers on Surgery had noted and had marvelled at the strange phenomenon of hepatic abscesses following such head injuries, but had generally overlooked the occurrence of secondary deposits in other organs and structures. There is, however, no reason to believe that hepatic abscesses are more common in pyæmia after head injuries than in that arising from any other injury. In eighteen cases Prescott Hewett found the lungs studded with abscesses in thirteen, and the liver in three; and of these three, in one case only was the liver alone affected.

The second great complication of scalp wounds exposing the bone is *intracranial suppuration*. It may occur with diffuse septic inflammation of the

diploë, but is more frequently met with independently of this. The pus may be situated immediately beneath the injured bone superficial to the dura mater, on the surface of the brain beneath the dura mater, or more deeply in the cerebral substance. The symptoms and treatment of this complication will be more conveniently considered with intracranial suppuration in general (*p. 774 et seq.*)

Treatment of Scalp Wounds.—From what has already been said it will be evident, that in cases of wound of the scalp not complicated by injury to the brain, the essentials of treatment are to avoid retention of the discharges and to prevent their putrefaction. In all cases the parts around the wound must be shaved for a sufficient distance. The wound may then be plugged with a piece of sponge soaked in some efficient antiseptic fluid, carbolic acid lotion (1 in 20), or perchloride of mercury (1 in 1,000) being the best, while the scalp around it and the remaining hair are washed with hot water and soap, or sponged with a weak solution of ammonia, and afterwards thoroughly soaked in the antiseptic fluid. If there be arterial hæmorrhage it may, if slight in amount, be arrested by the pressure of the dressing, the firm bone beneath affording excellent counter-pressure. Should the bleeding be more free, the vessels must be secured by ligature or torsion. In doing this some trouble may be caused by the density of the tissues in which the vessels are lying. Should other means fail, or not be at hand, a pin may be passed beneath the artery, and compression made over it by a figure-of-8 suture. The scalp having been cleaned, and the bleeding stopped, the wound itself may again be thoroughly cleansed with the antiseptic lotion and its edges brought together. In doing this, strapping should not be used. It seldom adheres well on the scalp, and tends to shut in the discharges. In small wounds, as the rigid tissues of the scalp have little tendency to gape, the mere pressure of the dressing will bring the edges in contact. In larger wounds, silk, horse-hair, or silver-wire sutures may be inserted. The use of sutures has been deprecated by many Surgeons in injuries of the scalp, as tending to favour erysipelas; undoubtedly, much mischief will arise if the wound be stitched up too closely and septic matter accumulate in it, and in small wounds sutures are generally unnecessary, but in extensive lacerations they cannot be dispensed with. In the majority of cases, dry dressings will be found most efficient. The wound may be sprinkled with iodoform, and a large pad of iodoform wool, salicylic wool or silk, sal alembroth gauze or wool, or some other dry absorbent antiseptic preparation, may be applied, and secured with a bandage, so to exert a moderately firm elastic pressure and to retain the separated parts in apposition and at perfect rest, while at the same time the accumulation of discharges is prevented. Drainage-tubes are seldom required if too many stitches be not put in. Such a dressing may frequently be left untouched for a week or ten days, at the end of which time union will be perfect. The indications for removing it earlier are a smell of putrefaction, a rise of temperature, pain, or a puffy swelling of the scalp beyond the dressing. The patient should be freely purged, and kept at rest on a rather low diet: any cerebral symptoms that occur being treated in accordance with the principles laid down in discussing traumatic affections of the brain. In this way, union will very probably take place through the greater portion of the injured surface; should it not do so, however, or should any part slough, granulations spring up, and repair goes on with surprising rapidity.

It frequently happens that the scalp is bruised and lacerated as well as wounded: and very commonly a large flap of integument is stripped off the skull, and is thrown down over the face or ear. In these cases, advantage is taken of the great vitality of the scalp. However extensively lacerated this may be, however much it may be begrimed with dirt, it is a golden rule in surgery not to cut any portion of it away, but, after shaving the head and ligaturing any bleeding vessels, to clean it thoroughly, and replace the flap in its proper position.

Should suppuration occur beneath the pericranial aponeurosis in con-

Fig. 290.—Head showing Lines for Incisions in Diffuse Cellulitis beneath the Pericranial Aponeurosis.

sequence of the antiseptic treatment having failed, and the wound being too tightly closed, active and efficient treatment is necessary to save the patient from the dangers of septæmia or pyæmia. As soon as pain, with some swelling round the wound and elevation of temperature, raises a suspicion that diffuse inflammation is spreading from the wound, all dressings should be removed. It will frequently be found that the edges of the wound are adhering to each other; if this be the case, they must be separated with a director, when a small quantity of the offensive pus frequently escapes. A fomentation of borie acid lint or salicylic wool may then be applied, and covered over

with oil-silk, and over this a sheet of cotton wool and a bandage. This must be changed about every four hours. In most cases this treatment will be successful in arresting the unhealthy inflammation, but should it fail and the cellulitis extend more widely, it will be necessary to make free incisions, reaching through the pericranial aponeurosis wherever the inflammation has extended. Before doing this the head must be completely shaved, without which cleanliness is impossible. It is more essential that this should be done in women even than in men, however much they may object, as their hair is longer. The incisions should be each about one inch in length, and should vary in number according to the extent of the mischief. They must be carefully planned so as to avoid the main arteries (Fig. 290). After bleeding has been arrested hot dressings must be applied as before described.

Simple erysipelas after a scalp wound presents nothing special in its treatment.

When the skull itself is extensively denuded in consequence of the pericranium being stripped off the subjacent bone together with a flap of the scalp it does not necessarily follow that necrosis and exfoliation of the exposed bone will occur. The flap must be laid down on the denuded osseous surface, to which it may possibly contract adhesion through the medium of granulations.

The treatment of intracranial suppuration will be considered later on (p. 774).

INJURIES OF THE SKULL.

These possess great interest, not so much from the lesion of the bone itself, as from its frequent complication with injury of the brain and its membranes.

This cerebral complication may either be produced by direct injury, the fragments of the fractured bone compressing or wounding the brain; or it may be the result of concussion or laceration of the brain by the same violence that causes the fracture.

BENDING-IN OF THE CRANIAL BONES WITHOUT FRACTURE is an accident that may occur in infants and young children, before the bones of the skull are completely ossified. In several instances, the displaced bone has been raised by aspiration with an india-rubber sucker. But no harm comes of leaving the bone depressed, as it will generally recover its proper level in time.

CONTUSION OF THE CRANIAL BONES without fracture, occasioned either by ordinary direct violence or by the oblique impact of bullets, is a very serious injury, more particularly when complicated with wound of the scalp. In it there are four sources of danger, any one of which may be followed by a fatal result; viz.: 1. Necrosis of the part of the bone struck, leading to exfoliation of the outer table, or to separation of the whole thickness of the cranium and exposure of the dura mater; 2. Suppuration under the bone, between it and the dura mater; 3. Pyæmia with secondary visceral abscesses, consequent on suppuration of the diploë around the necrosed point of bone, and septic thrombosis of the cranial veins,—a condition to which reference has already been made; and, 4. Laceration of the brain immediately beneath the point struck, or at the corresponding spot on the opposite side of the brain. The former condition occurs only when the blow is very violent, sudden, and limited to a small area, as when the skull is grazed by a bullet. Under other circumstances the chief laceration is always on the opposite side of the brain.

The following statement, taken from the records of the War Department of the United States army, gives a good summary of the results of gunshot contusions of the skull without fracture, or, at any rate, in which the fracture was limited to the inner table. In many of these there was without doubt some superficial laceration or bruising of the brain.

Of 328 cases, 55 died, 173 were disabled, 100 recovered. The deaths arose from hæmorrhage, 2; tetanus, 4; pyæmia, 4; dysentery and fever, 8; compression from blood or pus, 17; various intracranial injuries, 20. These injuries appeared to be most dangerous in the temporal and frontal regions, and least so in the occipital.

Amongst the 173 disabled, the following complications are specified as the causes of the disability:—

Persistent pain in the head, 10; paralysis of limbs, more or less marked, 23; impairment of vision, 16 (wounds mostly in the frontal region); impairment of hearing, 14 (wounds mostly in parietal and temporal regions, but some frontal and some occipital); epilepsy, 9; insanity, 10. Vertigo, giddiness, and dizziness were some of the commonest complaints among pensioners.

FRACTURES OF THE SKULL are invariably the result of external violence. This may act *directly* in breaking and splintering the part struck, the fissures often extending to a considerable distance and detaching large portions of the skull; or the violence may act in an *indirect* manner, producing the fracture either without being applied immediately to the cranium, or else at an opposite part of the skull to that which is struck. Thus the base of the skull may be fractured by the shock communicated to it when a person, falling from a height, strikes the ground heavily with his feet. A somewhat doubtful variety of indirect fracture in which the lesion occurs at a point of the skull

opposite to that which has been struck has received the name of Fracture by Contrecoup.

Fracture by Contrecoup has been described by some Surgeons as of frequent occurrence, whilst it has been denied by others. Aran laid down as an absolute rule that all fissured fractures without exception start from the point in the skull to which the violence has been applied. Every hospital Surgeon must, however, occasionally have met with fissures, especially in the thin parts of the base of the skull, which could not be traced to the point in the vault which directly received the injury, though such cases are undoubtedly rare. Moreover, it must not be concluded at once that such fissures are the result of *contrecoup*. A man may receive a violent blow on the frontal bone, wounding the scalp, and the fracture may be found in the occipital region. In such a case, it often happens that the fissure was really caused by a blow on the back of the head received in falling. In other cases in which the patient falls directly on the vertex and fractures the base of the skull, the fracture is often caused by the weight of the body communicated through the vertebral column to the condyles of the occipital bone. It has been shown experimentally by C. Bell, Bruns, and Felizet, that the skull possesses a considerable degree of elasticity, and that when a violent force, such as a blow acting on a considerable extent of the surface, or powerful pressure is applied to it, it undergoes an alteration in shape not merely at the point struck, but as a whole. There is a shortening of the diameter corresponding to the direction of the force, with lengthening of the other diameters. Thus, a force applied to the vertex tends to shorten the vertical diameter, and to cause a corresponding lengthening of the antero-posterior and transverse diameters. A skull in this way squeezed out of shape may yield at the weakest part, and a fissure may thus be formed at a point remote from that to which the force was applied, although much more commonly the blow determines the starting point of the fissure. That the fissures in a fractured skull may actually gape at the moment, and close again as soon as the force ceases to act, is occasionally proved by the presence of foreign bodies tightly grasped in them. Thus, hairs have been found firmly held in the crack, and Hoffmann records a case in which a fold of dura mater was nipped in a fissured fracture. The rending force thus exerted by the compression of the skull in one direction and its elongation in another, explains more readily than any other theory the distance to which a fissure often extends, and the way in which it frequently follows for a certain distance along the line of a suture, entering the solid bone again when the suture comes to an end, and also the fact that a foramen, even the foramen magnum, offers no impediment to the extension of the fracture.

In certain cases the thin orbital plates of the frontal bone have been found to be fissured after violent blows on the back of the head, and in these it has been suggested that the fractures resulted from the impact of the brain substance driven against the bone by the force of the blow.

If all these different forms of fracture be excluded, but little is left that needs the theory of *contrecoup* for its explanation.

Although, therefore, Aran's rule, that all fissures radiate from the point struck, is not absolutely accurate, yet it is so nearly true that it forms the best guide we have to the course of a fracture. Thus, if we have clear evidence that a man has received a blow on the parietal eminence and he has profuse bleeding from the nose, we may reasonably conclude that the fracture roughly

corresponds to a line drawn from the point struck to the cribriform plate. In a case under my care in University College Hospital the patient had received a violent blow, not causing a wound, on the right occipital region, and was bleeding freely from the left ear. Soon after admission the respiration became greatly embarrassed without any signs of general compression of the brain. Following Aran's rule, the diagnosis made was, that a fissured fracture crossed the foramen magnum, and that extravasated blood was pressing on the medulla oblongata; a conclusion which was confirmed by the *post-mortem* examination.

FISSURED FRACTURE.—An ordinary **undepressed fracture** of the skull consists in a fissure, sometimes single, at other times starred, extending often to a considerable distance through the bones, radiating sometimes across the skull, and in other cases completely detaching its upper from its lower part, or its anterior from its posterior segment. In some cases the fracture extends into one of the sutures; and in other instances, which, however, are very rare, the sutures are separated without any fracture.

A fissured fracture usually results from direct violence, but is also the only form of fracture that can be supposed to arise by *contrecoup*. A fissure gives rise to no signs by which its diagnosis can be effected, and often escapes detection altogether, more particularly when the scalp covering it is not wounded; or when so large a quantity of blood is extravasated as to render it impossible for the Surgeon to feel the subjacent bone. If, however, the scalp covering the injured bone have been wounded, the existence of a fracture may be ascertained by running the finger-nail, or the end of a probe, over the exposed surface of the bone, or by seeing a fissure which remains filled with blood after wiping the surface, or from which blood may be freely oozing.

As the whole importance and danger of fracture of the skull depend, not upon the injury that the bone has sustained, but on the concomitant or secondary lesions of which the contents of the cranium may be the seat, no special *Treatment* is required for the fracture itself when simple and undepressed, the Surgeon's whole attention being directed to the injury that may have been inflicted on the brain or scalp. Should the fracture be compound the patient's head must be completely shaved and cleaned as before described (p. 719), and the wound should then be carefully cleansed with carbolic lotion (1 in 20), or perchloride of mercury (1 in 1000), and some efficient antiseptic dressing applied (p. 720). The patient's safety depends to a great extent upon the prevention of decomposition. In all fissured fractures there is necessarily some blood extravasated between the dura mater and the bone, as well as in the diploe, supposing the fracture to be in a part where this exists. If this extravasated blood should decompose, the patient would run all the dangers of suppurative inflammation between the dura mater and bone or septic inflammation of the diploe. Moreover, it is always possible that the dura mater may be torn even beneath a simple fissure, though fortunately this is rare. Should this, however, have taken place, and decomposition of the discharges occur, the danger of septic meningitis setting in is very great: and should this happen, the death of the patient is a certain consequence.

Although the most important precautionary measures for guarding against inflammation of the brain and its membranes are doubtless those intended to prevent septic processes in the wound, yet other measures should on no account be neglected. The head should be shaved if this has not already been done in dressing the wound, and cold may be applied. This can easily be done

over the carbolic gauze dressing or over the carbolic oil, but it can hardly be efficiently employed over iodoform or salicylic wool: and this, perhaps, in some cases forms an objection to their use. Care must always be taken not to soak the dressing with water oozing through a half-putrid bladder; the india-rubber ice-cap should be used when possible, or if that be not at hand a common sponge-bag will answer the purpose fairly well. The bowels should be well opened, and the room kept cool and quiet. Should any symptoms of inflammation of the brain make their appearance, free, and if need be, repeated bleeding is, perhaps, of more service than any other means, and should never be omitted, except in feeble, very young, or aged subjects.

Simple fissured fractures of the vault of the skull in infants and young children are, in rare cases, followed by the formation of a fluctuating tumour under the scalp containing cerebro-spinal fluid. Such cases have been recorded by W. Haward, R. C. Lucas, T. Smith, R. J. Godlee and others, and P. S. Conner has suggested the name of **Traumatic Cephalhydrocele** for the condition. The tumour becomes tense when the child cries, and can be slightly diminished by pressure, but not without causing some signs of cerebral disturbance. In most cases it pulsates distinctly, synchronously with the heart. The tumour usually appeared soon after the injury, and has often been mistaken at first for a cephalhematoma. According to Conner about half the recorded cases have recovered, but the patients have been left with more or less marked irritability of temper or other signs of cerebral mischief. The remainder died sooner or later, usually with symptoms of meningitis. In a few cases the child has been the subject of chronic hydrocephalus, although in this condition the thinned and expanded cranial bones being at the same time preternaturally elastic and mobile, are seldom fractured. In one case however that was under my care, a hydrocephalic child fell from the top of a house on to its head, and sustained a long fracture through the left side of the skull, but without any scalp wound. Shortly after the accident, a large soft fluctuating tumour formed under the scalp opposite the line of fracture: and, on this being tapped, about three ounces of cerebro-spinal fluid were drawn off. This operation was repeated, but the child died about ten days after the injury, with hemiplegia of the opposite side, and convulsions.

In the fatal cases a fissured fracture has been found most commonly in the parietal, temporal and frontal regions. In several the fracture was gaping to the extent of half an inch or more, and in these the margins of the fissure seem to have been absorbed and not merely to have been separated by intracranial pressure. In all cases the dura mater was torn in the line of the fissure, a condition which is not to be wondered at when we consider the firm adhesion of that membrane to the bone in young children. In a majority of the cases the brain substance beneath the fissure was also lacerated, and in some even to the extent of opening up the descending cornu of the lateral sinus. In these cases there can be no doubt that the fluid in the tumour is derived from the subarachnoid space. The treatment of this condition is very unsatisfactory, and from the evidence before us it seems much better to leave the tumour to mature unless it threatens to give way, which does not seem a common accident. The tumour may then be aspirated, and if this fails to do any good, as it probably will, a small puncture may be made and a fine drainage tube inserted as a last resource.

FRacture OF THE BASE OF THE SKULL.—The most serious, and indeed a

very commonly fatal form of fracture of the skull, is that which extends through its *base*. It may occur in three ways. 1. It is usually caused by direct violence, as by a fall or a blow upon the vertex or side of the head, producing a fracture which extends from the point struck across to the base of the skull (p. 722). 2. It may possibly take place as the result of *contrecoup*, the blow being received on the forehead, back, or side of the head, and the jar of the bones expending its greatest violence on and fracturing the base of the skull; although as before stated (p. 722), there is but little evidence of this form of fracture; and 3, by the impact of the spine against the condyles of the occipital bone causing a fracture that radiates from the foramen magnum. This kind of fracture of the bone is well illustrated by the annexed cuts (Figs. 291, 292), taken from patients of mine who fell from a height on the head. The effects will vary according to the character of the

Fig. 291. Splintering of edges of the Foramen Magnum and Radiating Fracture of Base of Skull from Fall on Vertex.

Fig. 292. Fracture of Base by Fall on Vertex. Both Condyles broken off and driven in. Vertex was fissured.

surface on which the person falls. If hard, as on stone, the vertex will be smashed in, and if there be fracture of the base, it will be occasioned in the first way. If the head strikes soft ground, the body will be violently projected against the base of the skull, and the third variety of fracture may be occasioned by the force of the impact. One great danger in fracture of the base arises from the concomitant injury to the brain, either by direct laceration or by the extravasation of blood on its under surface. The important nervous centres that lie directly upon the parts of the skull that are broken are specially liable to injury, and free hæmorrhage often takes place from a torn sinus or a ruptured cerebral artery. Another danger of equal importance is septic meningitis, which is a cause of death in a considerable number of these cases. Its occurrence is explained by the fact that a very large proportion of all fractures of the base of the skull are compound. All cases which implicate the tympanum with rupture of the membrana tympani, all those which fracture the basilar process and tear the mucous membrane at the upper part of the

pharynx, and all those implicating the sphenoidal sinus and the cribriform plate of the ethmoid are compound fractures, and are exposed to all the accidents to which those injuries are liable. A good example of the way in which such injuries may prove fatal occurred in a case under my care in 1872. The patient was a woman, aged twenty-seven, who fell from a first-floor window into the street below. She received a violent blow on the face, fracturing the upper and lower jaws, the zygomatic arches, and the nasal bones. She soon recovered consciousness, and showed no signs of serious cerebral injury. However, on the second day symptoms of meningitis set in, and on the third day she died comatose. The *post-mortem* examination showed the usual signs of septic meningitis, and the source of the mischief was found to be a small puncture of the dura mater made by a triangular fragment of the thin bony roof of the sphenoidal sinus which had become displaced vertically, opening up the sinus below by tearing the mucous membrane. The fragment was isolated by the branches of a fissured fracture which extended backwards from the frontal bone, but at no other part was the dura mater injured. The brain showed superficial bruises in the frontal lobes.

Fractures of the Base, though very frequently fatal, are not invariably so. Not only does it occasionally happen that patients with all the signs of fracture of the base of the skull make a complete recovery, but in the different Museums specimens illustrative of repair after this accident may be met with. Thus, in the Museum of the Royal College of Surgeons, there is the skull of a person who lived two years after a fracture of this kind.

Signs.—Fracture of the base of the skull is very commonly suspected when

Fig. 293. Fracture of Base of Skull proving fatal by injury to Medulla.

symptoms indicative of serious injury to the brain speedily follow a severe blow upon the head. Those parts of the nervous centres that are most important to life are more liable to injury in this than in other fractures of the skull; the same violence that occasions the fracture injuring the contiguous portions of brain, or lacerating some of the large venous sinuses at the base of the skull, and thus giving rise to abundant intracranial extravasation of blood. The patient whose skull is represented in Fig. 293 died from injury to the medulla oblongata and hæmorrhage into its substance; a result which can hardly be wondered at, when the splintered condition of the margin of the foramen magnum is taken in consideration. There was no other serious injury to the brain. After a short period of unconsciousness, the patient became noisy and talkative, and was somewhat troublesome on his way to the hospital, but almost immediately after admission, his respiration and pulse failed, and he died in half an hour or less from the time of the accident.

The signs of fracture of the base of the skull will necessarily vary according to the seat of injury. When the fissure extends through the *anterior fossa*, there may be extravasation of blood into the orbit or beneath the conjunctiva, or free hæmorrhage from the nose. When it implicates the *middle fossa*, there is, very frequently, fracture of the petrous portion of the temporal bone, with rupture of the tympanic membrane, and then there will be bleeding or a watery discharge from the ears. When the *posterior fossa* is the seat of fracture, the signs are more equivocal. In some cases, however, discoloration of the skin from extravasated blood behind the mastoid process and at the back of the neck, when there has been no direct injury in that situation, may indicate the situation of the fissure.

There are two signs, the occurrence of which, separately or together, affords strong presumptive evidence of the existence of this kind of fracture: 1. The Escape of Blood from the interior of the Cranium through the ears, nose, or into the orbit; and 2. The Discharge of a Serous Fluid from the Ears, and occasionally from other parts in connection with the base of the skull.

1. The occurrence of **Bleeding from one or both Ears** after an injury of the head cannot by itself be considered a sign of much importance, as it may arise from any violence by which the membrana tympani is ruptured, or the cartilage of the pinna separated from the bone, without the skull necessarily being fractured. If, however, the hæmorrhage be considerable, trickling slowly out of the external auditory meatus in a continuous stream; if the blood with which the external ear is filled pulsate; and more especially if the bleeding last for three or four hours and be associated with other symptoms indicative of serious mischief within the head, and if it have been occasioned by a degree

Fig. 294. Fracture of Temporal Bone passing through the Tympanum and tearing the Meningeal Artery (A).

of violence sufficient to fracture the skull, we may look upon the hæmorrhage as strong evidence that a fracture of the base, extending into the petrous portion of the temporal bone, has taken place, and that, perhaps, one of the venous sinuses in its neighbourhood is torn (Fig. 294). The evidence, however, is only presumptive; it is not positive as to fracture of the base of the skull through its petrous portion, nor indeed of any intracranial injury whatever. Copious hæmorrhage from the ear to the extent of many ounces has been known to occur from a fracture of the anterior and inferior part of the meatus auditorius externus, in consequence of the condyle of the lower jaw being forcibly driven up against it, the jaw itself having been fractured.

Hæmorrhage into the Areolar Tissue of the Orbit and Eyelid. giving rise to extensive ecchymosis of the lid, possibly with protrusion of the eyeball itself, often accompanies fracture of the orbital plate of the frontal bone. The ecchymosis that occurs in these cases arises from the filtration of blood from the interior of the skull, through the fracture, into the loose areolar tissue adjacent to the injured bone. It differs remarkably in appearance from an ordinary "black eye." In the latter case, the extravasated blood lies in the subcutaneous tissue immediately beneath the skin, and sometimes the skin of the lids is also bruised, giving them a reddish-purple colour, but the blood does not find its way to the subconjunctival tissue, being shut off by the attachment of the palpebral ligament to the margin of the orbit. In the ecchymosis from fracture the extravasated blood advances from the orbit, and is shut off from the subcutaneous tissue of the lids by the palpebral ligament, while it readily finds its way beneath the conjunctiva. In the more severe cases the lids may be tense, greatly swollen, and of a bluish-purple colour, the subconjunctival tissue may be distended with blood, and the eyeball distinctly protruded. It is only when abundant that subconjunctival hæmorrhage is of any value in the diagnosis of fracture. A small extravasation may be the result of a direct blow on the eyeball, or a conjunctival vessel may have ruptured during the violent exertion which may have accompanied the accident. In well-marked cases the hæmorrhage may be venous or arterial. When venous, it probably arises from a fracture implicating the body of the sphenoid bone, and tearing the wall of the cavernous sinus. When arterial, it may, as Hewett has shown, be the forerunner of a circumscribed traumatic aneurism of the orbit.

Bleeding from the Nose or Mouth may of course arise from any injury of these parts without the skull being implicated: yet in some cases of fracture of the skull the hæmorrhage proceeds from the interior of the cranium, through a fissure in the roof of the nasal fossa; it then indicates a fracture through the ethmoid and sphenoid bones. In a patient of mine who died five weeks after an injury of the head, accompanied by bleeding from the nose, a fracture was found extending across one orbital plate of the frontal bone, and separating its articulation with the ethmoid. In this case, the nature of the injury was suspected from the fact of the nose itself having been uninjured by the blow, although the hæmorrhage from it was very considerable and continuous: for it is in the quantity and duration of the hæmorrhage that its value as a diagnostic sign consists.

Vomiting of Blood may occur in these cases, from the blood having found its way through the fractured ethmoid or sphenoid down the nose and through the posterior nares into the pharynx and stomach. The vomited blood is dark, grumous, and mixed with the contents of the stomach. In some rare cases, in which the petrous portion of the temporal bone is fractured, and the middle ear opened, but without injury to the tympanic membrane, no bleeding from the external ear ensues, but the blood escapes into the pharynx through the Eustachian tube. In some cases there may be a combination of these different signs. Thus, in a patient of mine at the hospital, there was hæmorrhage into the left orbit and from the left nostril, with copious vomiting of blood, and bleeding from the right ear, following a blow upon the forehead. The diagnosis, which was verified after death, was a fissure of the skull extending through the left orbital plate of the frontal

bone, the ethmoid, and probably the sphenoid on that side, and a fracture of the petrous portion of the right temporal bone.

2. The **Discharge of a thin Watery Fluid** from the interior of the skull sometimes occurs; and, when it does, it is the most certain sign of fracture of the base that we possess. Although the occurrence of a discharge from the ear after certain injuries of the head had been observed by Van der Wiel, O'Halloran, and Dease, in the early part and middle of the last century, no attention was paid to the subject by later surgical writers; and it appears to have been completely lost sight of until Langier, in 1839, again directed the attention of Surgeons to this interesting phenomenon. Since this period, it has often been observed and attentively studied; and the nature and sources of the discharge have been particularly investigated by Langier, Chassaignac, Robert, Guthrie, and Prescott Hewett. The discharge usually takes place through the ear, but it may occur from the nose; I have seen one instance of this, and Robert mentions another. Still more rarely it takes place from a wound in the scalp communicating with the fracture. Cases of this kind have been described by Hey, O'Callaghan, Robert, Hewett, and other Surgeons. One such instance was communicated to me by one of the pupils of University College, a few years ago. A boy received a wound on the back of the head, with a depressed and comminuted fracture of the skull. On the nineteenth day after the receipt of the injury, a large quantity of serous fluid began to escape through the wound, and continued to do so profusely until his death from coma four days later.

This watery discharge is an exceedingly valuable though most serious sign; and Robert, who investigated the phenomenon with much closeness, stated that the cases in which it happens always terminate fatally. This, however, is an error; for a number of cases have occurred at University College Hospital and elsewhere, in which adult patients recovered, although many ounces of fluid were discharged from the ear. It is usually associated with symptoms indicative of serious injury to the base of the brain; but to this there are also exceptions, for I have seen it in cases of injury of the head unaccompanied by any severe cerebral symptoms. Generally it occurs in young people. Robert says that it does so invariably; but Hewett states that in most of the instances in which he has seen it the patients were above thirty years of age. In one of my cases, the patient was fifty-eight years of age; and in six other instances in which I have observed it, the patients were all adults. In all cases of recovery that I have witnessed, some deafness of the ear from which the discharge occurred has been left, though this does not seem to be an invariable consequence of the injury.

The *Quantity* of fluid that is thus discharged is always very considerable, the pillow usually becoming soaked by it, which may be the first thing to attract attention to it. It is often necessary to keep a piece of sponge or a pledget of lint against the ear, in order to prevent the fluid from wetting the patient as it trickles out; and, if a cup be so placed as to collect it, an ounce or two will speedily accumulate. Langier states that he has seen a tumblersful discharged in a short time, and as much as twenty ounces has been known to be poured out in three days. The flow is usually continuous for several days, after which it ceases. At first the fluid that is discharged is usually tinged with blood, but this soon ceases, and it then flows clear. Its *physical and chemical characters* are those of a perfectly clear, and watery fluid, of

low specific gravity (1007-8), containing a considerable quantity of chloride of sodium, with a little albumose in solution, and traces of a substance, known as pyrocatechin, which, like sugar, reduces copper salts. The fluid is not coagulable by heat or nitric acid.

The **Source of this Discharge** has been the subject of much speculation, but the characters of the fluid, and the large quantity in which it sometimes escapes, prove it to be undoubtedly the cerebro-spinal fluid. Langier's theory that the discharge consists of the serum of the blood filtered through a crack in the bone has nothing to support it. The large quantity of the fluid, and above all the fact that it occasionally escapes from the nose, demonstrate the fallacy of the view that it is furnished by the internal ear.

In order that the fluid be discharged, the membranes of the brain must have been torn opposite the outlet by which it is poured forth, in such a way as to open up the subarachnoid space. This has actually been ascertained to be the case, by carefully conducted dissections. When it is discharged through the ear, the laceration, as Bérard has remarked, must have extended through the prolongation of the arachnoid which surrounds the auditory nerve in the internal auditory canal. When it is poured out through the nose, the fracture has probably extended through the cribriform plate of the ethmoid bone, and laid open the arachnoid surrounding the filaments of the olfactory nerve.

The diagnostic value of watery discharge from the ear varies, according to Prescott Hewett, with its relation to the hæmorrhage which may occur. He divides cases of watery discharge from the ear after injuries of the head into three classes. In the first class, the discharge is watery from the first, and abundant, being preceded by little or no blood, and beginning immediately after the accident. This is undoubtedly cerebro-spinal fluid, which escapes through a fracture of the petrous bone implicating the internal auditory canal. In the second class, there is copious and prolonged bleeding from the ear, followed by the watery discharge. Here, too, there is fracture of the petrous bone; but its exact situation is uncertain. In these cases, the diagnosis will rest upon the prolonged hæmorrhage, rather than on the watery discharge. In the third class, there is but little bleeding after the injury, and the watery discharge, which is variable in quantity, varies also in the time of its appearance. In these cases the diagnosis must remain doubtful. Hewett mentions two cases which occurred at St. George's Hospital in which a copious watery discharge flowed from the ear. In neither of these was any fracture of the petrous portion of the temporal bone found after death. In one the *membrana tympani* was ruptured, and the cavity of the tympanum was "intensely vascular;" in the other, "the discharge was connected with a fracture of the lower jaw just below the condyle: the lower fragment had perforated the wall of the *meatus auditorius*."

The facial nerve may be so injured by a fracture of the petrous portion of the temporal bone as to become paralysed at the time of the accident. But more frequently paralysis of this nerve does not come on until a later period, about the second or third week after the injury, and disappears after lasting about a month. This transient facial paralysis, accompanying some fractures of the base of the skull, has been attributed by Marshall to the pressure of inflammatory exudation, which gradually becomes absorbed as the fracture unites, and thus the compression of the nerve is removed after a time.

Treatment.—In the treatment of fracture of the base of the skull it must

not be forgotten that whenever bleeding appears externally, the fracture is compound, and that decomposition of the discharges, with consequent septic meningitis, forms one of the greatest dangers of the case. Fortunately, however, in a large proportion of cases the dura mater is intact, and consequently the danger is greatly diminished. In fractures implicating the ethmoid and sphenoid bones, with hæmorrhage from the nose, little can be done to prevent decomposition; but the nasal fossæ may be washed out with some antiseptic solution to remove decomposing clots or discharge, and some iodoform should be blown into the cavity as high up as possible. In fractures affecting the tympanum, with rupture of the *membrana tympani*, the prevention of decomposition is more hopeful, although the Eustachian tube communicating with the upper part of the pharynx causes some degree of uncertainty. Yet, as it is lined with ciliated epithelium, it is quite possible that the causes of decomposition may not reach the fracture by that route. The ear should in such cases be carefully syringed out with a solution of carbolic acid in water (1 in 30), after which some iodoform may be blown on to it. It may then be plugged either with antiseptic gauze or wool, a large dressing of the same material being applied over the side of the head. The syringing must be gently done, and the carbolic solution should not be too strong, or it may cause some inflammation in the middle ear. The dressing must be changed as often as may be necessary. In other respects the treatment of fracture of the base of the skull must be conducted on those general principles that guide us in the management of simple fractures of the cranium, such as ice to the shaved head, a calomel purge, low diet, and absolute quietude in a darkened room. In many cases, the brain is so injured in its most vital parts that speedy death is the result. When recovery takes place, it is necessarily slow and liable to retardation from meningitis of an acute or subacute and chronic character.

DEPRESSED FRACTURE OF THE SKULL.—It occasionally though very rarely happens that, in consequence of a blow, a portion of the skull is depressed without being fractured, and even without any serious cerebral symptoms occurring. Such depression without fracture can, however, occur only in children, whose skulls are soft and yielding. In adults it cannot happen without the occurrence of partial or incomplete fracture. Many, if not all, of the so-called "congenital depressions" that are met with in the skull are the result either of violence inflicted on the cranium at birth, usually in instrumental labours, or of falls and blows upon the head in early infancy. Such depressions are smooth, concave, and sometimes symmetrical, and present very different characters from the irregular outline of an ordinary fracture. They never present the characters of a fissure; there is no such thing as a congenital fissure of the skull.

In the **Diagnosis** of depressed fracture, it is important to remember that the apparent depression produced by an extravasation under the scalp may simulate this injury very closely. (See p. 716).

Varieties.—Depressed fractures of the skull may either be simple, without wound of the scalp; compound; or comminuted. In the majority of cases, whether the fracture be simple or compound, there is comminution of the bone; the fragments being perhaps driven into the brain.

Sometimes, though very rarely, the **external table** alone is depressed and driven into the diploe. Over the frontal sinuses, it may be broken in, as I

have seen happen from the kick of a horse, without the inner table being splintered, or any bad consequence ensuing.

The **inner table** may be fractured without any apparent injury to the outer table; and it may not only be so fractured, but a portion of it may be depressed without the outer table being injured (Figs. 297, 298).

In all ordinary depressed fractures, both tables are depressed, but the internal table is splintered to a greater extent than the external one. This is especially the case when the fracture is the result of gunshot injury, or when it has been occasioned by blows with a pointed weapon, as the end of a pick, or a large nail, or the sharp angle of a brick. In these latter fractures, which constitute the dangerous variety termed **Punctured**, the outer table may be merely perforated or fissured, whilst the inner is splintered into numerous fragments, for the extent of a square inch or more. This splintering of the inner lamina of the skull to a greater extent than the outer has attracted much attention, being of considerable practical moment. It is often said to be owing to its being more brittle than the external table. This

Fig. 295. Fracture of the Skull from Gunshot Injury from within: Splintering of Outer Table.

Fig. 296. — The same, natural size.

however, I do not consider to be the only cause, for if the force be applied in the opposite direction, the outer table will be found to be more extensively splintered than the inner. It is seldom that we have an opportunity of examining such a case; but, some years ago, a man was brought to the Hospital who had discharged a pistol into his mouth and upwards through the brain. The bullet had perforated the palate and passed out at the upper part of the cranium, near the vertex. On examining the state of the bones, it was found that the outer table of the skull was splintered to a considerably greater extent than the inner one, showing clearly the influence of the *direction* of the fracturing force (Figs. 295, 296). This case led me to make further experiments on the dead body; and I found that the outer table is always more splintered when the blow is struck from the inside of the skull outwards. Teeyan, as the result of numerous experiments by firing bullets and driving pointed bodies through the skull, came to the same conclusion and under all circumstances the aperture of exit is the larger. This effect is produced by three causes: 1st, the bullet or pointed instrument loses some of its momentum in passing through the first table with which it comes in contact, and thus does not make so clean a puncture in the second; 2ndly, if the instru-

blunt body, such as a bullet, it drives before it fragments of the bone, it passes through, and thus the aperture of exit is made by the ball and fragments, and the blow being more diffused splinters the second table widely; lastly, the first table penetrated is well supported by the second, supposing it to be the inner, has only the imperfect support of the soft brain. That this last is an important cause we may see from the familiar illustration of driving a nail through a board. If the board is supported on its under side the nail will probably carry before it a large fragment from that surface as it passes through the wood. But if the same nail is supported on a block of wood and the nail driven through, then the aperture of exit will be as small as that of entry. It occasionally happens as in the case of sabre or hatchet cuts on the head that a longitudinal incised fracture occurs, in which the outer table is merely notched, whilst the inner table is fractured along the whole line of the blow. This is in point of fact an oblique punctured fracture, and the wide area of splintering of the inner table is due to the same cause as when a nail is driven in. In other cases,

Fig. 287. - External Table Slightly Depressed.

Fig. 288. - Internal Table Depressed and Fissured.

a portion of the skull is completely sliced off, hanging down in a flap, and exposing the brain or its membranes.

A most and very important kind of punctured and depressed fracture is produced, by the thrust of a stick, umbrella, or other blunt-ended body, through the orbital plate of the frontal bone, or the cribriform lamella of the ethmoid, is perforated, and the dura mater or brain wounded. In such cases there is sometimes no obvious external wound, the stick having passed up under the upper eyelid; and it is conceivable that the same result might be produced by a thrust up the nostril. Death results either from wound of the olfactory sinus and intracranial extravasation of blood, or from septic meningitis following the wound of the dura mater and brain.

It is very important to observe that the inner table may be very extensively depressed, without any fracture of the outer table. Of this kind of injury twenty cases are recorded as having happened in the Crimean civil war. One recovered, the diagnosis being made by finding the depressed inner table in a sequestrum which was removed. The rest died of intracranial mischief, and the diagnosis was not made during life.

Most commonly when the inner table is thus fractured or depressed the outer table is fissured. The accompanying cuts (Figs. 297, 298), taken from photographs of a preparation in the Army Medical Museum, Washington, represent a case of extensive gunshot fracture with depression of the inner table of the left parietal bone without fracture of the external table. The patient was struck obliquely on the side of the head by a musket-ball, which inflicted a scalp-wound. There was no sign of cerebral disturbance until two days after the injury, when symptoms of compression set in. The skull was carefully examined through the wound for fracture; none could be found. The symptoms of coma increased and proved fatal on the tenth day, when the inner table of the left parietal bone was found extensively starred and depressed (Fig. 298), without any fracture of the outer table (Fig. 297). There was a wound of the dura mater and an abscess in the cerebral hemisphere—in fact, all the appearances and sequences of an ordinary “punctured fracture.” This case demonstrates clearly the possibility of extensive fracture with depression of the inner table, whilst the outer remains unbroken.

The **Symptoms** of a depressed fracture of the skull are of two kinds: those that are dependent upon the injury to the bone, and those that result from the concomitant compression or laceration of the brain.

When the scalp is not wounded, the depression may sometimes be felt; but very commonly it is masked by extravasation of blood about it. In all cases of doubt, *when symptoms of compression of the brain exist* (p. 745), an incision should be made through the scalp at the seat of injury, and the state of the skull examined. When there is a wound in the scalp communicating with the fracture, the Surgeon detects at once the existence of depression and comminution by examining the bone with his finger through the wound. When the fragments that are depressed are impacted and firmly locked together, so as to form an unyielding mass, symptoms of compression of the brain, to a more or less marked degree, may result. But if the fracture be very extensive, and the fragments, though somewhat depressed, lie loose, and if they be yielding and do not exercise a continuous pressure on the brain, it occasionally happens that the symptoms of compression are entirely wanting, and no cerebral disturbance comes on for some days, even though the injury be very extensive. A man twenty-four years of age was admitted into University College Hospital, having been struck on the forehead by the sharp edge of a quoit. The frontal bone was extensively comminuted, twelve fragments being removed, and the dura mater being exposed to a considerable extent; yet no bad symptoms occurred until the ninth day, when inflammation of the brain and its membranes set in, and he speedily died.

In other cases again, more especially in children and young persons, in whom the bones are soft and yielding, fracture with depression may exist to a considerable extent, without any symptom of compression being produced.—the patient living with a portion of his skull permanently beaten in. I have several times seen persons in after-life with large flat depressions of the skull, the result of injuries sustained in childhood, who presented no signs of cerebral disturbance. It is rare, however, to meet with a recent case of depressed fracture in the adult without signs of compression of the brain. But, though rare, it is not impossible; and Green mentions a case of a man whose skull was depressed to the extent of the bowl of a dessert-spoon, without any symptoms of compression.

When the signs of compression are well marked, it must not be assumed that the pressure caused by the depressed fragments of bone is in all cases the sole or even the chief cause of the symptoms. It is scarcely possible for a man to suffer from a severe depressed fracture without serious bruising and laceration of the brain substance beneath and a more or less extensive intracranial extravasation of blood. Both these conditions are important factors in producing the symptoms. The celebrated case so often quoted, in which Cline trephined a man who had been unconscious for thirteen months after a fall on the head, which caused a slight depression in the skull, restoring him almost immediately to consciousness, will hardly bear investigation. The man had been pressed into the navy, and was consequently likely to feign disease to escape from it, and there are many cases of malingering on record quite as extraordinary as his. During the whole period of his "insensibility" he was able to make signs with his "lips and tongue" when he wanted food. This fact alone would be sufficient to throw the gravest doubts upon the genuineness of the case.

Wounds of the Dura Mater.—The great danger in cases of depressed and comminuted fracture arises not only from the compression of the brain, but from the rapidity with which inflammation (p. 771) so frequently follows the injury. This is due partly to the sharp fragments wounding and irritating the membranes of the brain, but chiefly to the septic matter which almost inevitably forms within the skull after these injuries, unless efficient means are taken to prevent it. In a compound depressed fracture the conditions present are as follows: Sharp fragments of the inner table are lying pressed against the dura mater, or possibly penetrating it and the arachnoid; the subarachnoid space is thus opened and the brain itself possibly wounded; the fragments are surrounded by more or less extravasated blood, and in a few hours a considerable amount of inflammatory exudation will necessarily be added. All this decomposable material is in communication with the air through the fissures in the bone, and at the same time these fissures allow of but imperfect drainage from within the cavity of the skull. Consequently, the decomposing discharges are pent up and burrow within the cranial cavity. If the dura mater were not wounded at the time of the accident, it will inevitably soon be perforated by ulceration at the point at which the sharp fragments of the inner table, bathed in putrid pus, are pressing against it. In either case, the subarachnoid space is opened and the septic matter diffuses itself widely, giving rise to the usual symptoms with the fatal termination characteristic of meningitis. If the fragments are removed early and the external wound is left open so as to provide perfect drainage from within the skull, the dangers of secondary perforation of the dura mater are very slight; and even should that membrane have been wounded at the time of the accident the patient has a fair chance of escaping diffuse meningitis; for adhesive inflammation may occur within a few hours, and thus present a barrier to the diffusion of any septic matter that may form afterwards. If, with the removal of sharp fragments and the provision of good drainage, we combine some perfect method of antiseptic treatment of the wound, the danger to the patient, though still great, will be most materially diminished. Indeed, a wound of the dura mater, however slight, is a dangerous complication. This is more especially the case in those injuries in which the inner table is extensively splintered, as in the different forms of punctured fracture. In these cases

Hæmorrhage into the Areolar Tissue of the Orbit and Eyelid. giving rise to extensive ecchymosis of the lid, possibly with protrusion of the eyeball itself, often accompanies fracture of the orbital plate of the frontal bone. The ecchymosis that occurs in these cases arises from the filtration of blood from the interior of the skull, through the fracture, into the loose areolar tissue adjacent to the injured bone. It differs remarkably in appearance from an ordinary "black eye." In the latter case, the extravasated blood lies in the subcutaneous tissue immediately beneath the skin, and sometimes the skin of the lids is also bruised, giving them a reddish-purple colour; but the blood does not find its way to the subconjunctival tissue, being shut off by the attachment of the palpebral ligament to the margin of the orbit. In the ecchymosis from fracture the extravasated blood advances from the orbit, and is shut off from the subcutaneous tissue of the lids by the palpebral ligament, while it readily finds its way beneath the conjunctiva. In the more severe cases the lids may be tense, greatly swollen, and of a bluish-purple colour, the subconjunctival tissue may be distended with blood, and the eyeball distinctly protruded. It is only when abundant that subconjunctival hæmorrhage is of any value in the diagnosis of fracture. A small extravasation may be the result of a direct blow on the eyeball, or a conjunctival vessel may have ruptured during the violent exertion which may have accompanied the accident. In well-marked cases the hæmorrhage may be venous or arterial. When venous, it probably arises from a fracture implicating the body of the sphenoid bone, and tearing the wall of the cavernous sinus. When arterial it may, as Hewett has shown, be the forerunner of a circumscribed traumatic aneurism of the orbit.

Bleeding from the Nose or Mouth may of course arise from any injury of these parts without the skull being implicated; yet in some cases of fracture of the skull the hæmorrhage proceeds from the interior of the cranium, through a fissure in the roof of the nasal fossa; it then indicates a fracture through the ethmoid and sphenoid bones. In a patient of mine who died five weeks after an injury of the head, accompanied by bleeding from the nose, a fracture was found extending across one orbital plate of the frontal bone, and separating its articulation with the ethmoid. In this case, the nature of the injury was suspected from the fact of the nose itself having been uninjured by the blow, although the hæmorrhage from it was very considerable and continuous: for it is in the quantity and duration of this hæmorrhage that its value as a diagnostic sign consists.

Vomiting of Blood may occur in these cases, from the blood having found its way through the fractured ethmoid or sphenoid down the nose and through the posterior nares into the pharynx and stomach. The vomited blood is dark, grumous, and mixed with the contents of the stomach. In some rare cases, in which the petrous portion of the temporal bone is fractured, and the middle ear opened, but without injury to the tympanic membrane, no bleeding from the external ear ensues, but the blood escapes into the pharynx through the Eustachian tube. In some cases there may be a combination of these different signs. Thus, in a patient of mine at the hospital, there was hæmorrhage into the left orbit and from the left nostril, with copious vomiting of blood, and bleeding from the right ear, following a blow upon the forehead. The diagnosis, which was verified after death, was a fissure of the skull extending through the left orbital plate of the frontal

that this will relieve the symptoms, as the compression in almost all cases is not due solely to the depressed bone, but chiefly to extravasated blood within the cranium. (See Intracranial Hæmorrhage, p. 763.) Still the operation must to some extent relieve pressure, and may enable the Surgeon to remove the extravasated blood at the same time.

In a **Compound Depressed Fracture of the Skull**, as a general rule, the depressed bone should immediately be elevated.

If the fracture be accompanied by symptoms of compression the indications for operative interference are obvious. In these cases it is better always to expose the dura mater either by removing some fragments, as in all probability the compression is in great part due to intracranial hæmorrhage which may be between that membrane and the bone. If the dura mater should seem much distended with blood it may safely be incised with proper antiseptic precautions.

If the fracture be not accompanied by symptoms of compression it is still the duty of the Surgeon, as a general rule of practice, to elevate, and remove partly or completely, the depressed fragments. The patient who is suffering from a compound depressed fracture of the skull is exposed to the dangers of intracranial suppuration, and in order to lessen the risks of this serious complication a free exit for discharges must be provided. This can be done only by the removal of the depressed fragments which offer a serious obstacle to the escape of the discharges, and by their irritation favour the occurrence of meningitis.

The sooner elevation is done the better. Danger does not arise from early operation, but from delay. I have several times trephined primarily in such circumstances as these with success, and have never had occasion to regret doing so. Indeed, there is no class of cases in which the operation of trephining is attended with such successful results as those of depressed and comminuted fracture. Even though several days have elapsed and inflammation has set in, the proper treatment will be to remove the depressed and splintered bone, and thus give the patient his only chance—a slender one, it is true—of recovery. A man was admitted under Liston with a long depressed fracture on the side of the head, produced by a blow from a brickbat; though no sign of compression existed, yet symptoms of cerebral inflammation were speedily set up, and Liston trephined him on the fourth day after the accident; the man, who was perfectly conscious, walking into the operating theatre. A considerable splintering of the inner table was found, the fragments of which were removed. The dura mater having been punctured by one of the spicula of bone, diffuse suppuration of the membranes of the brain set in, and the patient died in a few days. In this case, however, the necessity for early trephining was clearly indicated, notwithstanding the absence of any symptom of compression.

Some cases of compound depressed fracture have recovered without operative interference. I had once under my care a case which illustrated this. The patient, a middle-aged man, fell on his head into an area, and had the greater part of the scalp stripped off from the anterior part of the head and the vertex; on the upper part of the left parietal bone was a starred and depressed fracture as large as a florin. As the depression was smooth, not more than a quarter of an inch in depth, and there was no symptom of compression, I drew the scalp forwards and left the bone untouched, the patient making an

low specific gravity (1.007-8), containing a considerable quantity of chloride of sodium, with a little albumose in solution, and traces of a substance, known as pyrocatechin, which, like sugar, reduces copper salts. The fluid is not coagulable by heat or nitric acid.

The **Source of this Discharge** has been the subject of much speculation, but the characters of the fluid, and the large quantity in which it sometimes escapes, prove it to be undoubtedly the cerebro-spinal fluid. Laugier's theory that the discharge consists of the serum of the blood filtered through a crack in the bone has nothing to support it. The large quantity of the fluid, and above all the fact that it occasionally escapes from the nose, demonstrate the fallacy of the view that it is furnished by the internal ear.

In order that the fluid be discharged, the membranes of the brain must have been torn opposite the outlet by which it is poured forth, in such a way as to open up the subarachnoid space. This has actually been ascertained to be the case, by carefully conducted dissections. When it is discharged through the ear, the laceration, as Bérard has remarked, must have extended through the prolongation of the arachnoid which surrounds the auditory nerve in the internal auditory canal. When it is poured out through the nose, the fracture has probably extended through the cribriform plate of the ethmoid bone, and laid open the arachnoid surrounding the filaments of the olfactory nerve.

The diagnostic value of watery discharge from the ear varies, according to Prescott Hewett, with its relation to the hæmorrhage which may occur. He divides cases of watery discharge from the ear after injuries of the head into three classes. In the first class, the discharge is watery from the first, and abundant, being preceded by little or no blood, and beginning immediately after the accident. This is undoubtedly cerebro-spinal fluid, which escapes through a fracture of the petrous bone implicating the internal auditory canal. In the second class, there is copious and prolonged bleeding from the ear, followed by the watery discharge. Here, too, there is fracture of the petrous bone; but its exact situation is uncertain. In these cases, the diagnosis will rest upon the prolonged hæmorrhage, rather than on the watery discharge. In the third class, there is but little bleeding after the injury, and the watery discharge, which is variable in quantity, varies also in the time of its appearance. In these cases the diagnosis must remain doubtful. Hewett mentions two cases which occurred at St. George's Hospital in which a copious watery discharge flowed from the ear. In neither of these was any fracture of the petrous portion of the temporal bone found after death. In one the membrana tympani was ruptured, and the cavity of the tympanum was "intensely vascular;" in the other, "the discharge was connected with a fracture of the lower jaw just below the condyle: the lower fragment had perforated the wall of the meatus auditorius."

The facial nerve may be so injured by a fracture of the petrous portion of the temporal bone as to become paralysed at the time of the accident. But more frequently paralysis of this nerve does not come on until a later period, about the second or third week after the injury, and disappears after lasting about a month. This transient facial paralysis, accompanying some fractures of the base of the skull, has been attributed by Marshall to the pressure of inflammatory exudation, which gradually becomes absorbed as the fracture unites, and thus the compression of the nerve is removed after a time.

Treatment.—In the treatment of fracture of the base of the skull it must

It be forgotten that whenever bleeding appears externally, the fracture is compound, and that decomposition of the discharges, with consequent septic meningitis, forms one of the greatest dangers of the case. Fortunately, however, in a large proportion of cases the dura mater is intact, and consequently the danger is greatly diminished. In fractures implicating the ethmoid and sphenoid bones, with hæmorrhage from the nose, little can be done to prevent decomposition: but the nasal fossæ may be washed out with some antiseptic solution to remove decomposing clots or discharge, and some iodoform should be blown into the cavity as high up as possible. In fractures affecting the tympanum, with rupture of the membrana tympani, the prevention of decomposition is more hopeful, although the Eustachian tube communicating with the upper part of the pharynx causes some degree of uncertainty. Yet, as it is lined with ciliated epithelium, it is quite possible that the causes of decomposition may not reach the fracture by that route. The ear should in such cases be carefully syringed out with a solution of carbolic acid in water (in 30), after which some iodoform may be blown on to it. It may then be covered either with antiseptic gauze or wool, a large dressing of the same material being applied over the side of the head. The syringing must be gently done, and the carbolic solution should not be too strong, or it may cause some inflammation in the middle ear. The dressing must be changed as often as may be necessary. In other respects the treatment of fracture of the base of the skull must be conducted on those general principles that guide in the management of simple fractures of the cranium, such as ice to the injured head, a calomel purge, low diet, and absolute quietude in a darkened room. In many cases, the brain is so injured in its most vital parts that speedy death is the result. When recovery takes place, it is necessarily slow and liable to retardation from meningitis of an acute or subacute and chronic character.

DEPRESSED FRACTURE OF THE SKULL.—It occasionally though very rarely happens that, in consequence of a blow, a portion of the skull is depressed without being fractured, and even without any serious cerebral symptoms occurring. Such depression without fracture can, however, occur only in children, whose skulls are soft and yielding. In adults it cannot happen without the occurrence of partial or incomplete fracture. Many, if not all, of the so-called "congenital depressions" that are met with in the skull are the result either of violence inflicted on the cranium at birth, usually in instrumental labours, or of falls and blows upon the head in early infancy. Such depressions are smooth, concave, and sometimes symmetrical, and present very different characters from the irregular outline of an ordinary fracture. They never present the characters of a fissure; there is no such thing as a congenital fissure of the skull.

In the **Diagnosis** of depressed fracture, it is important to remember that the apparent depression produced by an extravasation under the scalp may simulate this injury very closely. (See p. 716).

Varieties.—Depressed fractures of the skull may either be simple, without wound of the scalp; compound; or comminuted. In the majority of cases, whether the fracture be simple or compound, there is comminution of the bone; the fragments being perhaps driven into the brain.

Sometimes, though very rarely, the **external table** alone is depressed and driven into the diploe. Over the frontal sinuses, it may be broken in, as I

signs of inflammation of the brain, three from the effects of cold weather, and one only from diffuse meningo-encephalitis. In many of these animals large portions of cerebral substance were cut away without causing any inflammatory disturbance beyond the area actually injured. The experiments also showed conclusively that a five per cent. solution of carbolic acid may be applied with impunity to the brain or its membranes.

The statistics given by Kramer in an inaugural dissertation at Breslau in 1880 show no less conclusively the great advantages to be derived from antiseptic treatment. Of twenty-five cases of compound fracture of the skull with wound of the brain, in which no operation was performed, ten died, five from meningitis, and one from pneumonia, and the rest directly from the injury to the brain. Of twenty-five cases of primary trephining for injury, only two died, one from circumscribed meningitis and one from diffuse meningo-encephalitis; in twenty-one the wound healed by first intention. Of six cases in which secondary trephining was performed only one died with hernia cerebri. These results are certainly much better than any that had been obtained previous to the introduction of the antiseptic treatment.

The treatment should be carried out as follows: The wound must as soon as possible be covered with a piece of linen rag soaked in a three per cent. solution of carbolic acid in water. The whole head is then to be shaved and carefully cleaned with soap and water. If necessary it may be sponged with a weak solution of ammonia to get rid of grease; but, of course, in doing this the liquids used in washing must not be allowed to flow into the wound. The head is then cleaned with the carbolic solution (1 in 20), and this may be allowed to enter freely into the wound. It must not on any account be forcibly injected, as by so doing it might become widely diffused in the subarachnoid space or the brain might be injured. When the operation is completed the edges of the wound must be brought together, pared, if much contused, and very dirty, provision being made for drainage, and some efficient antiseptic dressing may be applied. It is not always possible to render the wound thoroughly aseptic, as much dirt may have been ground into it, and some time may have elapsed before the case is seen; but the dangers of septic meningitis are so great that it is always worth while to make the attempt even in apparently hopeless cases. In doubtful cases the wound should be freely powdered with iodoform. If no special antiseptic dressing is at hand the wound, after having been thoroughly washed with carbolic acid lotion, may be dressed with carbolic oil (1 in 10), or terebenthine and oil, and during the time it is necessarily exposed in dressing it may be irrigated with the antiseptic solution. Failing all other antiseptic dressings the wound may be washed out with spirit and water and dressed with dry lint or cotton-wool, in the hope that decomposition of the discharges may be prevented by drying. The one thing that is more certain than anything else to ensure decomposition is washing the wound with common water and applying simple wet lint to it, as was formerly the universal practice.

All the precautions applicable to cases of injury of the brain, such as low diet, purging, perfect quiet, dry cold to the head, &c., must be employed as rigorously when the antiseptic treatment is adopted as when it is not.

It has been recommended in cases of simple depressed fracture, without injury of the brain or its membranes, to make an attempt to draw the depressed portion of bone to its normal level by means of a cupping-glass.

adapted to the uneven surface of the skull by means of a cell of glazier's putty.

Treatment of Punctured Fracture.—In all cases, as before stated, in which there is but slight injury of the external table, with considerable splintering and depression of the inner one, or when there is a narrow and deep depression of the bone, the trephine must be applied on different principles from those that guide us in its use in ordinary depressed fractures. In the punctured fracture it is applied, not to remove symptoms of compression which, in all probability, do not exist; but with the view of preventing the inflammation which will to a certainty be set up if the splinters of the inner table and pent-up decomposing discharges be allowed to continue irritating the membranes and brain. Hence it is a rule in surgery, in all cases of punctured fracture, to apply the trephine at once. In these cases a trephine with a large crown should be used, and the circle of injured bone itself must be sawn away (Fig. 303). Should, however, the use of the trephine have been delayed in these cases until inflammation has been set up, the instrument may still be applied with advantage. Many years ago a boy was admitted into University College Hospital, on the sixteenth day after having been struck on the side of the head by a large nail, which projected from a door that fell upon him. No symptoms of any kind had occurred until the eleventh day after the accident, when he became dull and lost his appetite; on the sixteenth day, that of his admission, he had suddenly become drowsy and delirious, but answered rationally when spoken to, and complained of pain in the head. The pupils were dilated, the skin hot, and the pulse quick. On examination, a small round aperture, from which some fetid pus exuded, was discovered on the right parietal eminence. On introducing a probe, which the hole just admitted, some rough bone could be felt. S. Cooper immediately trephined the boy, removing a circle of bone including the small aperture. The inner table corresponding to this was found splintered to some extent, and the dura mater was thickened and inflamed; but the patient recovered without a bad symptom.

Fig. 303. — Trephined circle round Punctured Fracture. Natural size.

Linear Cuts, as by sabre or hatchet, into the skull, penetrating the outer table, are apt to splinter the inner one, in the same way as occurs in a "punctured" fracture, to which they bear a close analogy. They require the same preventive trephining that is needed in the true punctured fracture, having for its object the removal of splinters and spicula, which would probably produce fatal meningitis if left.

The Ultimate Results of Fracture of the Skull in those who recover will more or less closely resemble the conditions described at p. 721, as the consequences of contusion of the cranium without fracture. Epilepsy was very frequent in the American war cases; partial or complete loss of vision was also one of the common sequences of such injuries. When deafness occurred, it was generally connected with impairment of other special senses, and often of the mental faculties.

When a depressed fracture of the skull is **complicated with a Fracture or other Injury of the Spinal Column**, it is sometimes difficult to know which symptoms are due to the one accident, and which to the other. In

such a case as this, however, we should, I think, treat the depressed fracture irrespectively of the spinal injury, thus giving the patient a chance of recovery, of prolongation of life, or, at least, of return of consciousness before death. A man was admitted under my care into the Hospital, with depressed fracture of the left parietal bone, and injury of the cervical spine, the precise nature of which could not be accurately determined. He was in a state of complete coma and paralysis. I trephined the skull and elevated the depressed portion of bone; he recovered his consciousness to a great degree, but died in a few days, apparently from injury to the spine. On examination after death, we found a fracture of the fifth cervical vertebra.

CEREBRAL COMPLICATIONS OF INJURIES OF THE HEAD.

These may be primary or secondary. The brain is subject to three principal **Primary States of Functional Disturbance** arising from injury: 1. Concussion, 2. Compression, and 3. Cerebral Irritation. Any one of these may be followed by, or be complicated with, subsequent inflammation, which derives peculiar characteristics from the conditions with which it is associated, and from the injury by which it is occasioned.

In describing these different conditions, we are compelled to define the symptoms that characterize them more distinctly than is the case in actual practice, where they are not so clearly individualized, and become merged together to a considerable extent.

1. **CONCUSSION OF THE BRAIN.**—Concussion, or stunning, appears to be a shock communicated to the head from the application of such external violence as will produce commotion of the substance of the brain, or interfere with the circulation through it; in consequence of which its functions become suspended, usually in a slight and transitory degree, but occasionally to such an extent that the patient does not rally for many hours from the depressed state into which he is thrown.

The **Pathology** of concussion of the brain is very obscure; so much so, in fact, that the term must be considered to have rather a clinical than a pathological significance. Clinically the term is used to cover all those cases in which insensibility of a temporary character not due to any evident cerebral lesion or compression of the brain follows an injury to the head. When cases of this kind, that have been clinically classed as concussion, have died without rallying, examination has always shown some actual lesion of the brain. In some cases the brain is ecchymosed in a punctiform manner, whilst in the most severe cases, portions of the brain substance, varying in size from minute points to patches an inch or more in diameter, have been disintegrated and more or less ecchymosed. In fact, no sharp line can be drawn either clinically or pathologically between the more severe cases of concussion and those of obvious cerebral laceration and contusion.

The theory that the symptoms of concussion can be produced simply as the result of a temporary arrest of the normal cerebral action by a violent vibration of the nerve tissue is not now generally accepted. There is, however, much reason for believing that a condition of cerebral anemia is the essential cause of the symptoms. This anemia partly no doubt depends upon the general vaso-motor paralysis and weak action of the heart, which allow the blood to stagnate in the relaxed vessels, especially in the veins of the abdominal viscera and

muscles. A blow on the top of the head may, however, produce as its chief effect small hæmorrhages about the base of the brain, especially in the medulla. The experiments of Duret, and more recently those of Miles, of Edinburgh, indicate that this damage to the base of the brain is produced by waves of cerebro-spinal fluid impinging upon it, and the latter observer suggests that the condition of cerebral anemia is caused by reflex stimulation of the bulb. We have already seen that, in fatal cases, minute hæmorrhages into the brain substance are frequently found, and it has been suggested that multiple capillary hæmorrhages may be the cause of the symptoms in cases ending in recovery. It seems, however, more likely that such hæmorrhages are the result of sudden disturbances in the cerebro-spinal fluid, rather than that they are themselves the cause of the symptoms.

The **Signs** of concussion vary according to the severity of the injury to the brain. In the slighter cases, the patient may merely feel giddy and confused for a few minutes. In others, consciousness is not affected, but the patient feels faint and weak, and is unable to stand. In the more severe form—in that degree, indeed, which usually accompanies any severe injury of the head—the surface of the body becomes cold and pale; the temperature falls to 97° F., or even to 96° F., if the accident has occurred in cold weather; the sufferer is motionless and insensible, or answers only when spoken to in a loud voice, relapsing again into speedy insensibility, or rather semi-consciousness; the pulse is feeble; the respiration is slow and shallow; the pupils are usually contracted, but may be dilated, and generally respond to the action of light, and the sphincters are usually relaxed; the limbs are flaccid, and muscular power is impaired or lost. After this condition, which is the first stage of concussion, has lasted for a few minutes or hours, according to the severity of the shock, the second stage comes on: the circulation gradually re-establishing itself, the pulse becoming fuller, and the surface warmer. As reaction becomes fully established, the temperature rises slightly above the normal standard, the degree of elevation being in proportion to the severity of the concussion. In slight cases the thermometer will rise to 99° F. or 99·5° F., while after more severe injuries it may reach 100° F., beyond which point it seldom passes in cases of simple concussion. About this time the patient very commonly vomits; probably as a consequence of cerebral hyperæmia following the anemia which exists during profound concussion. After vomiting, the sufferer quickly rallies. In the more severe cases, the symptoms that have just been described are so strongly marked that the patient appears to be moribund—prostration of all nervous and physical power being complete, the surface being cold and clammy, as in death, the eyes glassy, the pupils either contracted or widely dilated, the pulse scarcely perceptible and intermittent. In this state the patient may lie for hours, recovery being slow and the concussion merging into some other and perhaps more serious affection of the nervous centres; or, indeed, in some cases, speedily terminating in death, apparently by failure of the heart's action or arrest of respiration. But it may truly be said that every case of concussion in which unconsciousness, though but momentary, has been produced, is a most serious one.

The **Terminations** of concussion are various. We have already seen that in most cases this affection speedily gives way to complete recovery; although slight headache, some degree of giddiness, confusion of thought, and inaptitude for mental occupation, may last for a few days before the mental powers are

completely re-established. In these it is probable that no coarse lesion of the brain substance has taken place. In other cases, the concussion may rapidly terminate in death, and in these it will always be found that distinct contusion or laceration of the brain substance has occurred. Between these conditions there are several intermediate states. Thus, recovery may be complete, but a permanently irritable state of brain may be left; the patient, though capable of the ordinary duties of life, becoming readily excited by slight excesses in diet or in the use of stimulants, or by mental emotion, though not of an inordinate intensity. Individuals thus affected, suffering from a preternaturally irritable brain, sometimes die suddenly in the course of a few months, or a year or two, after the receipt of the injury.

In other cases the patient's recovery is incomplete. He remains for a long time unable properly to follow his usual occupation or to mix in the ordinary business of life. In such cases there is frequently a certain degree of impairment of mental power; the memory failing either generally or in certain important points, as with reference to dates, persons, places, or language. The speech is perhaps indistinct and stuttering. Impairment of vision is a very common consequence of these injuries. Asthenopia, with perhaps squinting or paralysis of the eyelid, may be left. The hearing may be impaired, or noises of various kinds set up in the ears. Epileptiform convulsions occasionally occur; sometimes, as the patient is recovering consciousness, he may be seized with a severe fit; but more commonly the convulsions do not come on as a primary consequence, but rather as a remote secondary result of the brain injury. There may be diminution or loss of muscular and of virile power, especially, as Hennen observes, when the injury has been inflicted upon the back of the head; and Holberton has noticed that, when the medulla oblongata has been injured, the pulse may continue preternaturally slow—an observation which I have had several opportunities of confirming. The symptoms here enumerated are spoken of collectively as "general nervous shock," or "traumatic neurasthenia," and are evidence of a more or less marked condition of nervous depression resulting from the injury. The condition will be further considered in connection with injuries of the spine, which are often followed by similar symptoms. In some of these cases the symptoms of concussion are but slight; perhaps even none are apparent, and the sufferer congratulates himself on his escape; but gradually impairment of nervous power, manifesting itself in one or other of the ways just mentioned, comes on, and the health continues broken through life.

In other cases, again, the symptoms of concussion may gradually terminate in those of compression; and not unfrequently reaction is followed by some inflammatory mischief when the concussion has been accompanied by laceration or contusion of the brain. Hippocrates truly observed that no injury of the head is too trivial to be despised, or too serious to be despaired of.

2. COMPRESSION OF THE BRAIN.—This is a common condition in injuries of the head, arising from a great variety of causes:—from the pressure of a portion of bone, of extravasated blood, of inflammatory exudation, or of pus formed within the skull, or from a foreign body lodged there.

In considering the **Pathology** of compression of the brain, it is of the greatest importance to distinguish clearly between the local effects of a compressing body on the part of the brain upon which it lies, and the effects of a general rise of intracranial pressure. We are here concerned only with the

latter condition. The brain is surrounded by the incompressible cerebro-spinal fluid, and hence it follows that the slightest diminution of the capacity of the cranium, as by the introduction of a foreign body, must raise the intracranial pressure, unless the fluid has a ready means of escape. Such an escape does undoubtedly occur, chiefly into the theca vertebralis, and the experiments of Dean show that the slightest pressure on the dura mater of a trephined animal does actually cause a corresponding rise in the pressure of the subarachnoid space. We must therefore conclude that an increase of intracranial pressure produces symptoms only when it reaches a degree sufficient to interfere with the circulation through the brain.

In whatever way occasioned, the **Symptoms**, although presenting some differences, are tolerably constant. The patient lies in a state of coma, stupor or lethargy, being paralysed more or less completely, heavy and drowsy, or insensible, not answering when spoken to, or only when addressed in a loud voice, and perhaps shaken at the same time. The breathing is carried on slowly and deeply, with a stertorous or snoring noise, and usually a peculiar blowing of the lips. The stertor appears to be owing to paralysis of the soft palate, which is thrown into vibrations during expiration by the passage of the air: the distension of the cheeks and blowing of the lips are due to the paralysis of these parts. One or both pupils are dilated and insensible to light; the pulse is full, often slow—in fact, a full, slow, laboured pulse is one of the most marked features in these cases; the feces pass involuntarily from paralysis of the sphincter ani, and the urine is retained from paralysis of the bladder; the skin may be cool, but in many cases, on the contrary, is rather hot and perhaps perspiring; the temperature may rise to 106° F. If the pressure be unilateral, Horsley has observed that the temperature of the extremities is often higher on the side opposite that on which the pressure exists, probably as a consequence of vaso-motor paralysis. In some cases, on the other hand, there appears to be depression of temperature on the side of the body opposite to the lesion. Not unfrequently during this condition of stupor violent fits of convulsions may occur. This state of coma may become complicated by symptoms of inflammation; and, unless the cause that produces the compression be removed, it usually terminates speedily in death, the patient gradually sinking into more complete unconsciousness, and dying in an apoplectic condition. In other, but much rarer cases, the insensibility may continue almost an indefinite time, for many weeks or even months, until the compressing cause is removed, when the patient may recover consciousness, and the symptoms disappear.

The **Diagnosis** between *concussion* and *compression* has been sufficiently indicated in the preceding description not to require special mention here. But it must be remembered that, in many cases, one state merges into the other, so that the symptoms are not so distinctly marked as has been indicated; and they are more especially obscured when associated with inflammation.

With regard to compression it may be broadly stated that whenever the symptoms follow an injury to the head within twenty-four hours they are due to the pressure of fragments of bone in depressed fractures, foreign bodies in penetrating fractures, or extravasated blood in simple injuries. Compression from inflammatory exudation does not occur till the third day at the earliest.

3. **CEREBRAL IRRITATION.**—The third form of primary cerebral disturbance

which is met with in injuries of the head, differs very remarkably from both the preceding. The patient presents symptoms neither of concussion nor compression, nor is there any combination of the phenomena characterizing these two states; but the symptoms are altogether peculiar. For convenience of description, they may be divided into two groups, the *bodily* and the *mental*.

The **Bodily Symptoms** are as follows. The attitude of the patient is peculiar and most characteristic:—he lies on one side and is curled up in a state of general flexion. The body is bent forwards, the knees are drawn up on the abdomen, the legs bent, the arms flexed, and the hands drawn in. He does not lie motionless, but is restless, and often, when irritated, tosses himself about. But, however restless he may be, he never stretches himself out nor assumes the supine position, but invariably reverts to the attitude of flexion. The eyelids are firmly closed, and he resists violently every effort made to open them; if this be effected, the pupils will be found to be contracted. The surface is pale and cool, or even cold. There is no heat of head. The pulse is small, feeble, and slow, seldom above 70. The sphincters are not usually affected, and the patient will pass urine, when the bladder requires to be emptied; there may, however, though rarely, be retention.

The **Mental State** is equally peculiar. Irritability of mind is the prevailing characteristic. The patient is unconscious, takes no heed of what passes, unless called to in a loud tone of voice, when he shows signs of irritability of temper or frowns, turns away hastily, mutters indistinctly, and grinds his teeth. It appears as if the temper, as much as or more than the intellect, were affected in this condition. He sleeps without stertor.

The course taken by these symptoms is as follows. After a period varying from one week to three, the pulse improves in tone, the temperature of the body increases, the tendency to flexion subsides, and the patient lies stretched out. The mental state also changes. Irritability gives way to calmness, there is less manifestation of temper, but more weakness of mind. Recovery is slow, but, though delayed, may at length be perfect; although in these, as in all other cases of cerebral disturbance, ulterior consequences may be manifested.

This form of cerebral disturbance may, from the peculiar irritability that characterizes it, be with propriety termed *cerebral irritation*.

The symptoms that have just been described usually follow blows upon the temple, or forehead, or occiput, and are probably due to superficial lacerations of the frontal lobes of the brain.

TREATMENT.—The treatment of these various conditions is often difficult, owing to the fact that they seldom occur in practice with that amount of distinctness and particularity by which alone their characters can be conveyed in description, but are associated together in such a way that the exact state of the patient cannot so readily be made out. It would be useless to attempt to describe the shades and modifications of treatment required in the management of the different groupings of these various forms of traumatic cerebral disturbance. We must, therefore, content ourselves with describing the treatment of each state broadly and separately, and leave the consideration of the varieties that commonly present themselves in practice to the discretion of the Surgeon.

In the **Treatment of Concussion**, the first great indication is to re-establish the depressed energies of the circulation and of the nervous system. In effecting this, we must be careful not to overstimulate the patient. The safest practice is that which is applicable to the treatment of shock generally—to wrap the patient up warmly in blankets, to put hot bottles around him, or to employ frictions to the surface, and when he is sufficiently recovered, to allow him to swallow a small quantity of warm tea. Aleoholic stimulants of all kinds should be avoided, unless the depression be so great that reaction cannot be brought about without their agency; but an enema containing some ether or aromatic spirits of ammonia may be administered.

When reaction has come on, steps should be taken to prevent the occurrence of inflammatory mischief. If the concussion has been slight, it may be quite sufficient to purge the patient well, and to keep him quiet on a regulated diet for a few days, directing him carefully to avoid all alcoholic stimulants and mental exertion for some time. If the concussion has been more severe, and if the symptoms of reaction have been accompanied by indications of continuous cerebral disturbance, or have been followed by giddiness, headache, or confusion of thought, the safer plan will be to adopt immediate steps for the prevention of further mischief. Venesection used formerly to be extensively practised as a precautionary measure, in order to prevent undue reaction and inflammatory mischief following on head injuries. Perhaps our predecessors erred in the too frequent and liberal use of the lancet in these cases: I believe that Surgeons of the present day are too sparing in its use. In the young and robust the best possible effects follow venesection in head injuries, to the extent of from 12 to 16 ounces. In children, leeches advantageously take the place of the lancet. The patient should be freely purged, kept on a low diet, and, above all, should remain quiet in bed for some days.

Should impairment of the mental faculties or senses be left, the more prudent plan will be to have recourse to a mild antiphlogistic treatment, consisting of leeching, cupping, blistering, purging, and more especially a mild mercurial course, with strict avoidance of all mental and bodily stimulation. The patient must be carefully watched, and kept under proper supervision for some length of time, as serious symptoms are apt suddenly to declare themselves.

In all cases of **Coma from Compression** the pressure must be relieved before it can be expected that the coma will subside. But, besides this great and obvious indication, which must be carried out in different ways according to the nature of the compressing cause, there are certain general considerations to be attended to, by which the patient's condition may be much relieved. Thus the bowels should be freely opened by placing a drop of croton oil, mixed with a little mucilage, in the patient's mouth, or by the use of oleaginous or terebinthinate enemata. The urine is to be drawn off twice in the twenty-four hours, the room darkened and kept quiet, and ice or an evaporating lotion applied to the head. If the breathing becomes extremely laboured and the pulse very slow and full, free venesection is often of use, but no treatment can be of any real service unless the cause of the compression be removed.

The treatment of **Cerebral Irritation** will require to be varied in different stages of the condition. In the early stage, the treatment that I have found most successful consists in the avoidance of all active measures. Much harm

may result from bleeding, purging, and mercurializing the patient. Complete rest, the removal of all mental and sensory excitement, shaving the head, the application of ice, a mild aperient or an occasional enema, are all that can be done in the way of medical treatment. As the constitutional powers are depressed, they must not be too much lowered by complete abstinence from food; small quantities of milk and beef-tea must be given at intervals, but stimulants are rarely, if ever, required. Bromide of potassium is often very useful in 30-grain doses. In some cases where there is great restlessness, and some delirium, without any sign of encephalitis having supervened, chloral will be found of great value, or an opiate even may be given to quiet the patient and induce sleep. This cerebral irritation is the only form of primary cerebral disturbance in which I have seen opiates act beneficially; but their administration requires great care, and must not be ventured on if there be any elevation of temperature or quickness of pulse. Should the signs of depression give way to those of subacute meningitis, the patient becoming noisy, restless and sleepless, venesection may be practised with great advantage. The bleeding should be followed up by the administration of bromide of potassium or chloral. In the treatment of all these conditions, it is impossible to insist too strongly on the paramount importance of absolute rest and quiet. No conversation, lights, or noise should be allowed in the patient's room, and no injudicious attempts should be made to rouse him or to ascertain by inquiry if he is conscious. Much depends on careful and quiet nursing; on attention to minor details, as the avoidance of noises, of flickering lights; and on the frequent administration of liquid food in small quantities, or *per rectum*.

Summary of Treatment.—The following treatment should be applied in all cases of head injury attended with unconsciousness, whether special operative interference be needed or not:—

1. The head must be shaved and slightly elevated on hard pillows.
2. Any scalp wound must be treated antiseptically.
3. Hot bottles applied to the feet—an ice-bag to the head if there be signs of compression, but not in simple concussion or if the patient be collapsed.
4. From two to five grains of calomel placed on the tongue on the second day.
5. The lower bowel emptied by a turpentine enema on the second or third day, and the catheter used if necessary.
6. The room darkened—the necessary fire and lights being screened.
7. No conversation in the room allowed; all noises avoided; slippers substituted for creaking boots; the coal put on with the hand; the fire stoked with a stick.
8. The diet to consist of spoon-food—iced milk or at most chicken-broth thickened with arrowroot or cornflour. Stimulants avoided if possible.
9. If the patient cannot swallow, nutritive enemata may be given every fourth hour.

CONTUSION AND LACERATION OF THE BRAIN.

Contusion and Laceration of the Brain and of its Membranes are frequent in injuries of the head, and are among the most important con-

fications of these accidents. The extent of injury inflicted upon the cerebral substance has wide limits, from slight laceration without exposure, to enudation of the brain, disintegration, and escape of large portions of its substance.

Causes.—Injury to the brain may be occasioned in various ways. The simplest form is, perhaps, that which is frequently met with in undepressed fracture of the skull and sometimes happens without fracture, from simple concussion or commotion.

Under these circumstances the laceration of the cerebral substance occurs in most cases on the side of the head opposite to that on which the violence is applied, usually at a point exactly opposite to that struck: much less frequently it is found immediately beneath the part of the skull which received the blow. Laceration of the brain is the commonest cause of death in simple fracture of the skull, the fracture itself when not compound being no more dangerous than a similar injury of any other bone. It is attended with extravasation of blood proportional to the amount of injury done to the brain tissue, and in severe cases this is sufficient to give rise to symptoms of compression which mask any special signs of cerebral laceration.

The regions of the brain most commonly injured are the anterior parts of the frontal and temporo-sphenoidal lobes. This is due partly to the irregularity of the surfaces of the bones against which these lobes lie, but much more to the fact that the posterior and postero-lateral parts of the skull and the vertex are the most exposed to injury from falls and blows. Thus when a person slips suddenly in frosty weather and strikes the back of his head on the pavement, there may be no external sign of serious injury, nor any fracture of the skull; yet laceration of the anterior portions of the cerebral hemispheres frequently occurs at the point exactly opposite to that struck.

The explanation of this fact—that the chief laceration is opposite the point struck—is that the blow starts a wave in the soft cerebral substance which breaks against the bone on the other side. In very rare cases it is possible to trace the course of this wave by hæmorrhages in the cerebral substance in its track. Thus not long ago a case occurred in University College Hospital in which a man received a blow from a fall on the left side of the forehead. He lived ten days, and at the *post-mortem* examination a bruise of the brain was found in the frontal lobe at the point which first received the violence, and exactly opposite this on the right occipital lobe was another bruise; in a straight line between the two bruises was a hæmorrhage into the right optic chiasmus. Very sudden and violent blows, such as non-penetrating bullet-wounds, usually lacerate the brain immediately beneath the part of the skull struck, and some of the most typical cases of localized cortical injuries of the brain are consequently to be found in the records of military surgery.

The brain and its membranes are often lacerated by the *sharp spicula of a depressed fracture*, which may penetrate to a considerable depth in its substance. And, lastly, the injury may be occasioned by *foreign bodies*, such as bullets, traversing or lodging in the head; by sabre or axe wounds, or by *stabs and punctures* through the inner portions of the skull, especially the orbital plate of the frontal bone. In this way a piece of stick, a tobacco-pipe, the point of a knife, or a scissor-blade, may puncture the anterior part of the brain.

The effects produced by the passage of a bullet through the head require short consideration. The experiments of Koerber have shown that the injury

produced by firing through an empty skull is limited more or less closely to the apertures of entry and exit. If, however, the contents of the skull be still within it, the sutures are at the same time widely torn open. This difference depends upon the so-called "hydrodynamic effect" of the bullet, viz., upon the passage of waves of increased pressure through the fluid contents of the skull at the moment when the bullet enters it. The experiments of Hensley and Kramer tend to show that in dogs these waves of pressure are of great importance in the production of sudden death from gunshot injuries of the brain. The pressure waves impinge upon the base of the brain, and by their effect upon the medulla cause sudden arrest of respiration. In these experiments prolonged artificial respiration usually succeeded in resuscitating the apparently lifeless animal. It is probable that the sudden death which occasionally follows a severe blow on the head, as by a cricket ball, may be susceptible of a like explanation.

The **Post-mortem Appearances** of laceration of the brain vary with the degree of injury and the time the patient survives. In a recent case every stage may be met with, from a mere superficial bruise, marked by a few points of extravasated blood in the grey matter, which still maintains its natural form and consistence, to extensive laceration and crushing, in which the grey matter, and a greater or less amount of the white, is reduced to a pulpy, disintegrated mass, mixed with clots of blood. In the cases of simple bruising, there is no extravasation of blood in the neighbourhood of the injury: in severe laceration clots are found superficially adhering to the injured part of the brain, and extending widely in the subarachnoid space, sometimes completely covering one hemisphere with a thick layer of coagulum. Occasionally the extravasated blood may have forced its way into the substance of the brain, and even have burst into the lateral ventricle: but this is very rare.

In lacerations due to penetrating wounds or accompanying compound fractures in which the dura mater is torn, if the patient survive beyond the third day, marked inflammatory changes may be found at the injured spot. In these cases the brain substance is softer than natural in the area of laceration, and is readily washed away with a stream of water. At the injured part are the remains of the extravasated blood; round about it the brain substance is redder than natural. In addition to the local mischief, the whole brain usually presents the appearances indicating septic meningo-encephalitis: the pia mater is gorged with blood, and infiltrated with greenish, puriform, inflammatory exudation, starting from the injured spot and extending more or less widely in all directions; there is a slight excess of cerebro-spinal fluid in some cases, but in others the surface is almost dry, and the convolutions are slightly flattened from swelling of the brain: the grey matter is everywhere redder than natural, the red points seen in sections of the white substance are also numerous, and the ventricles often contain an excess of fluid.

In simple fractures, or in compound fractures in which sepsis has been maintained, the patient is not free from the danger of spreading mischief extending from the injured area. According to Bergmann the blood extravasated round the laceration is often sufficient in amount to press on the veins of the pia mater, and thus to cause a serious interference with the return of blood from the injured part. If the extravasation is small in amount the result is but a limited area of oedema which soon disappears as the blood is absorbed and the pressure removed. But in extensive lacerations with more

abundant extravasation the swelling reaches a dangerous degree. Not only does it extend concentrically until it reaches uninjured and possibly vital parts of the brain, but the cerebro-spinal fluid becomes increased in amount by the transudation until it may give rise to fatal compression of the brain. The whole of this process is independent of true inflammation or infection from without, and is due to the anatomical arrangement of the vessels of the brain by which the blood returns chiefly through the large veins of the pia mater which are necessarily compressed by blood extravasated between them and the bone. In these cases a narrow zone, yellowish red in colour and dotted with points of extravasation, is found around the area of laceration: beyond this as far as the swelling extends the brain substance is moist, glistening, and softer than natural, that is to say highly cedematous.

Supposing the patient to have escaped these dangers, it is still possible that death may occur at a more remote period from softening round the injured spot. This softening is a result of the interference with the circulation from the injury to the vessels and the consequent hæmorrhage, and possibly of local inflammation following the injury. As the effect of this, the brain tissue and any inflammatory exudation that may be present undergo fatty degeneration, forming a yellowish pulpy mass, which washes away readily under a stream of water, the condition being known as *yellow softening*. The microscope shows innumerable fatty granules and granular cells, with sometimes recognizable *débris* of the nerve-fibres of the white matter. It is possible that recovery may take place even after softening of an area of some size, the degenerated tissue being absorbed and a small superficial defect left in the surface of the brain.

In cases in which recovery takes place without these unhealthy changes, a small tough, opaque scar, depressed below the surface, is left in the cortex, to which the membranes become firmly adherent. In the centre of the cicatrix may be a darker patch containing crystals of hæmatoidin, indicating its hæmorrhagic origin. If much blood have been extravasated into the subarachnoid space, it occasionally happens that, instead of being completely absorbed, it becomes decolorized and partly organized, forming a layer, often of almost leathery consistence and of dirty brownish colour, which remains permanently adherent to one or both sides of the subarachnoid space. Occasionally it forms a complete cyst, flattened out in the space, and containing a trace of fluid. Such cysts are usually adherent to the dura mater, but have been found loose beneath the arachnoid.

Symptoms and Effects.—The symptoms and results of wound or laceration of the brain vary greatly according to the nature of the accident, the seat of the injury, the age of the patient, and other conditions which cannot always be very readily determined.

The ordinary symptoms of laceration of the brain are at first merely those of concussion already described (p. 743). As before stated, "concussion of the brain" is a clinical expression only, and probably in all cases in which the patient rallies slowly, and certainly in those in which a return of consciousness is delayed over twelve hours, there is more or less bruising and laceration of the cerebral substance. If, as the patient rallies, the symptoms of concussion gradually merge into those of compression (p. 745), within twelve or eighteen hours, we may be sure that this is due to hæmorrhage within the skull, either from a laceration of the brain or from wound of a meningeal artery or a

venous sinus. The diagnosis of this latter condition will be referred to further on (p. 767). If soon after the injury cerebral irritation (p. 745) sets in, we may be certain that laceration of the brain is present, probably in the frontal region. Violent convulsions occurring within twelve hours of an injury to the head are almost invariably due to hæmorrhage from a laceration of the brain, either tearing down the brain substance in the region of the motor centres or diffusing itself widely beneath the arachnoid. Lastly, impairment of function in any part of the brain with the function of which we are acquainted, occurring as the direct result of injury, may be looked upon as evidence of bruising or laceration of that part. On the second day the temperature rises to about 100° F. in all cases of laceration of the brain, and by the third day it is usually 101° F. or 102° F., even when the air is excluded from the injured part.

In many cases of lacerated brain the patient recovers after having regained consciousness without any further trouble than a fixed headache for some days or weeks over the injured spot. This is especially common when the laceration is in the frontal lobes. In cases of compound fracture with laceration, septic meningo-encephalitis is a frequent complication, though at the present time much less common than formerly owing to the more efficient treatment of the wound. Should this occur, the symptoms of this affection (p. 772) mask all those specially indicative of laceration. Even if the patient escapes this danger he is still liable to local inflammation possibly terminating in suppuration, or to spreading œdema (p. 750) round the injured area. These complications when they occur usually manifest themselves by definite signs from the third to the fifth day. If the lesion is not seated in the region of the cortical motor areas the only symptom may be increasing insensibility with gradual development of the signs of compression of the brain. If the region of the cortical motor centres is implicated, convulsions usually form a prominent feature of the case. These, though very alarming to the Surgeon and to the friends of the patient, are by no means to be looked upon as hopelessly fatal. If the fits are not accompanied by gradually spreading paralysis, and if consciousness returns between them, there is a good hope of recovery, especially if the patient be young and otherwise healthy.

Suppuration is a very rare complication of laceration without an open wound, but it is sometimes met with, coming on occasionally some weeks after the accident. It is indicated by elevation of temperature and a gradual increase in the disturbance of function—as spreading paralysis, loss of consciousness, and convulsions if the motor area is affected, with the special symptoms subsequently to be given in describing intracranial suppuration (p. 774).

The recovery after laceration of the brain is often incomplete, localised paralysis or permanent loss of some mental faculty not uncommonly remaining.

These being the general symptoms of laceration of the brain, it remains to be considered how they may be varied or modified by the nature of the injury and other circumstances.

The Nature of the Injury. If the brain be injured directly by some sharp-pointed or cutting instrument, as a sword or hatchet, the symptoms of concussion may be entirely wanting; the patient may not suffer from even momentary loss of consciousness. The same may occur when a blow with some angular body is received on the thin portions of the skull. Thus a young

man was admitted into University College Hospital suffering from an injury to the brain which caused aphasia and facial paralysis, received in a fall against some steps. In spite of the severity of the injury he did not lose consciousness, or, if he did, it was certainly for less than one minute. In punctured fractures the patient frequently walks to the hospital unconscious of having received any more serious injury than a cut head. It is not even uncommon to see a patient with a wound from which broken down fragments of brain substance are protruding, and who is yet perfectly conscious and has been insensible only for a few minutes. On the other hand, when the laceration is due to a more diffused blow on the head—in those cases in fact in which it is situated on the side opposite to that struck—concussion is almost always more or less distinctly marked. In these the injury is more diffused and seldom at first capable of accurate localization, for in addition to the local injury the whole brain has been more or less violently shaken. Under such circumstances, it is not surprising that the return of consciousness is often delayed for days or even weeks.

The Locality of the Injury. Until comparatively recently we had no means at our command by which we could with any certainty recognize the exact part of the brain which was bruised or lacerated by an accident unless the nature of the injury were such as to leave no doubt that the cerebral substance was wounded directly beneath the part of the skull to which the violence had been applied. It was known that injuries to one side of the brain caused paralysis of the opposite side of the body and face, and that sometimes the paralysis affected merely a part of one side, and were very temporary in their character; that in other cases extensive injuries of the brain were not accompanied by any interference with motor power; but there was no accurate knowledge by which the seat of the injury could even approximately be determined by the symptoms. The earliest definite attempt to localize an injury in the cerebral hemispheres was made by Broca, who pointed out in 1861 that the condition now known as aphasia, in which the patient loses the faculty of converting his ideas into articulate speech, is associated almost invariably with some definite lesion of the posterior part of the third left frontal convolution. As the result of the investigations of subsequent observers it has been clearly demonstrated that the cortical grey matter of the brain in the region of the sulcus of Rolando is the seat of various centres, which are connected with the voluntary muscular movements of the body. The means by which our knowledge on this subject has been gained have been experimental and clinical. Excitation of certain spots in this so-called "motor area" by a weak faradic current causes definite muscular movements. Destruction of these areas, on the other hand, is followed by a paralysis of the corresponding movements, although such paralysis may be more or less temporary. It appears indeed that each centre in the motor area corresponds with certain definite movements rather than with individual muscles. Hitzig and Ferrier showed that if the strength of the exciting current be increased the resulting movements are no longer accurately limited but extend to a whole limb or the whole side of the body; a still stronger current gives rise to a general epileptiform convulsion affecting the whole body and accompanied by loss of consciousness.

The accompanying figure (Fig. 304) represents the principal motor areas on the outer surface of the cerebral hemisphere of the Bonnet Monkey as determined by Beever and Horsley. The exact limits of the different centres

primary or secondary mischief, a distinct group of muscles is paralysed, the term "monoplegia" is applied to the condition: when a similar group is thrown into spasm, it is spoken of as "monospasm." Thus, if the upper limb alone is affected it would be described as brachial monoplegia, or monospasm, as the case might be. If a patient receive a blow upon the head, and, on his recovering consciousness, it is found that a localized paralysis is present, we conclude that there exists a laceration of some severity in the cortical centre corresponding to the muscles implicated. If almost immediately after the injury there is a distinct spasm, affecting a localized group of muscles, we conclude that hæmorrhage is going on from the lacerated brain substance, and irritating or breaking down the tissue of the centre corresponding to the affected muscles; if the monospasm extends, first affecting the whole side of the body and finally both sides, so that the attacks assume the form of true epileptic fits, it is probable that the extravasated blood is extending over the surface of the brain and irritating more or less widely the whole motor area. As shown by the experiments before mentioned, however, it is not necessary for both sides of the brain to be injured in order to produce a general spasm: a violent irritation at one spot only is sufficient. Consequently it is possible that such convulsions might be caused by hæmorrhage breaking down the brain tissue in a limited area. The convulsions in these cases usually assume a regular course: the fit commences by twitching of that part, which, in the intervals of the fits, is most clearly paralysed. Thus, in an injury in which the centre of the right side of the face is chiefly affected, and in which facial paralysis is well marked, the fit commences by twitching of the right side of the face, then the head is turned forcibly to that side, then the right arm enters into the spasm, then the right leg, after which the left leg, left arm and left side of the face are affected in the order mentioned. During the spasm the muscles of respiration become fixed, the face becomes livid, and the patient froths at the mouth as in a genuine epileptic fit. The attacks of convulsions often occur in rapid succession, and after each the paralysis may be found to have extended; the return to the normal state between the fits may become less and less perfect, and finally coma may set in. In such a case if coma is complete within twenty-four hours of the accident hæmorrhage from a laceration might be diagnosed with tolerable certainty, and the question of trephining might arise, the site of the operation being determined not by the situation of any external wound or bruise, but by the indications of cortical lesion furnished by the paralyzes and spasms. It may happen, however, that the convulsions may not come on till the third, fourth or fifth day. They are then in some cases of compound fracture due to septic meningitis extending over the motor area. In cases without an open wound convulsions at this period are due to inflammatory hyperemia or spreading œdema from interference with the circulation in the injured area (p. 750), extending round the injured spot. In favourable cases this frequently subsides, and the patient recovers; but in others it goes on to such an extent as seriously to damage the brain substance, the convulsions increase in intensity, and are repeated more frequently, the return to the normal state between the fits becomes less and less perfect, and finally coma sets in and death occurs. If the laceration be situated near, but not in the motor area, there may be no paralysis till after the convulsions, and the paralysis may then gradually extend after each convulsion, indicating the gradual spread of the mischief into the region of the

motor centres. In other cases again, the superficial motor centre may be affected at a much later period by the formation of an abscess in the substance of the brain. It is in these cases, perhaps, that the study of the localization of the functions of the cerebral hemispheres is of the greatest importance, enabling the Surgeon to determine the exact seat of the secondary lesion. In the primary lesion, the external injury of the scalp or skull will often suffice to lead the Surgeon to a correct conclusion as to the seat of the injury to the brain; but in secondary or consecutive disease, such guides may be entirely wanting.

The following is a short summary of the combined results of experimental, clinical, and pathological observations as applied to the human brain:

Fig. 200.—Cast of Head, showing the Convolution of the Brain and their relations. (From a preparation by Cunningham.) R, sulcus of Rolando; S, S' (Sylvian fissure); I, inferior middle convolution; IP, intraparietal sulcus; P.C., precentral sulcus; A.F., ascending frontal convolution; A.P., ascending parietal convolution; S.P.L., superior parietal lobule; A., angular gyrus; S.M., supramarginal; S.F., superior frontal convolution; S.T., superior temporal convolution.

1. **Aphasia** is dependent on a lesion of the posterior extremity of the third or inferior frontal convolution of the left side—Broca's convolution.

2. **Facial Paralysis** depends on a lesion of the lower third of the ascending frontal convolution, and the contiguous part of the posterior end of the second frontal. The anterior part of this area is chiefly concerned in the movements of the upper part of the face. The posterior part, which extends to the lower third of the ascending parietal convolution, controls the movements of the lip and mouth. The fact that these centres are close to Broca's convolution, explains the frequent combination of facial palsy and aphasia.

3. **Paralysis of the Upper Limb** or brachial monoplegia indicates an affection of the middle portion of the ascending frontal convolution, and the contiguous part of the ascending parietal on the other side of the sulcus of

Rolando. This centre being immediately above those for the face, it is common to meet with a combination of facial palsy and paralysis of the arm.

4. Paralysis of the Lower Limb indicates a lesion of the upper extremity of the ascending parietal convolution, and of the posterior parietal lobule lying behind it, and reaching to the margin of the longitudinal fissure.

The above facts may be made more clear by a few typical cases.

In 1881, a young man, aged 20, was admitted into University College Hospital on the second day after he had received a rather violent blow on the left temple in a fall from some steps. On manipulating his head, a sensation was felt as if a small round piece of the thin part of the bone in that region had been broken loose; it was not depressed, and as further manipulation seemed dangerous, pressure was not repeated on it. He was not stunned by the accident, or at most for a few seconds only, but immediately lost the power of speech; he could understand what was said to him, and could say "yes," and "no," but nothing more. On the third day there was distinct paralysis of the lower facial muscles on the right side; on the fifth day, a clonic spasm commenced in the lower facial muscles, and gradually extended to the upper, and he lost consciousness. This lasted nearly half an hour, when he recovered, and was leeches over the injured spot, after which he fell into a sound sleep, and from that time rapidly improved, being practically well by the fifteenth day.

A gentleman, aged 39, was thrown from his horse, striking his head violently on the ground. He was taken up insensible, and was found to have a considerable extravasation in the right occipital region; there were no signs of fracture. He soon partially regained consciousness; he was quite unable to speak, and did not seem to recognize anyone, but from the first he got out of bed to make water, and showed signs of discomfort when he wanted to use the bed-pan. On the second day he was restless and his mental condition the same. On the fifth day, he could give the right or left hand when asked, though his mind was very far from clear; his speech was, however, evidently worse than the state of his mind could account for; he used only a few words, repeating them frequently; there was no paralysis. On the sixth day, he had violent convulsions, commencing with twitching of the right side of the face, followed by turning of the head to the right, a rigid spasm of the right arm, then of the leg; the spasm then became clonic and affected the left leg and arm, and finally the left side of the face. Between 10.30 A.M. and 2.30 P.M., he had twenty-one convulsions; his head was shaved, and he was leeches, and the convulsions ceased. The following day it was noticed that the right side of the face was paralysed. From this time his recovery was slow, but uninterrupted. It was many months before he regained the full use of words, and during that time he was haunted by an idea which he could not explain. Six months after, he had a violent epileptiform fit, preceded by aphasia, lasting some minutes, but he recovered without any evil consequences; he was suffering at the time from dyspepsia and constipation. On the first anniversary of his accident, he had a similar fit, and since that time several more have occurred at gradually increasing intervals. They have always been preceded by aphasia, lasting some time. On one occasion he signed an important cheque during the aphasic period, knowing the fit was coming on.

In the surgical history of the American war is recorded the case of a man who received a bullet wound which grazed the skull from the upper part of

the frontal region to the vertex. The right arm was immediately paralysed, at first only partially, but gradually the whole limb became powerless. Nine months after the wound he was, however, well enough to be returned to duty.

Guthrie records the case of a soldier, aged 40, who was wounded at Waterloo by a bullet, which passed across his head close to the vertex, fracturing and depressing both parietal bones. He was stunned by the blow, and when he recovered found he had lost power in both lower limbs. He was trephined ten days after the battle and made a good recovery, ultimately regaining much power in his legs.

These cases sufficiently illustrate the chief clinical features of injuries affecting the motor region of the cortex of the hemispheres. On each side of this motor region is an area the functions of which have not been defined with sufficient accuracy to be of much value in practical diagnosis. Considerable portions of the anterior parts of the frontal lobes may be lost without the patient showing any appreciable change either mentally or physically. It has already been seen, however, that those peculiar mental symptoms which occur in the condition known as Cerebral Irritation (p. 745) are almost certainly associated with bruising or laceration of this part of the brain. The sense of vision appears to be located in the occipital lobes; that of hearing in the temporal lobes, especially the superior convolution. The representation of general sensation in the cortex is little understood, but there is evidence to show that lesions of the so-called "motor areas" may result in tactile anaesthesia as well as paralysis.

As these cases of paralysis may require the use of the trephine, it is of great importance that we should be able clearly to answer the question whether the paralysis is dependent on central or cortical lesion. If due to compression or laceration of a central ganglion, it is obvious that the trephine would be useless. In these cases the paralysis will probably have been immediate, its completeness will be very marked, and the whole of one side of the body at least will in all probability suffer. In *cortical lesions*, in which the trephine may sometimes be advantageously applied, the paralysis, although it may be present immediately after the accident, often does not appear for some time: it is less complete and less extensive, sometimes affecting single groups of muscles, and is often preceded by convulsions.

The *Age of the Patient* has some influence on the symptoms and course of a case of laceration of the brain. Children, especially, have been known to bear extensive injuries of the brain, and even the loss of a considerable quantity of cerebral matter, without any very serious effects, either immediate or remote; and it is by no means uncommon to see them live several days with an extent of injury to the brain which would rapidly have proved fatal to an adult. Indeed it may be stated generally, that the younger the patient the greater the chance of recovery. So, also, the prognosis may be considered more favourable in men of the labouring class, whose minds are but little exercised, than in persons of more cultivated intellect.

Foreign bodies even of large size and considerable weight have been lodged for a considerable time within the skull without causing death. T. Hennen states that he has seen five cases in which bullets were lodged within the skull that did not prove immediately fatal. Cunningham relates the case of a boy who lived for twenty-four days with the breech of a pistol, weighing nine drachms, lying on the tentorium, and resting against the occipital bone.

O'Callaghan has recorded the remarkable case of an officer who lived about seven years with the breech of a fowling-piece, weighing three ounces, lodged in his forehead; the right hemisphere of the brain resting on the flat part, from which it was separated only by false membrane. Guthrie records two cases in which, although a ball had lodged in the brain, the patients apparently recovered. Both, however, died suddenly when drunk within a year after having received the wound. In one, who lived almost exactly a year, the bullet was found in a sort of cyst lying in the corpus callosum; in the other, who lived only a few months, it was lodged deeply in a cyst in the occipital lobe.

The **Diagnosis of Cerebral Laceration** varies much in difficulty, for, as before stated, the special symptoms indicative of laceration may be masked by those of compression or septic meningo-encephalitis. A careful consideration of the history and all the features of the case will, however, usually enable the Surgeon to come to a conclusion as to the presence of laceration; long continued insensibility without profound coma, convulsions, irregular and localized paralysis and spasms, are amongst the most important signs. Cerebral irritation may be looked upon as always indicating laceration. Some confusion may occasionally arise from the fact that the paralysis or convulsions resulting from a cerebral lesion are always manifested on the side of the body opposite to that on which the injury to the brain exists; but not necessarily opposite to that on which the blow has been inflicted on the head, for the injury to the brain may, by counter-stroke, be in that cerebral hemisphere which is opposite to the side of the head that has been struck. Thus, if a person struck on the right side of the head sustain a rupture of the middle meningeal artery, and have extravasation of blood on the right hemisphere of the brain, he may have hemiplegia on the left side, and *vice versâ*. But, if the blow that is inflicted on the right side gave rise to extravasation by counter-stroke on the left side of the head, the paralysis would develop itself on the side that had been struck. So it is with convulsive movements; they will occur in the arms and legs, on the side opposite to that on which the brain has been injured, whether that injury be on the side struck from direct violence, or on the opposite side from counter-stroke. In this way the hemiplegia may occur on one side, and the convulsions on the other. A man was struck a violent blow on the *right* temple. He was seized with hemiplegia and facial paralysis on the *left* side, and with convulsive movements of the *right* side of the face, the *right* arm and leg. He died a few days after the injury. On examination, we found a fissure of the right parietal bone, laceration of the middle meningeal artery, and a large clot pressing on the *right* side of the brain: hence the hemiplegia on the *left* side of the body. There was laceration of the middle lobe of the brain on the *left* side: hence the convulsive movements of the *right* side of the face, body, and limbs.

The **Prognosis** in wounds of the brain varies greatly according to the part that is injured, the nature of the injury, and the age of the patient. The danger is greatest and most immediate in injuries which affect the base of the brain, the pons, crura cerebri or medulla; it is least when the upper and anterior part of the hemispheres is the seat of lesion. Lacerations with open wounds, or compound fractures of the skull, or with penetration of a foreign body, are necessarily much more dangerous than those unaccompanied by such complications. Age has a very marked influence on the prognosis; the

younger the patient the more hopeful the case, other conditions being equal. The following may be looked upon as grave symptoms: early violent convulsions, extensive paralysis, and the rapid supervention of coma; a very high temperature with great restlessness. The later convulsions about the fifth day, although grave, are by no means hopeless symptoms; they become grave if they are frequently repeated, and if in the intervals there is found to be an extension of any paralysis that may be present, and especially if the condition of insensibility is found to be gradually deepening after each attack. When the symptoms of intracranial suppuration set in, the case, although desperate, is not quite hopeless.

Treatment.—In the treatment of injuries of the brain, little can be done after the patient has rallied from the shock, beyond attention to strict antiphlogistic treatment, though this need not be of a very active kind. In these cases, indeed, as much as possible should be left to Nature, the Surgeon merely removing all sources of irritation and excitement from his patient, and applying an antiseptic dressing when there is a wound.

If any foreign body be lodged in the skull, it must of course be removed, if possible. This may be done if it be situated near the external wound, or fixed in the bone; but if it have penetrated deeply into the substance of the brain, and have gone completely out of reach, it would perhaps be more dangerous to trephine the skull on the chance of reaching it, or in any other way to go in search of it, than to leave it where it is. Bullets should always be extracted if they can be found. On this point military Surgeons are agreed. If they enter the skull, and strike against and fracture the opposite side without escaping, should they be sought for? I think not. Larrey and Bell, if it true, have extracted the ball on the side of the head opposite the point of entrance. But it may not be found there. In a case of suicide to which I was called some years ago, a gentleman had shot himself through the right temple; immediately opposite the wound, on the left temple, was a raised, loose, and stellate fracture of the skull, over which the scalp was uninjured. I cut down on this and removed the fragments of bone, expecting to find the ball beneath them; but in this I was disappointed, and after death the bullet was found lying in the base of the skull, whither it had rolled. All operations performed in such cases should be carried out with strict antiseptic precautions.

In cases of laceration of the brain without open wound nothing is required at first beyond keeping the bowels open, applying cold to the head, and perfect quiet. Should there, however, be early convulsions or paralyzes sufficiently definite to indicate the seat of the lesion, followed rapidly by coma evidently from its early occurrence due to hemorrhage from a laceration, the question of trephining over the point of injury to the brain may arise. The indications for this operation are considered on page 771.

When the convulsions and paralyzes occur at a later period, and are sufficiently defined to enable the Surgeon to localize the seat of the injury, the head should be shaved, and leeches applied over the seat of the laceration, and after this an ice-cap. If the pulse be full and hard, and the patient young, blood may also be taken from the arm. Venesection is especially likely to be of service if the symptoms be due to non-inflammatory spreading oedema (p. 760). The bowels should be freely acted on by some brisk purgative. Bromide of potassium should always be given in full doses as soon as convulsions appear.

A case showing the value of this occurred in University College Hospital a few years ago. The patient had typical symptoms of a lesion in the region of the centre for the right arm following a blow on the head. He was perfectly conscious and, beyond the weakness of the arm, showed no symptoms of any kind. About the fifth day epileptiform convulsions commenced; rapidly increasing in frequency and violence, and accompanied by gradual extension of the paralysis to the face and leg. It was evident that unless relief could be speedily given death was inevitable, and the question of trephining was discussed; but before doing so, bromide of potassium was given in full doses. The fits immediately ceased, and within a few days the patient, feeling perfectly well, insisted on leaving the hospital.

If in spite of these measures the convulsions become more violent and general, the paralysis more extensive, and the state of insensibility deeper, the question of treatment becomes more anxious. The extension of the mischief may be due to inflammation extending around the laceration, and in this case it is doubtful if much good could be hoped for from trephining. But on the other hand it may be the effect of non-inflammatory spreading oedema (p. 750), and under these circumstances the removal of the clot surrounding the laceration and the relief of tension by giving exit to the exuded fluid might be productive of the best results. At any rate, when other means have failed and the patient is evidently going from bad to worse, it is the Surgeon's duty to give him the last chance offered by trephining.

The operation is, however, more hopeful, and certainly should never be neglected when symptoms of intracranial suppuration supervene at a later period with localized paralysis sufficiently defined to indicate the part of the cortex affected.

The guide to the application of the trephine in these cases is the *line of the sulcus of Rolando on the side opposite to that in which the paralysis exists*.

It is thus essential that the Surgeon should be acquainted with a reliable method of ascertaining the position of this sulcus. The upper end of the sulcus of Rolando lies between one and a half and two inches behind the coronal suture, whilst the lower end is about one inch behind the same suture. Thane gives the following method for marking the position of the sulcus of Rolando and the fissure of Sylvius on the surface of the head (Fig. 307). A line (A B) is drawn from the infraorbital margin to the centre of the aperture of the ear, and parallel to this the line (C D) from the fronto-malar suture backwards. On this line mark a point (E) $1\frac{1}{4}$ inch from its commencement, and raise here a perpendicular $\frac{3}{4}$ inch long. The upper end of this line (Sy) may be called the *Sylvian point* and marks the place where the anterior branches are given off from the fissure of Sylvius. From the fronto-malar suture, draw a line through the Sylvian point to the parietal eminence; this lies over the posterior limb of the fissure of Sylvius. A point (iR) on this line 1 inch behind the Sylvian point is immediately below the lower end of the sulcus of Rolando. The upper end of the sulcus of Rolando (sR) is situated half an inch behind the mid-point between the root of the nose and the external occipital protuberance. A line drawn from sR to iR marks the position of the sulcus of Rolando, and forms with the median line anteriorly an angle of 70° or more. The parallel sulcus and the external parieto-occipital fissure are in a line (F L) drawn from the marginal tubercle of the malar bone to the lambda.

The position of the sulcus of Rolando having been defined on the head, the

exact point to which the trephine is applied must be determined by the seat of the paralysis.

Lucas-Championnière gives the following rules which indicate the point to be selected in the combinations of paralysis most commonly met with:—

1. When there is general hemiplegia the trephine should be applied over the middle of the line of the sulcus of Rolando.
2. When the arm and leg are paralysed, the trephine should be applied to the upper part of that line, but not at its very summit.
3. In paralysis of the upper limb only, the trephine should be applied a little in advance of the middle third of the line.
4. In simple aphasia it must be applied lower down, below and a little in front of the line.
5. When both lower extremities are paralysed, the top of the line and the vertex must be trephined.
6. When the upper and lower extremities are paralysed, the middle and upper part of the line should be trephined.

Fig. 507. — Diagram showing the method of marking the sulcus of Rolando, &c., on the surface of the head. (Thane.)

7. Paralysis of one upper extremity with facial paralysis requires trephining in front of the line at its lower third.
8. Paralysis of one upper extremity with aphasia requires the trephine to be applied below and in front of the line.
9. In facial paralysis and aphasia the trephine must be applied in front of the line and below its level.

In all cases a large trephine should be used, and if necessary it may be applied in more than one place.

Saccharine Diabetes is an occasional consequence of injuries of the brain. A man 43 years of age was admitted into the Hospital under my care with paralysis, the result of a fall on the back of his head. The urine was found to contain sugar in very large quantity. Previously to the accident he had been perfectly well and robust; and, as the paralytic symptoms improved, the sugar lessened in quantity, until it disappeared, and this notwithstanding the continued use of saccharine and amylaceous matter in the food.

Claude Bernard has recorded some similar instances in illustration of the interesting facts pointed out by him, that in rabbits wounds or irritation of the central portion of the medulla, between the origins of the vagus and auditory nerves in the floor of the fourth ventricle occasion saccharine diabetes, and that in the dog artificial traumatic diabetes may be induced by fracture of the skull and injury of the brain. In patients already suffering from diabetes, a blow on the head is frequently followed by fatal aggravation of the complaint.

The **Cerebral Nerves** are occasionally injured at their roots, or torn across and detached from their connexion with the brain, in injuries of the head. These nerves may be wounded by the same violence that injures the brain, as by a bullet; or they may be detached from their connexion with the brain in laceration of the cerebral substance; or, lastly, they may be torn across in fracture of the base of the skull, by the fissure extending across the foramen through which the nerve passes.

From these causes, or from extravasation of blood into its sheath, blindness may result from injury to the optic nerve at any part of its course. Ptosis, and strabismus in different directions, according as the third, the fourth, or the sixth nerve has been injured, are also occasionally observed. But the nerves that most commonly suffer are the seventh and eighth, which are torn across in fractures of the petrous portion of the temporal bone, producing either paralysis of the face or deafness, or both together. Injury to the tenth nerve is not common, or rather it is rare for patients to survive who exhibit evidence of the lesion. I have, however, seen repeated vomiting, with palpitation, and a sense of suffocation continuing for months after apparent injury to the origins of the pneumogastric. In other cases, owing to lesion to the spinal accessory, spasm of the trapezius and sterno-mastoid muscles, simulating tetanus, may set in.

COMPLICATIONS OF WOUNDS OF THE BRAIN AND ITS MEMBRANES.

Extravasation of Blood within the Skull necessarily occurs in all injuries of the head accompanied by laceration of the brain, and in many in which the skull is fractured without wound of its contents. Indeed, when we reflect on the great vascularity of the parts within the skull, the large sinuses, the numerous arteries that ramify both within the bones and at the base of the brain, and the close vascular network extending over the surface of this organ, we can easily understand that extravasation of blood is one of the most frequent complications of these injuries and a common cause of death, when they terminate fatally at an early period after their infliction.

Causes.—Intracranial extravasation of blood may occur, as the direct result of a fracture, in consequence of the fissure tearing across one of the meningeal arteries, or of a fragment of bone wounding a sinus. In some cases the inner table only has been fractured, the middle meningeal artery being torn in this way where it lies in a groove in the bone. When the brain is lacerated either by the broken bone or by indirect violence, the torn substance necessarily bleeds more or less abundantly. In rare cases, especially in children, extravasation may result from apparently trifling injuries of the head without fracture, from rupture of one of the meningeal arteries.

Situations.—Extravasation may occur in four situations:—1. Between the

dura mater and the skull when it proceeds from a wounded meningeal artery, or more rarely, a sinus. 2. In the subdural space. 3. In the subarachnoid space and in the meshes of the pia mater on the surface of the brain; and 4. In the substance of the brain or in its ventricles. In the last three situations the blood is derived from the vessels of the pia mater, or the substance of the brain. Intracranial extravasation is most commonly met with on the surface of the brain from laceration of the cortex, but here it is seldom very abundant. It is much less common between the dura mater and the bone, but when occurring in this situation the quantity is often large, but even then seldom exceeds four ounces, although I have seen a clot from rupture of the middle meningeal artery weighing five ounces and a half.

Results.—The extravasation of blood into a closed cavity such as that of the cranium necessarily causes pressure on its contents, varying with the amount poured out. It is thus one of the most frequent causes of death in injuries of the head, giving rise to fatal compression of the brain and coma. In smaller amounts on the surface of the brain it may cause serious effects by interfering with the venous return from the injured area from which the hæmorrhage proceeded (p. 750). When of moderate amount it most frequently causes no evil consequences. The blood that is so extravasated may undergo various changes: 1. It may be absorbed entirely; 2. The serous portion, and a great part of the colouring matter, may be removed, leaving a fibrinous buff-coloured layer, which may occasionally become organized. This occurs only in arachnoid hæmorrhage. Such layers are sometimes double, and then, forming a flattened cyst, the cavity of which is merely moistened by a little fluid, are occasionally found unexpectedly in the subarachnoid space many years after the injury which gave rise to the extravasation; 3. The exterior of the clot may become consolidated, whilst the interior contains fluid and disintegrated blood. This occurs in the cerebral substance, and the cysts thus formed are permanent.

Symptoms.—The only definite symptom of extravasation of blood is gradually increasing insensibility, ending in coma within twenty-four hours of the injury. It is, however, a matter of the greatest practical importance to determine, if possible, whether the hæmorrhage is taking place between the dura mater and the bone, or whether it arises from a laceration of the brain substance, or is taking place into the membranes.

In a typical case of *Extravasation between the dura mater and the bone* there are three distinct stages: viz., concussion, a return and some continuance of consciousness, and then gradual supervention of coma. In exceptional cases in which the injury is very slight, more especially in children, concussion may not occur, and in a considerable proportion, the interval of consciousness between the concussion and the commencement of the symptoms is absent or very imperfectly marked. Jacobson, who has published a most exhaustive paper on this subject in the Guy's Hospital Reports, states that in 66 cases collected by him it was wanting in 21, and so little marked that it might easily have been overlooked in 10. The duration of the interval of consciousness is very variable, but it seldom extends beyond an hour or an hour and a half. The following cases illustrate these various conditions. A lady going into the opera stumbled on some stairs and struck the side of her head against the wall. She felt giddy and confused, returned home, went to bed, and was found comatose next day. I was sent for, but before

I could trephine she died. On examination, a four-ounce clot was found in the dura mater, under a ruptured meningeal artery, but without fracture. I have seen the same in a boy, who, running down stairs to his dinner, struck his head against the opposite wall; he ate his dinner, vomited, became drowsy and died. A large clot was found between the dura mater and the bone at the part struck. In neither of these cases was there any external bruise or other sign of injury. In a case of murder at Liverpool the man, after receiving the fatal blow, walked half a mile home, half a mile to see a medical man, and finally home again, and did not become unconscious for three hours and a quarter after the injury. In the cases in which the interval of consciousness is wanting, this is due either to very rapid hæmorrhage or to simultaneous laceration of the brain.

As the hæmorrhage takes place the symptoms of compression set in, and gradually increase in intensity. The extravasation being in the great majority of cases over the motor area of the cortex, paralysis is usually an early and important symptom. Most commonly, if the case be seen early, there is paralysis of the side opposite to the extravasation—in rare cases, more marked at first, perhaps, in one limb. As the pressure increases the paralysis usually becomes general, but even when this state is reached the thermometer in most cases shows that the temperature of the extremities is higher on the side opposite to the clot. Convulsions may occur early in the case but are not common. Vomiting is a very frequent symptom. In the early stages the patient becomes drowsy and dull, with a slow and labouring pulse, dilated and sluggish pupils, and a tendency to slow respiration. As the compression increases complete coma sets in with loud stertorous breathing.

When the symptoms follow the typical course with a distinct interval of consciousness we may feel tolerably sure that the extravasation results from injury of one of the meningeal arteries or large venous sinuses, and that there is no laceration of the substance of the brain; for it may safely be assumed that if the patient recovers consciousness after the accident, he cannot have such a degree of tearing and bruising of the cerebral substance as to lead to an escape of blood sufficient to cause compression. The vessel most commonly ruptured is the anterior branch of the middle meningeal artery, (Fig. 308a) which, from its situation in a deep groove in the parietal bone, is peculiarly apt to be torn in injuries of the side of the skull.

When this artery is the source of the blood, the clot extends deeply down into the base of the skull; and Hutchinson pointed out that in this way it may exert powerful pressure on the cavernous sinus, leading to fulness of the vessels, with protrusion of one eyeball and wide dilatation of the pupil. This occurs on the *same side* as the extravasation, and thus we may get hemiplegia of the opposite side, while the more dilated pupil is on the same side as the injury. It may, however, be pointed out, that in his experiments upon compression of the brain Dean found that under certain circumstances localized pressure on the cortex caused wide dilatation of the pupil on the *same side*. In cases complicated with a fissured fracture, some of the blood forces its way through the fissure, and thus may cause marked fulness of the temporal fossa on the affected side, clearly to be seen when the head has been shaved. A few years ago a man was admitted into University College Hospital who had fallen from the driving-seat of a van. He got up again and took

the reins, but feeling sick and giddy he left the box and lay down in the van, while his companion undertook to drive. About one hour afterwards he was found comatose. His head was shaved on admission, and on careful inspection a distinct fulness was noticed in the right temporal fossa, and on the parietal eminence of the same side was a bruise. He was trephined in the line of the artery and a large clot found and removed, but the brain failed to expand, and he died a few hours afterwards. In another case the patient fell eight or nine feet, and a quarter of an hour afterwards she came to the hospital. She was conscious, and related how the accident happened. There was a wound on the right side of the head, near the parietal eminence. She rapidly became unconscious, and two hours after the fall she was apparently dying. At this time the right eyeball was protruded, and the pupil widely dilated: the left was dilated, but less so than the right. She was trephined on the right side, and a large clot found and removed: the symptoms of compression were relieved, but she died eighteen hours after the accident. In both cases the brain was uninjured.

In some of these cases the respiration becomes greatly embarrassed, and this must always be looked upon as a grave symptom, indicating operative treatment.

The **mechanism of meningeal extravasation** has given rise to much discussion, and the following remarks of Sir Charles Bell ("Surgical Observations," London, 1816) are well worthy of attention:—"It is extraordinary that any one who has ever raised the skull-cap in dissection, and felt the strength of the universal adhesions of the dura mater to the lower surface of the bone, could for an instant believe that the *arteria meningea media* has power of throwing out its blood to the effect of tearing up these adhesions from the entire half of the cranium!" He then describes the following experiment to show that the dura mater is first of all separated from the skull, and that the extravasation is consequent on that separation:—"Strike the skull of the subject with a heavy mallet: on dissecting, you find the dura mater to be shaken from the skull at the part struck. Repeat the experiment on another subject, and inject the head minutely with size-injection, and you will find a clot of the injection lying betwixt the skull and dura mater at the part struck, and having an exact resemblance to the coagulum found after violent blows on the head. I imagine this is conclusive" (pp. 466—467). It is possible also that the alterations in form of the skull which accompany blows causing fracture see (p. 722) may tend to loosen the attachment of the dura mater. That the meningeal artery does, however, pour out blood with sufficient force to strip the dura mater further from the bone, when it is once loosened, can hardly be doubted, as it is difficult to conceive that that membrane can be shaken from the base of the skull by a blow on the parietal eminence: and yet meningeal extravasation often extends as far as the cavernous sinus. It must not be forgotten that when once a cavity is formed, the blood forced in acts on the principle of the hydraulic press. Taking the pressure in the artery to be about two pounds to the square inch, when four square inches of dura mater are separated we have a force of eight pounds pressing against it; when it is separated for three inches in each direction the pressure equals eighteen pounds. To resist this we have only the adhesion of the dura mater and the blood-pressure in the capillaries of the brain substance. It is not surprising, therefore, that the force exerted by the escaping blood produces such marked effects.

Extravasation of blood into the membranes may occur with little or no bruising of the brain substance itself. The amount of blood extravasated may be considerable, so that a layer of varying thickness is found over a large part of one or both hemispheres, whilst the remainder gravitates towards the base. Under these circumstances the symptoms of compression may speedily develop, and are not preceded by that distinct interval of consciousness which is so common in cases of hæmorrhage outside the dura mater. But on the other hand the development of coma is likely to be less rapid than is the case when the blood is derived from lacerated brain substance. Localized extravasation of blood into the membranes is not necessarily accompanied by the symptoms of general compression. If it occur over the motor areas the irritation produced by its pressure on the brain is likely to result in convulsions followed by paralysis, the distribution of which may serve as an indication of the seat of the lesion.

The extravasation of blood dependent on laceration of a portion of the brain may be termed *Cerebral Extravasation*. It is far more common than the other forms: in it the patient never recovers consciousness after having been stunned, the symptoms of concussion speedily passing into those of compression. In these cases the paralysis is commonly incomplete, often hemiplegic, and is associated with twitching of the limbs or convulsive movements of the body generally, and much restlessness with incoherent muttering: the pupils are sometimes contracted, sometimes dilated, and occasionally squinting is observed.

Diagnosis.—The diagnosis of these forms of extravasation is important, as it is in the extra-dural variety especially that operative procedure is likely to be attended with success. It can, however, be made with any degree of certainty only when the typical symptom of the interval of consciousness is present. When the different forms occur together accurate diagnosis becomes almost impossible. If the interval of consciousness is absent, the protrusion of the eye with dilatation of the pupil on the same side as the injury, the fulness in one temporal region and the difference of temperature in the two axillæ, may indicate the nature of the case. In doubtful cases the Surgeon should cut down on the skull in the region of the meningeal artery and examine for fracture.

The diagnosis between the compression from *extravasation* and that from *depressed bone* or *inflammatory effusions within the skull* is easily made. In the case of depressed fracture, the symptoms of compression continue uninterruptedly from the very first, and proper examination of the skull will always lead to the detection of the injured bone. When inflammatory effusions exercise undue pressure upon the brain, the signs of compression come on at a later period and are preceded by symptoms of cerebral inflammation, accompanied by a good deal of pyrexia, quick pulse and hot skin.

From *apoplexy*, the diagnosis is not always easily made, more particularly when there is no evidence that the head has been injured. I could give numerous instances of this. The following will suffice:—A man was brought to University College Hospital in a state of profound coma, in which condition he had been found lying in the street. There was no evidence of injury about the head beyond a bruise, which had probably been received when he fell. The case, which was supposed to be one of apoplexy, and was treated accordingly, proved fatal in a few hours. On examination after death the skull was found

fractured, but not depressed. On the side opposite to the bruise and fracture, a coagulium, weighing nearly four ounces and compressing the brain, lay between the dura mater and the bone. In such a case, it is evident that the history can alone afford a clue to its true nature. Even when the head has been injured, the diagnosis is not always easy. A man was admitted under my care, comatose. A fortnight previously he had been struck on the left side of the head behind the ear. He was stunned, bled freely from the left ear, but then recovered tolerably, and went about his avocations as usual until the day before his admission, when he suddenly became comatose. The respiration was stertorous, the pulse quick, and there was some heat of head; the right pupil was natural, the left contracted. He was treated antiphlogistically, but died on the third day. On examination, a fracture on the left side of the skull was found, extending into the left internal meatus; on the right side of the head there was a large coagulium in the subarachnoid space, with some seroplastic exudation about it. Here was an extravasation, the result of laceration, existing without symptoms for fourteen days, and then proving rather suddenly fatal in consequence of the supervention of inflammation. A woman fell in the street whilst walking. She was taken up insensible: was thought to have a fit; became comatose, hemiplegic on the right side, and died the next day. After death the left parietal bone was found to be fractured, and a clot which weighed five and a half ounces was lying over the ruptured middle meningeal artery on the dura mater.

The insensibility of *drunkenness* may usually be distinguished from the coma resulting from injuries of the head, by the absence of local mischief, by the smell of the breath, and by the face of the drunkard being flushed and turgid, and not pale like that of a person who is suffering from the effects of a severe injury. When a drunken person has met with an injury of the head and is insensible, he should always be carefully watched, however slight the injury may appear to be, until sufficient time has elapsed for him to recover from his drunken fit, as it is impossible to say whether the stupor be the result of intoxication, or of mischief within the skull. I have known cases to be sent away from hospitals as drunk, when in reality the stupor was occasioned by depressed bone.

In the stupor from *poisoning by opium*, the condition of the pupils, which are contracted to the size of a pin's point, instead of being widely dilated as in coma from cerebral compression, will enable the Surgeon to make the diagnosis.

In considering the question of the **Treatment** of extravasation of blood within the skull, we must, as far as possible, define the conditions in which it may be hoped that the application of the trephine may give relief. The only alternative consists in the adoption of general and local measures, having for their object the arrest of further hæmorrhage, the promotion of absorption, and the prevention of inflammation.

If the *symptoms point with tolerable certainty to meningeal extravasation between the dura mater and the bone*, probably from the middle meningeal artery, the Surgeon should cut down at once upon the skull and examine the bone and trephine in the line of the fracture if one be found; if not, in the line of the middle meningeal artery. The artery may be wounded at any part of its course within the skull, but it is very rare for the main trunk to be ruptured; almost invariably it is the anterior branch that suffers. This branch is first directed forwards across the great wing of the sphenoid to near

the tip of the small wing : here it takes a sharp curve backwards, and often enters a canal in the bone ; from this point it is directed backwards and upwards in the groove which crosses the anterior inferior angle of the parietal bone (Fig. 308). Its course may be found externally by the following rule :— Draw a straight line (A, B) backwards from the external angular process of the frontal bone ; take a point (C) at any distance between one inch and two and a half inches from the angular process in this line and draw a vertical line (D, E) through it from the zygoma ; measure a corresponding distance up this line, and the point so found (M) will be over the artery. If the distance taken be under one inch and a half, the artery will very frequently be found in a canal in the bone ; beyond this it is usually in a groove. Accuracy is of importance only when a fissured fracture is found, as the centre of the crown

Fig. 308. Relations of the Middle Meningeal Artery and Lateral Sinus to the surface of the Skull. M, meningeal artery, with *a*, anterior, and *p*, posterior branches ; L.S., lateral sinus ; m, mastoid vein.

of the trephine should, if possible, be at the point at which the fissure crosses the line of the artery. In other cases a very sufficient and practical guide is to put the pin of the trephine two and a half inches vertically above the condyle of the lower jaw.

The bone should be exposed by a semicircular incision around the spot to which the trephine is to be applied. This incision divides the scalp and the temporal aponeurosis and muscle. A large branch of the superficial and one or both deep temporal arteries will require ligature. The flap, together with the periosteum, is turned downwards from the bone with an elevator, and the crown of a large trephine applied, with the pin of the instrument over the spot where the vessel is supposed to lie. If the diagnosis have been correct, as soon as the circle of bone is removed a dark solid clot pushes its way up into the opening. As a rule, however, it is too solid to come out without the use of a scoop, and for this purpose a small lithotomy scoop may be used. The Surgeon, having now trephined and removed the blood-clot, is confronted with what is truly the greatest difficulty of the case. The artery in the majority of cases follows the dura mater, for it is only if it be in a canal in the bone that it remains superficial. If the brain expands as soon as the pressure is removed, the injured artery may come into view ; if not, all that is

seen is a profuse flow of blood pouring out of the opening in the skull, and apparently in some cases threatening to be almost immediately fatal. Under these circumstances all that can be done is to raise the patient into a sitting position, to compress the carotid, and to apply ice to the side of the head and neck. Under this treatment the bleeding usually ceases rapidly and does not recur. If the actual wounded spot can be seen, a fine catgut or carbolized silk ligature must be passed round it with a sharp needle. If the artery lies in a canal, and its torn end can be seen bleeding where the trephine has cut through it, the hæmorrhage may be arrested by inserting a small plug or by touching it with the cautery. If the situation of the wound can be recognized at some distance from the trephine opening, more bone may be cut away either upwards or downwards so as to expose it. The operation should, of course, be performed with the strictest antiseptic precautions.

In some cases the hæmorrhage is due to the tearing of a large number of small vessels, and not to the wound of any special branch. Thus, in one of the fatal cases in University College Hospital, a child, aged seven, the most careful examination failed to detect any wounded artery. The hæmorrhage was in this case situated behind the region of the large branches of the meningeal artery, and the clot was reached by cutting away a portion of the skull behind the trephine hole with bone-forceps.

The instances in which the symptoms are sufficiently definite to guide the Surgeon with precision to a wounded meningeal artery are not numerous. Out of many hundred cases of serious and fatal injury to the head that were admitted into University College Hospital during the time I had charge of wards in that institution, in four cases only, I believe, was it found advisable to have recourse to trephining for the removal of extravasated blood. In three of these cases death speedily ensued, the coma being unrelieved by the operation. In the fourth case, recovery took place. This case was that of a man admitted comatose, three days after receiving an injury of the head by a fall from a cab. There were no serious symptoms for some hours after the accident; but then stupor gradually came on, amounting at last to complete coma. On examination, a bruise of the scalp was found on the left temple; through this I made an incision, and, finding a starred fracture over the sinus of the middle meningeal artery, trephined the bone, when a large coagulum was found lying upon the dura mater, and, on removing this, fluid arterial blood freely welled up. The coma was relieved, and the patient made a good recovery.

From 1870 to 1881 four cases were trephined in University College Hospital for meningeal hæmorrhage; three by Beck, all of which terminated fatally, and one by Godlee, which was successful. In this case the bleeding artery was seen and secured by a ligature.

In cases in which the diagnosis of middle meningeal hæmorrhage cannot be made the indications for trephining are not so clear. If the signs are those of general compression, without any localizing symptoms, it is certain that operation can do little if anything to relieve them. The effused blood is, under these circumstances, usually most abundant about the base of the brain, which cannot be reached by any operation; and, even if it be situated chiefly over the convexity of the hemispheres, the Surgeon has no guide for the application of the trephine, and no means of removing the blood which spreads widely in every direction.

In other cases, however, as we have seen, careful observation of the convulsions or paralyses which supervene may indicate the position of the extravasation. If, under these circumstances, the extension of the motor phenomena shows that the hæmorrhage is continuing, or if signs of general compression, especially deepening coma, develop, the Surgeon should lose no time in applying the trephine over the spot indicated by the symptoms.

Even with the strictest antiseptic precautions the operation, which necessarily involves opening the dura mater, is a serious one. It should not be undertaken as an immediate means of treatment, if the general symptoms of compression be absent, and if the local symptoms be not progressive. But at a later period trephining may be required with the object of relieving persistent paralysis or signs of irritation. The hope of a successful result is necessarily greater when the effusion of blood is in the subdural space than when it proceeds from lacerated brain substance. Of the several cases of this kind in which the application of the trephine has been guided entirely by the symptoms, one of the most striking is recorded by Macewen. A boy, after a fall on the head, had for six days been subject to convulsions beginning in the left side of the face and spreading to the left arm and leg. There was also paresis of the same parts. The trephine was applied over the lower end of the right sulcus of Rolando, and two ounces of blood-clot were evacuated from the subdural space. The recovery of the patient was complete.

If it be decided that no operation is advisable, the head must be shaved and ice applied, and the patient kept at perfect rest. If the respiration and pulse become much embarrassed, free venesection may give some relief.

TRAUMATIC MENINGITIS AND ENCEPHALITIS.

Acute diffuse meningitis—Acute Lepto-meningitis—Meningo-encephalitis.—Inflammation of the brain and its membranes from injury is a complication of great frequency and of corresponding importance.

Causes.—Every wound or laceration of the brain must necessarily be followed by a localized traumatic inflammation in the injured area, but there is no greater tendency for this to spread or to persist in the brain than in any other part of the body. Its natural course is to subside and to give place to the normal processes of repair in from twenty-four to forty-eight hours. If the inflammation extends or persists it is due to some source of irritation, other than the wound, introduced subsequently to its infliction. It is extremely rare to find meningitis following simple injuries of the head, however severe, in which there is no wound of the skin or fracture of the skull. When such a condition is met with it is most commonly due to general infection from some unhealthy wound in another part of the body inflicted at the same time as the injury to the head. In unhealthy children diffuse meningitis may follow a simple injury in rare cases, just as diffuse infective peritonitis may follow a blow on a bone, the source of infection in these cases often remaining uncertain. Acute meningitis, after open wounds of the head, is almost invariably of septic origin. It is needless to explain how readily infection occurs in open fractures with wound of the dura mater, unless special precautions are taken to prevent it. In compound fractures, in which the dura mater is intact, it occurs less frequently, but is by no means uncommon and is

a frequent cause of death after fracture of the base of the skull. In these cases the septic matter doubtless finds its way through the dura mater by means of the lymphatics, for Schwalbe has shown that fluids injected between the dura mater and the bone pass readily into the subdural space. In cases of scalp wound, with exposure of the bone, meningitis may be set up as a consequence of necrosis or diffuse inflammation of the diploe (p. 718), or according to Schwalbe it may occur even without this, as he showed that fluids injected between the pericranium and the bone, especially in the neighbourhood of the sagittal suture, found their way by the lymphatics to the outer surface of the dura mater. In other cases the meningitis has been a consequence of septic thrombosis of the sinuses of the dura mater which has subsequently extended to the veins of the pia mater. Lastly, the septic matter may find its way along a nerve to the membranes, as in some cases of wound of the optic and in fracture of the base of the skull with exposure or rupture of the facial or auditory nerve.

Period of Invasion.—Septic meningitis, following compound fractures of the skull, usually manifests itself on the second or third day, when the septic processes are well established in the wound. In cases in which the bone is exposed without fracture it may occur at any time until the wound is healed, but it is most common during the second and third weeks after the injury. In the rare cases in which it is said to have followed simple laceration without external wound it has usually been the result of drunkenness or exposure before the injury to the brain was soundly healed.

Pathological Changes.—After death we usually find on raising the dura mater that the brain is somewhat swollen, its convolutions being more or less flattened. The surface is generally dry, though there is frequently an excess of fluid in the ventricles. The characteristic feature of meningitis is the presence of greenish-yellow lymph, often almost purulent in character, lying partly in the subdural space and partly in the meshes of the pia mater. It is most abundant in the neighbourhood of the injury. The pia mater is intensely injected, and the sinuses are distended with blood. The cerebral substance is always affected with the membranes covering it, and therefore this condition is sometimes spoken of as meningo-encephalitis. The brain substance, when cut into, exhibits an increase in the number of red points; the grey matter is darker than natural, and often distinctly reddish in tint. If there is a laceration of the brain, the cerebral substance round it is usually softened, washing away with unnatural readiness under a stream of water.

The **Symptoms** usually commence within forty-eight hours of the infliction of the injury. The patient, if he is conscious at the time, complains of severe, constant, and increasing pain in his head: the scalp is hot, the carotids beat forcibly, the pupils are contracted, the eyes intolerant of light and the ears of noise; the pulse is full, vibrating, and bounding; and wakefulness, with delirium, commonly of a violent character, speedily comes on. All the symptoms of severe pyrexia set in at the same time. The temperature rises rapidly, usually reaching 103° F., or more, by the third day.

Under proper treatment, this condition may gradually subside until the health is re-established, but more commonly the symptoms of inflammation merge into those of compression—the delirium being replaced partly or

entirely by stupor, from which the patient is roused with difficulty, the pupils gradually dilating, the breathing becoming heavy and stertorous, the pulse sometimes continuing with its former rapidity, at others becoming slow and oppressed. The skin is hot but clammy: the patient falls into a heavy, dull, unconscious state, which alternates with convulsive twitchings or jerkings and occasional delirious outbreaks. As death approaches, the sphincters relax, the pulse becomes slower and more feeble, the surface cooler, the coma more intense and continuous, until the patient sinks from exhaustion and compression conjoined.

Diagnosis.—Acute meningitis is distinguished from pressure of extravasated blood by the later time at which it appears, by the elevation of temperature and the quick pulse. From spreading oedema (p. 750) extending round a laceration it is recognized by the presence of fever, but the distinction is not always easily made.

Treatment.—The preventive treatment is of the greatest importance, for when the symptoms of acute meningitis have set in, the patient seldom recovers, whatever may be done for him. The most scrupulous attention to the prevention of decomposition in all cases of wound of the scalp or compound fracture is the most efficient means at our command for the prevention of meningitis. Should the symptoms manifest themselves, active treatment should at once be adopted. The head must be shaved, and cold applied. In the use of cold, great care must be taken that the application is constant; intermittent cold is worse than useless. One of the best modes of application is the india-rubber ice-cap, which can be secured to the head by a strap passing under the chin: or Leiter's soft metal tubing, which can be moulded to any form, and through which a stream of cold water is kept constantly flowing, is even more efficient. Should these not be available, a bladder filled with ice may be used, but care must be taken that it is firmly secured in its position by bandages, and not, as is too often done, allowed merely to lie against the head, so that it is displaced by the slightest movement of the patient. A mackintosh cloth must be placed beneath it to protect the bed-clothes from being wetted. Bleeding from the arm, repeated as often as the pulse rises, as well as cupping, or leeches, may be had recourse to; the bowels should be freely opened, and rigid abstinence must be enjoined, the patient at the same time being confined to a quiet and darkened room, and removed from all causes of excitement of the special senses.

Chronic or Subacute Encephalitis is a most interesting and important affection following injuries of the head. Its pathology is not very clearly understood. In some cases after death the arachnoid is found opaque and thickened. In other cases the symptoms have been due to chronic inflammatory changes, or softening taking place round the site of a severe cortical laceration. The symptoms may come on within a few days of the injury or not until months have elapsed. The patient in many cases has apparently recovered entirely from the accident, though in others it will be found that some one symptom indicative of the brooding mischief still continues, such as headache, or impairment of sight or of hearing. Occasionally, the coming mischief is foreshadowed by unusual irritability of temper, by loss of mental vigour, or by some other functional disturbance of the brain. In such cases the subacute encephalitis may suddenly come on, ushered in perhaps by an aggravation of the persistent symptom, or by an epileptic fit. The sub-

sequent symptoms are very variable. There is usually pain in the head with heat of the scalp and irregularity of the pupils or contraction of both. There may be squinting, intolerance of light, convulsive twitchings, or epileptiform fits. At the end signs of compression may set in, terminating in coma. There may be a slight persistent elevation of temperature when the symptoms become pronounced. This affection is most dangerous and unmanageable, being very apt to terminate in loss or impairment of the senses, in diminution of intellectual power, or in local paralysis. The best results are obtained by the proper administration of mercury and the employment of counter-irritants. The best mode of administering the mercury is to give half a grain or a grain of calomel every four or six hours until the gums are affected, and to keep up the effect with diminished doses of the drug. The repeated application of blisters over the shaven scalp is perhaps the most useful form of counter-irritation. So long as any symptoms of inflammation continue, this plan of treatment must be steadily kept up.

In the more chronic forms of cerebral irritation following injury, more especially if there be any tendency to convulsive movements, bromide of potassium in moderate doses will be found of essential service. It soothes and secures sleep more effectually than any other remedy.

INTRACRANIAL SUPPURATION following injury may occur in three situations: (*a*) Between the bone and the dura mater; (*b*) in the membranes; and (*c*) in the brain itself. In the large majority of cases the suppuration is the result of the direct infection of the interior of the skull by pyogenic organisms which gain an entry at the seat of injury. Exceptions to this rule are apparently presented by those rare cases in which an abscess develops in the brain substance opposite the point struck, and possibly by recorded instances of intracranial suppuration, the result of injury without an open wound. The nature of the injury itself differs widely. In not a few cases suppuration has followed a wound of the scalp, exposing the bone, but not fracturing it. Under these circumstances it is probable that septic phlebitis occurs in the diploë, and that thence the infective process spreads inwardly along the small blood vessels. More frequently, however, the bone is fractured, and thus a ready entry for pyogenic organisms afforded. Punctured fractures are especially likely to be followed by intracranial suppuration. In such cases the brain may be directly infected at the time of injury; but, apart from this, suppuration is favoured by the splintering of the inner table, and the accumulation of blood on the inner surface of the bone, as well as by the imperfect escape for the discharge afforded by the small size of the external wound. Macewen points out that extensive compound fractures are less dangerous in this respect, as they allow a free exit for discharges, whilst being obviously serious they are likely to be more efficiently treated. The danger of the punctured fracture lies in its apparent simplicity. A cerebral abscess may be occasioned by the lodgment of a foreign body, such as a bullet, in the brain substance.

a. Subcranial Abscess forms between the bone and the dura mater. It occurs beneath the seat of injury, and is the result of infection from a scalp wound, with or without fracture. It usually occurs early, before the wound has healed, but an interval of several weeks may elapse and the scalp wound may be healed before the symptoms of intracranial suppuration manifest themselves. Subcranial abscess necessarily involves a localized inflammation

of the dura mater, and is not unfrequently a precursor of septic meningitis or cerebral abscess.

The *symptoms* of this condition are in many respects similar to those resulting from suppuration in other situations within the skull. They were first described by Percival Pott. There is heat of head with throbbing carotids and flushed face. These symptoms are accompanied by elevation of temperature, headache, intolerance of light and noise, and drowsiness.

Delirium and vomiting are occasionally observed. During the continuance of these symptoms fits of shivering or actual rigors may occur. If the scalp wound be still open, as is commonly the case, it is found dry, whilst the pericranium is separated from the bone, and the latter is yellowish brown and dry, or in a condition of necrosis. If however the wound be closed or scabbed over, the scar and surrounding scalp will be found to be raised into a soft oedematous swelling—Pott's "puffy tumour."

b. Intrameningeal Abscess is merely an exaggeration of the septic meningitis already described. It may be the result of the extension of an abscess between the bone and the dura mater, or on the other hand it may complicate an abscess in the brain substance. Occasionally it is met with as a result of pyæmia arising from some other injury complicating that of the brain.

The *symptoms* are those of acute septic meningitis already described (p. 772), and the diagnosis of the localized abscess can rarely be made.

c. Cerebral Abscess is met with in an acute or chronic form.

In the *acute* form the abscess usually forms close to the surface of the brain at the point of injury. It is often accompanied by suppuration in one or both of the other situations already mentioned, the symptoms of which may completely mask those due to the cerebral abscess itself.

A *chronic* or *subacute* abscess is almost exclusively met with after wounds of the scalp exposing the bone, with or without fracture of one or both tables. It has been said to occur after simple blows not wounding the scalp, but the evidence of this is not very satisfactory. The abscess is seated deeply beneath the cortex somewhere in the lobe of the brain corresponding to the part of the skull injured. There is no evidence that it is in any way due to bruise or laceration of the brain substance, as this always affects the cortex and not the white matter. These abscesses are exactly analogous to those which are not uncommonly met with as a consequence of chronic suppurative inflammation of the middle ear. The exact mode of formation is somewhat uncertain, but it is believed to be due to a limited septic thrombosis and phlebitis extending from the injured spot into the brain substance.

The *Symptoms* of cerebral abscess necessarily vary according to whether it occurs as an acute form situated near the surface of the brain at the seat of injury, or as a chronic form deeply seated in the white matter. In the former case the early symptoms are likely to be those already described as following suppuration between the bone and the dura mater, and indeed this condition is often present. Drowsiness is followed by insensibility, deepening into coma.

In the more chronic form, which may occur after a long interval, the symptoms are exactly similar to those produced by the cerebral abscess following chronic suppuration of the middle ear (Vol. II., Chap. LV.). Among them may especially be mentioned headache, vomiting, slow and full pulse, subnormal temperature, optic neuritis, and drowsiness deepening into

coma. In some cases the puffy swelling of the scalp already referred to may be observed.

In determining the probable position of the abscess the Surgeon may be assisted by the seat of the injury and by the presence of certain localizing symptoms. The abscess is usually found beneath the seat of injury, and the earlier it occurs the greater is the probability of this being its position. If however the abscess is situated in the region of the cortical motor centres the affection of these, with gradually spreading paralysis of the opposite side, may serve as a valuable means of localization. As early as 1876 Macewen successfully diagnosed the position of a cerebral abscess by the symptoms produced. A boy, eleven years of age, manifested symptoms of intracranial suppuration after a scalp wound in the left frontal region. On the twenty-sixth day a convulsion occurred, beginning in the right side of the face and spreading to the right arm and leg. This was followed by aphasia of one hour's duration, and right hemiplegia, which remained pronounced for several hours. A diagnosis was made of "abscess in the immediate vicinity of Broca's lobe, situated between the speech centre and the internal capsule." The parents of the boy refused to permit operation, but the diagnosis was confirmed by *post-mortem* trephining.

In one recorded case the position of the abscess in the occipital lobe was recognised by the presence of hemianopsia. In the frontal lobes especially, a large abscess may exist without localizing symptoms. The presence of optic neuritis is of no value in determining the position of a suspected abscess, nor does the absence of optic neuritis negative the diagnosis of abscess if the other symptoms be well marked.

Symptoms of lepto-meningitis may result from the extension of the abscess to the surface of the brain and the infection of the membranes: whilst the sudden onset of complete coma with weak pulse and respiration, dilated pupils, and muscular rigidities may be due to the bursting of the abscess into one of the lateral ventricles.

Diagnosis.—The acute form can rarely be distinguished from ordinary septic meningitis without an abscess. The chronic or subacute form can be diagnosed only by attention to the symptoms above given. It may, in many cases, somewhat resemble pyæmia, also a not uncommon complication of scalp wounds exposing the bone. Pyæmia can usually be recognised by the repetition of the rigors, the characteristic temperature, the absence of any signs of pressure on the brain, and the occurrence of local suppurations in other parts of the body.

Cerebral abscesses, either single or multiple, may occur as a consequence of pyæmic infection from any unhealthy wound, and conversely a case of cerebral abscess may be complicated by pyæmia secondary to it. In these cases accurate diagnosis is impossible.

The **Prognosis** of all cases of intracranial suppuration is almost hopeless if untreated. The only form in which recovery may occur without surgical interference is that in which acute suppuration occurs beneath a compound fracture with loss of bone. In these cases the pus may discharge itself through the wound and recovery may follow.

Treatment.—The preventive treatment of intracranial suppuration consists in efficient antiseptic treatment of any wound of the head. If this fails, exit must be given to the pus in some way, or the patient will die. In cases

of acute suppuration in compound depressed fractures or punctured fractures, if no primary operation has been performed, the bone should at once be exposed and the fragments elevated or removed and, if necessary, the opening enlarged with the trephine or chisel. This gives the patient his only chance, but if the case is complicated by septic meningitis the chance is but small.

In the chronic and subacute cases following injury with exposure of the bone the Surgeon's duty is equally clear. He should expose the bone thoroughly, and if he finds it bare, yellowish in colour and possibly necrosed, he should at once remove a circle of bone with a large trephine. The operation, if carefully performed, can do no harm, and, if pus has formed, it offers the only chance of saving life. If pus be found beneath the bone the cavity in which it lay should be cleaned out with some efficient antiseptic fluid and dusted with iodoform, after which the wound may be loosely closed, perfect provision being made for drainage, and an antiseptic dressing of some kind applied. The dura mater should be carefully examined, and if a small aperture be found in it this may be enlarged to facilitate drainage.

If the pus is immediately beneath the dura mater that membrane will be dull yellowish in colour, and will bulge into the wound, without pulsation. Under these circumstances an incision must be made through it. If pus is reached here it will spirt out with great force.

If the pus is more deeply seated in the cerebral substance, the dura mater will appear perfectly healthy and will pulsate as usual. In such a case Dupuytren plunged a bistoury into the substance of the brain and thus luckily relieved the patient from an abscess in this situation. This was doubtless a somewhat rash thing to do without previously ascertaining the presence of pus by milder means.

It is now well known that no harm results from careful puncture of the brain substance with a grooved needle or with the smaller needles of the aspirator. In these cases, therefore, a careful search should be made for the pus by means of a grooved needle or an aspirator. If the latter instrument be used only a partial vacuum should be produced, otherwise the soft cerebral substance will be forced into the needle and choke it. Care must be taken, however, that the needle is pushed straight onwards in the direction intended, all lateral movements being avoided, and in this way several punctures in different parts may safely be made. Hulke in this way detected the presence of an abscess in the frontal lobe of the brain in a boy aged 15, seven weeks after he had received a blow on the forehead causing a small stellate fracture of the outer table of the skull which was not discovered at the time of the accident. The abscess, which was situated about one inch below the surface of the brain, was opened by a knife passed along the aspirator needle and about 3ij of thin greenish pus were evacuated. The boy recovered, but unfortunately became completely blind from atrophy of both optic papillæ following on neuro-retinitis. Hulke was led to infer the presence of an abscess in this case chiefly by the fact of hemiplegia supervening gradually many weeks after an injury to the head, a symptom to which he attaches much importance.

In some cases the presence of localizing symptoms may indicate the position in which the trephine should be applied. The indications thus afforded must be taken as a more trustworthy guide than the position of the injury. Thus in Macewen's case already mentioned the scalp wound was over the left eyebrow, but the abscess was evacuated *post mortem* by trephining over

the base of the third frontal convolution. If the abscess be deeply seated, a small drainage tube must be inserted into the cavity, otherwise the swollen brain substance will prevent drainage. Macewen uses a decalcified chicken bone tube, but in the treatment of an acute abscess he usually dispenses with the drainage tube altogether, the cavity being rapidly obliterated by the brain bulging into it.

The difficulties in the diagnosis and treatment of these cases are, however, often very great, as the following cases will show. A man was admitted into University College Hospital with an extensive lacerated wound of the scalp, denuding the pericranium. He continued free from all cerebral disturbance until the tenth day after the accident, when he complained of headache, and had a quick pulse and a hot skin; at this time it was observed that the pericranium had separated from the skull. Active antiphlogistic treatment was followed by subsidence of symptoms, and the patient went on favourably until the thirty-fourth day, when he suddenly became delirious and then unconscious, though easily roused when spoken to loudly, and then answering rationally; his pulse fell to 48. He died on the thirty-ninth day, comatose. On examination after death, the pericranium was found detached at the seat of injury; under this the dura mater was thick, yellow, and opaque, but no pus was observable. On separating the hemispheres, however, a large abscess was found situated deeply in the anterior lobe on the injured side, and protruding into the median fissure. It contained about one ounce of pus.

Another case admitted into the Hospital was that of a man who had received a large lacerated wound on the left side of the scalp in consequence of a fall. There was no injury to the bone, and the patient went on perfectly well until the seventy-seventh day, the wound having cicatrized. He was then suddenly seized with hemiplegia of the right side, from which he recovered partially on being bled; some twitching of the muscles, however, continued. On the ninety-ninth day after the accident he became comatose, and was trephined by S. Cooper, but without relief, dying with symptoms of compression of the brain on the third day after the operation. On examination thick yellow lymph was found, covering the whole of the upper surface of both hemispheres, lying between the arachnoid and pia mater, and extending into the sulci between the convolutions. There was an abscess in the substance of the brain near the surface of the right hemisphere—the side opposite to the seat of injury. Here also, though the symptoms were well marked, and the diagnosis as to the existence of pus correct, trephining was useless, as the pus could not be evacuated. These cases serve to indicate the difficulties that surround any operation undertaken with the view of evacuating matter from within the cranium.

HERNIA OR FUNGUS CEREBRI.—In those cases in which a laceration of the brain and dura mater communicates with a fracture of the skull, it is occasionally found, more particularly in children, that a dark brown or bloody fungus-looking mass of cerebral matter protrudes from the wound. The period after the receipt of an injury at which this protrusion takes place, varies from a few days—eight or ten—to several weeks. It was remarked by Guthrie, and the observation has been fully confirmed, that hernia cerebri is more likely to take place through small, than through large, apertures in the cranial bones.

The protrusion is usually the result of abnormal intracranial pressure, from

inflammatory swelling of the brain substance round the injured spot, or occasionally from the formation of an abscess in the hemisphere. It may, however, result from simple non-inflammatory œdema of the brain substance, and thus may occur in a perfectly aseptic wound. As the protrusion increases in size, it becomes partially strangulated by the narrow opening through which it passes, and its size becomes increased by œdema, and by hemorrhage and effusion into its substance. Thus the tumour increases rather rapidly, pulsates synchronously with the brain, and may shortly attain the size of a hen's egg, or become even larger (Fig. 309.) In its composition and structure it varies. In some instances it is composed chiefly of extravasated blood; but the true fungus cerebri is composed of softened cerebral matter, often infiltrated with inflammatory exudation and blood. Softening of the brain,

Fig. 309.—Hernia Cerebri following Compound Comminuted Fracture of Right Parietal Bone.

with red discoloration, extends for some little distance under the base of the tumour. The mental condition of the patient is in many cases not much disturbed at first, there being merely some degree of cerebral irritation. Speedily, however, stupor comes on, and death in most cases eventually occurs from encephalitis, ending in coma, consequent on the inflammatory effusion that takes place within the skull.

Although the prognosis in fungus cerebri is extremely bad, it is not hopeless. In the American war seven cases of recovery are recorded. In the Italian war of 1859, Demme saw five recoveries out of twenty-one cases.

Treatment.—Preventive treatment is of the greatest importance, for if the complication be once established, its cure is very uncertain. The rigid antiseptic treatment of the wound by some efficient method is the most important preventive means at our command, for the condition is favoured by inflammatory swelling of the brain substance. Should the fungus form,

the treatment is extremely unsatisfactory. If the tumour be shaved off, as is usually recommended, it generally sprouts again, although in some fortunate cases this treatment is satisfactory. All that can be done is to slice off the growth on a level with the brain, and to apply firm pressure to the part. This may be done by means of a pad of antiseptic gauze, or a flat disc of lead or decalcified bone may be slipped beneath the edges of the opening in the skull.

SECONDARY OR REMOTE EFFECTS OF HEAD INJURIES.

Effects of Cerebral Injury on the Mental Powers.—The mental condition of patients who are recovering or who are supposed to have recovered from head injury, is one that deserves attentive consideration. It will frequently be found that the mental powers are weakened, either generally or in one special direction.

The memory will often be found to be weakened in a very remarkable manner on the recovery of the patient from the unconsciousness resulting from severe concussion. Not only is the mind a complete blank as to all that occurred during the period of the unconsciousness, but the memory may be lost for those events which immediately preceded it. Thus a driver will remember his horses taking fright: but he will never be able to recall to his recollection the various events that occurred before he was thrown from his box, and received that blow on the head which produced concussion of the brain and rendered him unconscious—events which had certainly produced impressions upon the brain before it was injured, impressions which were permanently obliterated by the concussion of the cerebral substance. The chain of memory is broken abruptly at some occurrence—often of a very trivial character—antecedent to the accident, and the gap then left can never be filled by any subsequent effort on the part of the patient.

The memory may be impaired in other ways, as for words, persons, or dates. The mind cannot grasp a subject or pursue a continuous train of thought, and is incapable of fixed attention or reasoning. Delusions of various kinds may occur, especially in connection with the mode of occurrence of the accident. I have known a patient give the most consistent and detailed accounts of the mode in which his head was injured, varying them from day to day—every one being false, but believed in by the patient at the time. The patient could be led, by a process of questioning and suggestion combined, to give almost any version that the interrogator desired: and this with great circumstantiality of detail. This is a matter of great interest and importance in a medico-legal aspect, as it is evident that an individual who has received a severe injury of the head might, in perfect good faith, give an entirely false account of the mode of infliction of the injury, by which an innocent person might be seriously compromised.

Epilepsy is not an uncommon consequence of injury of the head, especially when the blow has been inflicted in the region of the cortical motor centre. The form of epilepsy thus produced is that known as "focal" or "Jacksonian." Hughlings Jackson having maintained twenty years ago that it resulted from some organic lesion in the cortex. The attack is characterized by the definite spread of the convulsions, the spasm beginning in the part in con-

nection with the affected centre. The fit is frequently preceded by peculiar sensations in the part first affected by the spasm, and is often followed by transient paresis of the parts which are the seat of the convulsions. There is usually no loss of consciousness. It is obviously only in cases of epilepsy believed to be of the focal variety that any benefit can be expected from operative interference. The Surgeon must if possible observe for himself the exact character of the attacks, and must bear in mind that ordinary epilepsy and hystero-epilepsy may manifest themselves for the first time after an injury to the head.

Traumatic epilepsy has been said to arise from the following causes:—1st, from a neuralgic cicatrix on the scalp—the starting point of reflex convulsions; 2nd, from chronic osteitis of the part of the skull struck giving rise to thickening and induration in the bone; 3rd, from depression of bone, fracture of the inner table or the formation of osseous stalactites pressing on the surface of the brain in the motor area; 4th, from chronic thickening of the dura mater; 5th, from cystic collections of fluid in the membranes; and 6th, from scars or other lesions in the area of the cortical motor centres.

The cysts which have in many cases been found in the membranes, usually beneath the arachnoid, probably owe their origin to hæmorrhages produced by the injury, and the same explanation must be given of the cysts which have more than once been opened in the brain substance itself. In some cases no pathological appearances could be detected at the time of the operation, although it is remarkable that in some of these relief followed.

In the **Treatment** of traumatic epilepsy operative interference may be resorted to after the ordinary constitutional means have failed. If it seems to be due merely to a painful cicatrix in the scalp, we may follow Bryant's advice and dissect it up without removing any of the subjacent bone.

The practice of trephining in these cases is a very ancient one. The older Surgeons often employed it, and Cline cured a patient whose epilepsy was found to be occasioned by an osseous projection from the inner table, and whose last fit was on the operating table before the elevation of the disc of affected bone. The practice fell into disuse until revived by Lucas-Championnière, West, and others. Operative interference for epilepsy was formerly limited to removing a portion of bone in the scar of a previous injury, the Surgeon hesitating to perform any operation on the brain itself.

At the present day, however, if the Surgeon find no cause of irritation in the bone itself, he may proceed to open the dura mater with strict antiseptic precautions. The bulging of the dura and its imperfect pulsation may already have indicated the presence of a collection of clear fluid beneath it which may be evacuated.

It has been mentioned above that the epilepsy may be the result of scarring of the cortical brain substance. Under these conditions the prospects of a cure are not so good, but in the hands of Victor Horsley and others success has followed the removal of the scar with the brain substance around it. The details of the operation are the same as in removal of tumours of the brain, and will be described with the operation of trephining. In one of Horsley's first cases of this kind, the patient, a man of 22, had an old depressed fracture of the skull, giving rise to fits beginning in the right leg. During the thirteen days previous to the operation he had 2,870 fits. On exposing the brain, a scar involving the hinder end of the superior frontal sulcus and the membranes

covering it was found and removed with the brain substance around it. The patient recovered rapidly, and has had no fits since.

In some cases in which the brain presented nothing obviously abnormal that portion of the cortex has been excised stimulation of which with a weak faradic current has produced movements of the part in which the fits commenced.

Recurrence of the epilepsy after operation is in some instances no doubt due to the cicatrix which is again produced, but from the conditions present the scarring is likely to be much less marked than that following the injury itself. Putting together the statistics of Laurent, Agnew and Starr, we find a record of 201 cases of epilepsy treated by trephining, the large majority being evidently traumatic. Of these 71 are said to have been cured, 62 improved, 41 not improved, 2 were worse after operation, and 14 died. In the remainder the result was doubtful.

The operation thus holds out a chance of relief or cure in otherwise hopeless cases, but it should of course not be undertaken unless other means have failed, and the symptoms are so severe as to make the patient willing to run the inevitable dangers of the operation, and possibly to be permanently paralysed in a portion of his body. In such a case as that described on p. 75, in which the fits occur at long intervals, and the health between them is perfect, the patient had better be content to bear the ills he has.

OPERATION OF TREPHINING.

Before concluding the subject of injuries of the head, it is necessary to say a few words on the operation of **Trephining**, which may be required for any of the following conditions, viz. :—

1. Simple depressed fracture of the skull with symptoms of compression.
2. Simple depressed fracture of the skull in an adult without symptoms of compression, but in which the depression is deep and limited in area, and especially if situated over the motor region.
3. Compound depressed fracture of the skull, with or without symptoms of compression.
4. Punctured or incised fracture of the skull.
5. Extravasation of blood between the skull and dura mater from rupture of the middle meningeal artery.
6. Intrameningeal or cerebral extravasation of blood : (a) if definite localizing symptoms be associated with the general symptoms of compression ; (b) if the spread of the localized paralysis or convulsions suggest continuing hæmorrhage ; and (c) if the localized paralysis or convulsions remain unchanged after many days.
7. Intracranial abscess and septic thrombosis of lateral sinus.
8. For the removal of a bullet lodged within the cranium.
9. Traumatic epilepsy.
10. Tumours of the brain : (a) for the removal of the growth ; (b) for the relief of pressure symptoms.

The use of the trephine may also be required in the removal of tumours of the skull, and it has been employed in the operation of craniectomy in microcephalic idiots, and for the drainage of the ventricular cavities in chronic meningitis and hydrocephalus.

The instruments required in the operation of trephining are a scalpel and periosteal elevator, the trephine and elevator, Hey's saw, a chisel and mallet, bone-forceps, a strong pair of dissecting forceps, and several pairs of force-pressure forceps. In operations involving an extensive removal of bone, a circular saw, driven by an electro-motor, may prove of service.

As a preliminary step the head must be completely shaved and cleaned in the way described on p. 719. If the operation is not one of emergency the scalp should be covered with lint soaked in carbolic lotion (1 in 20), over which must be placed a layer of oiled silk. This must be applied for 12 hours before the operation and changed about every hour.

If the patient is sensible an anæsthetic must be administered. If the operation is being undertaken for the removal of a portion of the brain or a tumour, Victor Horsley, who has so highly distinguished himself in this branch of surgery, advises the use of chloroform, and that a hypodermic injection of a quarter of a grain of morphia should be previously given, as this not only makes it possible to produce the desired effect with a smaller

Fig. 310. - Trephine.

Fig. 311. - Trephine cut at edge of fracture.

amount of the anæsthetic, but Schäfer and he have demonstrated experimentally that it tends to cause a contraction of the arterioles of the brain, and thus to diminish hæmorrhage.

The bone should be exposed by a free incision, any wound that may exist at the time being utilized. If the scalp is unbroken a curved incision exposing the bone by a single flap will be found more convenient than a T-shaped or crucial incision such as is often recommended. The periosteum must be raised in the flap with the periosteal elevator.

The bone being exposed it may not be necessary to apply any saw in some cases of depressed fractures. In others a cut may be made with a Hey's saw between two branches of a fracture. In cases in which the bone is not broken the trephine must be used. This should have a well-tempered crown, serrated half-way up its exterior; the teeth should be short and broad; the centre-pin must not project more than about one-sixteenth of an inch, and care must be taken that the screw which fixes it is in good working order. The centre-pin may advantageously be fixed to a solid plug which can be removed when necessary, and the trouble of the screw avoided (Fig. 310). The trephine

covering it was found and removed with the brain substance around it. The patient recovered rapidly, and has had no fits since.

In some cases in which the brain presented nothing obviously abnormal that portion of the cortex has been excised stimulation of which with a weak faradic current has produced movements of the part in which the fits commenced.

Recurrence of the epilepsy after operation is in some instances no doubt due to the cicatrix which is again produced, but from the conditions present the scarring is likely to be much less marked than that following the injury itself. Putting together the statistics of Laurient, Agnew and Starr, we find a record of 201 cases of epilepsy treated by trephining, the large majority being evidently traumatic. Of these 71 are said to have been cured, 66 improved, 41 not improved, 2 were worse after operation, and 14 died. In the remainder the result was doubtful.

The operation thus holds out a chance of relief or cure in otherwise hopeless cases, but it should of course not be undertaken unless other means have failed, and the symptoms are so severe as to make the patient willing to run the inevitable dangers of the operation, and possibly to be permanently paralysed in a portion of his body. In such a case as that described on p. 757 in which the fits occur at long intervals, and the health between them is perfect, the patient had better be content to bear the ills he has.

OPERATION OF TREPHINING.

Before concluding the subject of injuries of the head, it is necessary to say a few words on the operation of **Trephining**, which may be required for one of the following conditions, viz. :—

1. Simple depressed fracture of the skull with symptoms of compression.
2. Simple depressed fracture of the skull in an adult without symptoms of compression, but in which the depression is deep and limited in area, and especially if situated over the motor region.
3. Compound depressed fracture of the skull, with or without symptoms of compression.
4. Punctured or incised fracture of the skull.
5. Extravasation of blood between the skull and dura mater from rupture of the middle meningeal artery.
6. Intrameningeal or cerebral extravasation of blood : (a) if definite localizing symptoms be associated with the general symptoms of compression ; (b) if the spread of the localized paralysis or convulsions suggest continuing hæmorrhage ; and (c) if the localized paralysis or convulsions remain unchanged after many days.
7. Intracranial abscess and septic thrombosis of lateral sinus.
8. For the removal of a bullet lodged within the cranium.
9. Traumatic epilepsy.
10. Tumours of the brain : (a) for the removal of the growth ; (b) for the relief of pressure symptoms.

The use of the trephine may also be required in the removal of tumours of the skull, and it has been employed in the operation of craniectomy in microcephalic idiots, and for the drainage of the ventricular cavities in chronic meningitis and hydrocephalus.

The instruments required in the operation of trephining are a scalpel and periosteal elevator, the trephine and elevator, Hey's saw, a chisel and mallet, bone-forceps, a strong pair of dissecting forceps, and several pairs of force-pressure forceps. In operations involving an extensive removal of bone, a circular saw, driven by an electro-motor, may prove of service.

As a preliminary step the head must be completely shaved and cleaned in the way described on p. 719. If the operation is not one of emergency the scalp should be covered with lint soaked in carbolic lotion (1 in 20), over which must be placed a layer of oiled silk. This must be applied for 12 hours before the operation and changed about every hour.

If the patient is sensible an anæsthetic must be administered. If the operation is being undertaken for the removal of a portion of the brain or a tumour, Victor Horsley, who has so highly distinguished himself in this branch of surgery, advises the use of chloroform, and that a hypodermic injection of a quarter of a grain of morphia should be previously given, as this not only makes it possible to produce the desired effect with a smaller

Fig. 310 - Trephine.

Fig. 311 - Trephine cut at edge of fracture.

amount of the anæsthetic, but Schäfer and he have demonstrated experimentally that it tends to cause a contraction of the arterioles of the brain, and thus to diminish hæmorrhage.

The bone should be exposed by a free incision, any wound that may exist at the time being utilized. If the scalp is unbroken a curved incision exposing the bone by a single flap will be found more convenient than a T-shaped or crucial incision such as is often recommended. The periosteum must be raised in the flap with the periosteal elevator.

The bone being exposed it may not be necessary to apply any saw in some cases of depressed fractures. In others a cut may be made with a Hey's saw between two branches of a fracture. In cases in which the bone is not broken the trephine must be used. This should have a well-tempered crown, serrated half-way up its exterior; the teeth should be short and broad; the centre-pin must not project more than about one-sixteenth of an inch, and care must be taken that the screw which fixes it is in good working order. The centre-pin may advantageously be fixed to a solid plug which can be removed when necessary, and the trouble of the screw avoided (Fig. 310). The trephine

with the pin protruded, is now to be firmly applied until its teeth touch the skull; it is then worked with rather a sharp, light and quick movement, the pressure being exercised as the hand is carried from left to right. The centre-pin must be withdrawn or removed as soon as a good groove is formed by the crown, lest it perforate the skull first and injure the dura mater. In this way the outer table of the skull is quickly divided, and the diploe cut into (Fig. 311); the detritus which now rises by the crown of the trephine is soft and bloody, instead of being dry, as it is whilst the outer table is being sawn. The teeth of the trephine must be frequently freed from sawdust with a sponge. As the instrument approaches the dura mater, the sawing must be conducted more warily, and must every now and then be interrupted in order that the Surgeon may examine, with the flat end of a probe, the depth that has been reached, care being taken that this is uniform throughout the circle. The Surgeon now makes each turn very lightly, and now and then tries with a slight to-and-fro movement whether the circle of bone is loose. As soon as it is, he withdraws it in the crown of the trephine, or raises the bone by means of the elevator.

The trephine used should always be one inch or more in diameter, except in those cases in which it is only required to remove a small piece of bone to insert the elevator under a depressed fragment.

In operations on the brain substance a single trephine-aperture is not nearly large enough. The opening may be enlarged by making another trephine-aperture and removing the bone between the two with a chisel, or by marking out a deep groove with the Hey's saw and cutting the bone away with strong bone-forceps.

If it is necessary to open the dura mater this is best done by an incision following the line of the opening in the bone, but about one-eighth of an inch away from it, so that the flap can be replaced and retained by catgut suture if necessary. Any vessels that bleed must be tied with fine catgut.

In operating for tumours or cicatrices the dura mater may be adherent to the portion of the brain to be removed, and it may then be necessary to cut it away.

On opening the dura mater the brain must be examined. A marked tendency to bulge into the opening is observed in abscess and in tumour of the brain, and its pulsation may be feeble or indistinct, or even wanting. The colour is often changed, and the membranes abnormally adherent to it. If a tumour is present an unnatural sense of resistance may be readily perceptible.

Portions of the brain may be removed by means of a common scalpel; or a blunt knife, like a tenotome in form, made of soft iron which can be bent to any form, will be found a very useful instrument. The bleeding is at first very free, but soon ceases on gentle pressure with a sponge. When the operation is complete, if the nature of the case admits of it, after the dura mater has been laid down, the bone which has been removed may be cut into small pieces, as recommended by Macewen, and planted about on the surface, where it will often adhere and help to close the opening with new bone. The flap of the scalp should then be laid down and very accurately adjusted with sutures. Drainage may be provided for by means of a small tube, but Horsley states that if one inch of the wound be left open at the most dependent part, no tube will be required, and primary union of the whole

wound, which is of the greatest importance, is favoured by this mode of treatment. Some thoroughly efficient antiseptic dressing must then be applied. The carbolic gauze, besides being very safe, has the advantage that cold can be applied over it, which cannot be efficiently done over cotton-wool dressings.

If the Surgeon is called upon to trephine with no antiseptic materials at hand, as may happen in military surgery, he should avoid the use of water; he may wipe away the blood with dry lint, and apply a dry dressing afterwards. By this means he will give the patient the best chance of escaping putrefaction of the discharges and septic meningitis in those cases in which the dura mater is wounded.

There are certain parts of the skull—over the venous sinuses, for instance, and near the base—to which no Surgeon would apply the instrument if it could possibly be avoided. If it were ever thought necessary to trephine at the frontal sinuses, the outer table must first be removed with a large crown, and the inner table sawn out with a smaller one.

The escape of cerebro-spinal fluid through a trephine aperture is a remarkable occurrence. In one such case recorded by Clement Lucas, the cerebro-spinal fluid began to escape the day after the operation. The patient, however, so far recovered as to be on the point of leaving the Hospital, when erysipelas set in, and he died of acute meningitis. After death, the track of damaged brain was found leading to the ventricle from which the fluid had escaped through the scalp. This case confirms the statement made by Clement Lucas, that when cerebro-spinal fluid escapes through the calvaria, the ventricular cavity of the brain has always been opened.

Death after the operation of trephining, when it occurs, is commonly the result of the condition for the relief of which the operation was undertaken, or of septic meningitis. As the Surgeons of former days never published statistics, we have nothing to show us the mortality that followed trephining in their times, when it was undertaken very recklessly, as we should now think; but it seems improbable that an operation so lightly undertaken could have been very fatal. The good results would appear to have been due to two causes—first, a large number of the cases in which it was done were uncomplicated by serious injury or disease of the brain; and secondly, the drainage after the operation must have been very perfect, as the piece of scalp corresponding to the bone removed was also taken away, the wound being left to heal by granulation.

In this century, before the introduction of antiseptic treatment, the death rate was very high. Of 17 cases in which the trephine proper was used at University College Hospital, by Cooper, Liston, and myself, 6 patients recovered, 1 other died of injury of the spine unconnected with the operation, and the remaining 10 died from various causes. In the late American Civil War, the results were more satisfactory than the previous experience of Army Surgeons would have led us to hope. Of 107 cases of trephining, 47 recovered; and of 114 cases where fragments of bones were removed by the forceps and elevator, without the use of the trephine, 53 recovered.

The introduction of antiseptic surgery has greatly reduced the mortality, especially in cases in which the dura mater is wounded. Kramer gives the following results obtained from published cases and the reports of hospitals in which the antiseptic system has been adopted. Of 25 cases in which primary

trephining was performed for compound fracture, 21 healed by first intention, 2 after suppuration, and 2 died, 1 of circumscribed meningitis, and 1 of meningo-encephalitis. In 6 cases of secondary trephining, 3 healed by first intention, 2 by second intention, and 1 died with hernia cerebri. In 22 cases in which the skull was opened, through a previously sound scalp, for tumours, epilepsy, old depressed fractures, &c., 21 healed without fever, 13 by first intention, and none died.

CHAPTER XXV.

INJURIES OF THE SPINE.

IN no class of injuries will the diagnostic skill and powers of observation of the practical Surgeon be more severely tested than in the investigation of a case of injury to the spine. When we consider the mode of construction of the vertebral column with its complicated articulations and its intricate arrangement of muscles, tendons and ligaments, we can only wonder that it is not more frequently injured in the ordinary movements of every-day life. And when again we consider the delicate structure of the spinal cord and of the other parts contained within the spinal canal, it is truly remarkable to what severe external forces they are frequently exposed without suffering even temporary interference with their functions.

Injuries of the spine and spinal cord occur not unfrequently in the ordinary accidents of civil life—in blows, falls, horse and carriage accidents, injuries in gymnasiums, etc.—whilst the shock of a railway accident may produce injuries of great severity and in some respects differing from those resulting from other causes.

In a railway accident several conditions are often present which tend to modify and impart a special character to the results produced. Thus we must ever bear in mind the important fact, that the symptoms presented by an individual who has met with an injury under such circumstances are often largely determined by the severe fright and nervous shock to which he has been exposed—symptoms which often cannot be explained by any direct effect of the injury upon the spinal cord. But, again, the exact nature of the disturbance produced by a railway collision is often peculiar. A thrill or jar,—the *ébranlement* of French writers—is transmitted through everything subjected to it. The carriage in which the patient is seated is perhaps shattered into fragments, and by the same force the patient's body is thrown violently backwards and forwards, and a sharp vibration like an electric shock passes through every part of it. Can we then marvel that after such a violent commotion strange nervous symptoms should often manifest themselves and that the victim may, as we often hear, "never be the same man again?" The wonderful influence of the mind over the body is rarely more clearly seen than after railway accidents; the man is often so firmly convinced that he has been seriously injured, that symptoms of small moment are magnified into most serious proportions, and to this inherent dread of impending paralysis must often be added the mental anxiety necessarily associated with legal proceedings for compensation. As the result of one or more of the above causes the symptoms produced by spinal injuries resulting from railway accidents are often invested with somewhat peculiar characters; but the Surgeon must remember that in their essential nature they differ in no important respect from those due to similar injuries produced in other ways.

Cases of spinal injury divide themselves practically into two great classes:—first, those in which there is obvious severe damage to the spinal column, as fracture or dislocation, associated in the large majority of cases with injury to the spinal cord and its branches by bruising or laceration; and secondly, those in which the signs of severe damage to the vertebral column are altogether absent, but in which, nevertheless, there may be unmistakable evidence of nervous derangement, the true nature of which it is often most difficult to determine.

In the consideration of this latter group of cases, the Surgeon must be reminded that the symptoms presented by the patient may be most diverse in character, and he will be called upon to decide between those due merely to slight damage to the spinal column and those resulting from injury to the nervous structures within it or to some general functional disturbance of the whole nervous system.

Our greatly increased knowledge of the physiology and pathology of the nervous system resulting from clinical experience and experimental research, and above all the study of the so-called "functional" diseases by Charcot and others, have enabled the Surgeon to distinguish between many conditions of nervous disorder resulting from injury which were formerly grouped together in one common category.

For convenience of description those cases of spinal injury which are not accompanied by the signs of fracture or dislocation will be considered under the following headings:—1. Concussion of the Spinal Cord; 2. Sprain of the Spinal Column; 3. Intraspinal Hæmorrhage; 4. Meningitis and Myelitis; 5. General Nervous Shock or Traumatic Neurasthenia; 6. Traumatic Hysteria.

Concussion of the Spinal Cord.—By this term must be understood that temporary interference with the functions of the spinal cord which may result from a more or less severe jarring or shaking of the spinal column. The condition is strictly analogous to that which we find in concussion of the brain, and in both the temporary character of the symptoms is good evidence that the nerve tissue has suffered no gross damage. In the more severe cases at least it is probable that capillary hæmorrhages occur in the substance of the cord, and as in the case of the brain, no sharp line of demarcation can be drawn between such a condition and those more serious coarse lesions of bruising and laceration. Cases of this variety are undoubtedly rare, but there is little doubt that simple uncomplicated concussion may result from falls, blows upon the spine, and from the severe shaking of the spine which occurs in railway collisions.

The *Symptoms* must necessarily vary according to the part of the cord which is affected, but, speaking generally, they are usually seen as transient motor disturbances in the limbs, less commonly with slight interference with the conduction of sensory impressions, and sometimes temporary paresis of the sphincters. Byrom Bramwell has recently drawn special attention to the occurrence of these symptoms amongst miners, as the result of the fall of heavy masses of coal and "roof" upon the back. Under such circumstances temporary paralysis of the bladder, necessitating the use of the catheter, is not uncommon, and this symptom may be accompanied by temporary numbness and loss of power in the legs. These symptoms usually pass off in a few days, and, according to those who have large experience in mining districts, subsequent symptoms indicative of organic disease of the spinal cord never, if ever, follow. Concussion of the brain and concussion of the spinal cord

are thus seen further to resemble each other in the complete and rapid recovery which in the large majority of cases follows; should this result not ensue, the Surgeon must look for some other cause for the persistence of the symptoms.

Sprain of the Spinal Column.—A large number of cases of spinal injury are included under the general term "sprain;" and, as we shall see, the symptoms produced are often so marked that the Surgeon may easily be misled into the belief that the spinal cord itself has been damaged. The actual injury produced undoubtedly varies greatly in different cases; in the slighter forms of sprain, muscles and ligaments are more or less damaged by the sudden stretching to which they are subjected; whilst in the more severe forms these structures are torn in varying degrees, and at times it is probable that the vertebrae may be wrenched apart without remaining permanently displaced. Synovitis of one or more of the articulations of the vertebrae has also been suggested as a likely occurrence. Not less varied than the actual results produced are the causes which may occasion a sprain of the spine; blows, falls on the back, wrenches and twists of the part, or even the lifting of a heavy weight may be mentioned as likely causes of this injury.

In an uncomplicated sprain the spinal column itself or the structures attached to it alone suffer, but it will easily be understood that in the more severe cases the symptoms thus produced will be complicated by others which indicate that the spinal cord or the nerve-roots have been damaged by bruising and hæmorrhage.

The *Symptoms* of a sprain of the back are usually sufficiently obvious and profoundly impress the patient, who is naturally apt to estimate the severity of the injury which he has suffered by the amount of pain which he feels. Localized pain in the spine is, in fact, the most prominent symptom; it may immediately follow the injury, or may be first felt some hours afterwards. The pain is often accompanied by marked local tenderness on firm pressure, and in some cases by superficial bruising. The slightest movement intensifies the suffering, and stiffness of the spine is the result. In addition to the definite localized pain which is the direct result of the sprain, widespread cutaneous hyperæsthesia over a large part of the back may supervene, and the Surgeon must be careful not to confuse this with referred pains due to irritation of the nerve-roots. Herbert Page, who has paid special attention to this class of spinal injuries, has shown how such cases may not unfrequently be associated with a condition of "pseudo-paralysis." The pain may be so severe, especially in sprains of the lumbar region, that the patient dreads to perform even the slightest movement of the lower limbs; and, for the same reason, he avoids those straining efforts which are essential for the acts of micturition and defæcation, and thus actual retention of urine and obstinate constipation may be the results. The patient will very naturally imagine that he is the subject of true paralysis, and the Surgeon must beware lest he fall into the same error. In considering the important question of treatment it will be seen how essential it is that the true nature of this pseudo-palsy be thoroughly recognized, and that exercise, and not prolonged rest in bed, be enforced as the best means of producing a cure.

Intraspinal hæmorrhage.—It will be seen in the subsequent consideration of fractures of the spine that the effusion of blood within the spinal canal plays an important part in the production of the symptoms. The cases now under consideration are those in which a similar intraspinal hæmorrhage

occurs independently of severe damage to the spinal column. Hemorrhage within the spinal canal may occur: (a) between the vertebrae and the dura mater; (b) into the membranes; (c) into the substance of the spinal cord. In these respects intraspinal extravasations closely resemble those which occur as the result of injury within the cranium. In the more severe forms of sprain of the spine it is probable that hemorrhage between the bones and the dura mater is not an unfrequent occurrence, especially where partial separation of vertebrae has occurred with laceration of the intervertebral substance. This, no doubt, in some cases accounts for the symptoms indicating slight damage to the nerve-roots, which we have already seen are occasionally met with in severe cases of sprain.

The exact way in which intraspinal hemorrhage is produced by injury without serious damage to the spinal column is somewhat doubtful. According to one view the cord is bruised by the severe shaking within the canal to which it has been subjected; whilst others would explain the hemorrhage by supposing that the cord is acutely bent at the time of the injury by the "partial dislocation with recoil" which occurs. Thorburn points out that the definitely localized characters of many hemorrhages into the spinal cord favours the latter view, as well as the fact that in cases of extravasation into the cervical portion of the cord, the favourite seat is that part which corresponds to the fourth, fifth, and sixth cervical vertebrae where the curve is most pronounced. Effusions of blood into the membranes may be more or less widely diffused, whilst an effusion into the substance of the cord—"hæmatomyelia"—usually occurs as a single focus. This is much more common in the cervical than in either of the other regions, and the central grey matter suffers more severely than the more superficial white substance.

In the slighter forms of intraspinal hemorrhage, especially of the meningeal variety, the effused blood is slowly absorbed and the symptoms correspondingly disappear. In the more severe cases, however, especially if the hemorrhage be in the substance of the nervous tissue, permanent damage of varying degree results and manifests itself by a corresponding persistence of the symptoms. A gradual extension of the symptoms due directly to the hemorrhage indicates the occurrence of a myelitis spreading from the affected area.

The *Symptoms* must necessarily vary according to the part of the spinal cord which is affected and the extent to which it is damaged by the effusion of blood. In many cases the symptoms will be found immediately after the accident, although, as in the case of intracranial hemorrhage, they will often not reach their maximum for a variable period, that is to say, not until the bleeding finally ceases. In other cases, especially of the meningeal variety, an interval will elapse before the quantity of effused blood is sufficient to cause any recognizable disturbance of function; whilst the evidence that hemorrhage has occurred may first declare itself after the temporary symptoms due to concussion have passed away.

The symptoms of *meningeal hemorrhage*, as pointed out by Gowers, bear some resemblance to those of meningitis. Pain in the back is common, with paroxysmal pains referred along the course of the nerves, which take origin in the affected area. Spasmodic contraction of the muscles supplied by the nerve-roots which arise at the seat of the extravasation takes place, and is followed by paresis. If the hemorrhage be extensive there may also be weakness and lessened sensitiveness in the limbs below the lesion. Meningeal hemorrhage

in the cervical region causes pain in the neck and arms, and according to Gowers, "dysphagia, interference with respiration, and dilatation of the pupils may be added to the other paralytic symptoms;" in the dorsal region a girdle pain may encircle the chest or abdomen; in the lumbar region there will be pain and paralysis of the lower limbs, affection of the sphincters, and diminution of the tendon-reflexes. In more than one recorded case of meningeal hæmorrhage symptoms of ascending paralysis have resulted from the accumulation of blood in the spinal canal around the cord.

The symptoms of *hæmorrhage into the spinal cord* are well marked from the first. The paralysis is usually not preceded by those irritation symptoms which so often occur as the result of meningeal hæmorrhage. If the lesion be extensive the effects may be the same as those which will subsequently be seen to follow complete or partial transverse lesions of the cord. Cases occur, however, in which, as the result of localized hæmorrhage into the grey matter, the conducting power of the cord is but little interfered with, but in which, if the cervical or lumbar enlargement be affected, varying forms of paralysis and loss of sensation may result.

In the case of the cervical enlargement much has been done to indicate the mode of representation of the muscles of the upper limbs in the cord. The root origin of the muscular nerves has been investigated experimentally in monkeys by Ferrier and Yeo; by the method of dissection by Herringham; and clinically by Gowers, Thorburn and others. Thorburn especially has studied the subject in connexion with hæmorrhage into the substance of the cervical enlargement of the cord as the result of injury. He is thus led to arrange the muscles of the upper limb in the following order according to their root supply:—

Supraspinatus and infraspinatus.	}	4th cervical nerve.
Teres minor (?).		
(Biceps.	}	5th cervical nerve.
(Brachialis anticus.		
Deltoid.		
(Supinator longus.		
(Supinator brevis (?).	}	6th cervical nerve.
Subscapularis.		
Pronators.		
Teres Major.		
Latissimus dorsi.		
Pectoralis major.		
(Triceps.		
(Serratus magnus.		7th cervical nerve.
Extensors of the wrist.		
Flexors of the wrist.		8th cervical nerve.
Interossei.	}	1st dorsal nerve.
Other intrinsic muscles of the hand.		

This table must be looked upon as merely indicating the general plan of arrangement and not the details of the nerve supply of each muscle, which in every case probably is related to more than one nerve-root. The arrangement

of the centres for the different muscles in the grey matter of the anterior cornua may also be looked upon as probably agreeing with that above given. The important bearing of these considerations upon the diagnosis of the position and extent of a hæmorrhage into the cervical region of the spinal cord is obvious, and is exemplified by many of the cases recorded by Thorburn. If the centre for any particular muscle be actually destroyed by the hæmorrhage, that muscle will be permanently paralysed, will undergo atrophy, and exhibit the electrical reaction of degeneration. If the damage be slighter complete recovery may take place. In some cases the muscles supplied from the most damaged area are paralysed, whilst those supplied from higher and lower levels may be affected by irritative spasm; as in a case recorded by Thorburn in which the triceps and latissimus were paralysed, whilst the biceps and subscapularis (supplied above the lesion) and the flexors of the hand and fingers (supplied below the lesion) were spasmodically contracted.

Ross has shewn that the sensory nerves supplying the upper limb, coming from the fifth cervical to the first dorsal nerve inclusive, supply the limb in numerical order from the radial to the ulnar side. Hence, as Thorburn points out, the higher the damage extends in the cord the further will the anaesthesia extend from the ulnar towards the radial side of the limb. In a case of fracture of the dorsal spine, recently in University College Hospital, the first evidences of the invasion of the cervical enlargement by the ascending myelitis were paresis of the intrinsic muscles of the hand and impairment of sensation along its ulnar border.

The remarks above made concerning the effects of hæmorrhage into the cervical part of the cord can be more or less applied to those cases in which the lumbar enlargement is the seat of the lesion.

These cases are, however, much rarer, and the arrangement of the lumbar and sacral roots at their origin renders them less liable than the cervical roots to separate damage. The exact relations of a small hæmorrhage may, however, be in some cases determined by reference to the following table, founded upon cases collected by Thorburn:—

Sartorius.	}	Third lumbar nerve.
Adductors of thigh.		
Flexors of thigh.		
Extensors of knee.	}	Fourth lumbar nerve.
Abductors of thigh.

The relation of the sensory distribution of the nerve-roots from the last dorsal to the coccygeal may be enumerated from above down as follows: Upper part of buttock, groin and scrotum, outer side, front and inner side of

a, front and inner side of leg, lower part of buttock, back of thigh, leg foot, perineum and anus, and lastly, skin from coccyx to anus. By fully noting the distribution of the anæsthesia and the muscular paralysis, injury may be referred to one or more nerve-roots, or to that part of the from which they take origin.

cases in which we have evidence of damage to in nerve-roots the level of the lesion in its relation to the spines of the vertebræ may vary within limits. The varying relations of the root of the nerves to the spines of the vertebræ are presented in the accompanying diagram (Fig. 312), and by Professor R. W. Reid of Aberdeen, to whom I am much indebted for permission to reproduce it. The right hand column represents the vertebræ, and each nerve is represented by a shaded

Meningitis and Myelitis.—The occurrence of *acute myelitis* after an injury to the spine is very

It may possibly result from the concussion to the spinal cord has been subjected, but it seems probable that the inflammation in such cases is due to capillary extravasations into the cord. The symptoms produced are much like those of hæmorrhage, but the difference consists in the time of their onset; amongst them may be mentioned spinal pain, tingling in the limbs, paraplegia with spasm, muscular paralysis of the limb muscles, girdle pain, affections of the sphincters. In the case of a man who was severely shaken in a railway collision, and who died paraplegic six weeks later, Gowers found evidences of subacute myelitis throughout the dorsal and lumbar. *Acute meningitis* following obscure spinal injuries is also very rare. It was, however, at one time supposed that *chronic meningo-myelitis* was a common cause of those complex symptoms which may finally develop after this class of injuries, and which will be considered below. The cerebral factors of many such symptoms were explained by supposing that the chronic inflammation had been extended from the membranes of the spinal cord to those of the brain. The subject is one of some interest, but it must suffice here to say that the view above expressed was founded on very scanty pathological information, and that Surgeons are now generally agreed that chronic diffuse meningo-myelitis rarely results from injury. It seems, however, that in some cases an injury to the spine is an important factor in the causation of some of the definite system diseases of the cord; thus locomotor ataxy, following such injury, has been recorded by Barbour, and others.

Fig. 312. Diagram showing the varying relations of the origins of the Spinal Nerves to the Spines of the Vertebræ (Reid).

General Nervous Shock. Traumatic Neurasthenia.—Two separate factors frequently act together in the production of the varied symptoms which may result from an injury to the spine: first, the physical injury itself which mechanically damages to a more or less marked degree the vertebral column or the parts contained within it; and, secondly, the severe fright which is an important element in many spinal injuries, especially such as are produced in railway accidents with all their attendant horrors.

The effects of the physical agent have already been briefly considered under the separate headings of concussion of the spinal cord, sprain of the spinal column, and intraspinal hemorrhage. The effects of this physical injury, although often most complex, can, however, be explained on an anatomical basis and are directly related in their severity and persistence to the nature and amount of the actual damage produced. The symptoms now about to be considered belong to an entirely different category and present this remarkable feature, that they are often altogether out of proportion to the amount of bodily damage sustained and cannot be satisfactorily explained by any direct injury to the spinal cord. In Chapter VIII. it has been pointed out how large a share the psychical effect of an injury may take in the production of the shock which more or less immediately follows it, so much so indeed that death may actually be caused in this way without the occurrence of any bodily damage whatever. If this be true of immediate shock, it is no less so of those more remote and persistent symptoms which frequently follow an injury to the back, and which from their frequent occurrence after railway accidents have been spoken of collectively under the name of "railway spine."

The symptoms which are given in detail below were formerly spoken of as secondary effects of spinal concussion, but in the light of more recent observations on the subject of "functional" affections of the nervous system, it seems necessary to modify this view as to their nature and to class them together as the result of "general nervous shock" or "traumatic neurasthenia," convenient terms largely used by writers on this subject, and probably expressing accurately their true nature.

The injury itself and the fright or mental shock accompanying it have together so seriously disturbed the healthy working of the whole nervous system—cerebro-spinal and sympathetic—that months or even years may elapse before complete recovery follows.

Symptoms.—From the above remarks it will be gathered that the symptoms of general nervous shock are indicative of a condition of more or less pronounced exhaustion of the whole nervous system—the "neurasthenia" of modern writers. The immediate shock produced by the accident may be slight or absent, and it is not until some hours or days have elapsed that the patient becomes gradually aware that something is wrong with him. In other cases, after the first and immediate effects of the accident have passed off, there is a period of comparative ease, and of remission of the symptoms, during which the patient imagines that he will speedily regain his health and strength. This period may last for many weeks, possibly for two or three months. Although there is often this long interval between the time of the occurrence of the accident and the supervention of the more distressing symptoms, it will be found, on close inquiry, that there has never been an interval of complete restoration to health. The patient's friends remark that "he is not the man he was." He has lost bodily energy, mental capacity, and

business aptitude. He looks ill and worn: often becomes irritable and is easily fatigued. He still believes that he has suffered no serious or permanent hurt, and so long as he is at rest, he will feel tolerably well; but any attempt at ordinary exertion of body or mind brings back all those feelings or indications of nervous prostration and irritation characteristic of these injuries. After a lapse of several months—from three to six—the patient will find that he is slowly but steadily becoming worse, and he then, perhaps for the first time, becomes aware of the serious and deep-seated injury that his nervous system has sustained.

The *countenance* is usually pallid, sometimes even livid, and has a peculiarly careworn, expressionless look—the patient generally looking much older than he really is, or than he did before the accident. I have, however, seen instances of flushing of the face, apparently due to disturbance of the vaso-motor action of the sympathetic.

The *thoughts* are confused. The patient cannot concentrate his ideas so as to pursue a connected line of reasoning; he attempts to read, but is obliged to lay aside the book or paper after a few minutes. All *business aptitude* is lost: partly from impairment of memory, partly from confusion of thought and inability to concentrate ideas for a sufficient length of time. The *temper* is often changed for the worse, the patient being fretful, irritable, and in some way—difficult perhaps to define, but easily appreciated by those around him—altered in character.

The *sleep* is disturbed, restless and broken. The patient wakes up in sudden alarm; he dreams much, and his dreams are distressing and horrible.

The *head* is usually of its natural temperature, but sometimes hot. The patient complains of various uneasy sensations in it; of pain, tension, weight, or throbbing; of giddiness; of a confused or strained feeling in it; and frequently of loud and incessant noises, described as roaring, rushing, ringing, singing, sawing, rumbling, or thundering. These noises vary in intensity at different periods of the day; but, if once they occur, they are never entirely absent, and are a source of great distress. Headache is a very common symptom: it is often occipital and is increased by the slightest mental effort.

The *organs of special sense* usually become more or less seriously affected, being sometimes oversensitive and irritable, whilst at others their functions are impaired or perverted. In many cases we find a combination of all these conditions in the same organ. Accommodative asthenopia is a common evidence of the general want of muscular tone. The ciliary muscle is unable to meet the demands made upon it for near vision, and hence reading, sewing, &c. become difficult or impossible. This form of asthenopia is especially pronounced in those who are already slightly hypermetropic or presbyopic. Photophobia is not uncommon. The pupil may be dilated and its movements sluggish. The condition of the optic disc in cases of spinal injury is separately considered on page 800.

The *hearing* may be variously affected. Not only does the patient commonly complain of the noises in the head and ears that have already been described, but the ears, like the eyes, may be oversensitive or too dull. One ear is frequently oversensitive, whilst the other is less acute than it was before the accident. Loud and sudden noises are peculiarly distressing to these patients. *Taste and smell* are sometimes, but more rarely, perverted.

The *sense of touch* is impaired. The patient cannot pick up a pin, cannot

button his dress, cannot feel the difference between different textures, as silk and velvet. He loses the sense of *weight*, and cannot tell, for instance, whether a sovereign or a shilling is balanced on his finger. *Speech* is rarely affected.

The *general muscular power* is often much impaired, especially in the lower limbs, and thus the gait of the patient becomes altered. He walks more or less unsteadily, generally uses a stick, or, if deprived of that, is apt to lay his hand on any article of furniture that is near to him, for the purpose of steadying himself. He keeps his feet somewhat apart, so as to increase the basis of support, and consequently walks in a straddling manner. As one leg is often weaker than the other, he totters somewhat, and raises the foot but slightly off the ground, so that the heel is apt to touch. He seldom drags the toe; but, as he walks flat-footed as it were on one side, the heel drags. This peculiar straddling, tottering, unsteady gait, with the spine rigid, the head erect, and looking straight forwards, gives the patient the aspect of a man who walks blindfolded. The patient cannot generally stand equally well on either foot. One leg usually gives way immediately under him if he attempt to stand on it. He often cannot raise himself on his toes, or stand on them, without immediately tottering forwards. His power of walking is always very limited, seldom exceeding half a mile or a mile at the utmost. He cannot ride, even if much in the habit of doing so before the accident. There is usually considerable difficulty in going up and down stairs—more in going down than up. The patient is obliged to support himself by holding on to the balusters, and often brings both feet together on the same step.

The loss of motor power in the hand is best tested by the force of the patient's grasp. This may be roughly estimated by telling him to squeeze the Surgeon's fingers, first with one hand and then with the other, or more accurately by means of the dynamometer, which shows on an index the precise amount of pressure exercised in grasping. It may be added that the electrical excitability of the muscles is not lost, and that their nutrition only suffers as the result of want of exercise and the general wasting of the body.

Modification or diminution of sensation in the limbs is one of the most marked phenomena in these cases. In many instances the sensibility is a good deal augmented, especially in the earlier stages. The patient complains of shooting pains down the limbs, like stabs, darts, or electric shocks. The surface of the skin is sometimes oversensitive in places on the back; or, in various parts of the limbs, hot, burning sensations are experienced. After a time these sensations give place to various others, which are very differently described by patients. Tingling, a feeling of "pins and needles," a heavy sensation as if the limb were asleep, creeping sensations down the back and along the nerves, and formication, are all commonly complained of. These sensations are often confined to one nerve in a limb, as the ulnar or the musculo-spiral. Numbness, more or less complete, may exist independently of, or be associated with, all these various modifications of sensation. It may be confined to a part of a limb, may influence the whole of it, or may extend to several limbs. Its degree and extent are best tested by Brown-Sequard's *esthesiometer*.

Coldness of one of the extremities, dependent upon loss of nervous power and defective nutrition, is often perceptible to the touch, and may be determined by the thermometer; but in many cases the sensation of coldness is far greater to the patient than it is to the Surgeon's hand, and not unfrequently no appreciable difference in the temperature of two limbs can be determined.

by the most delicate clinical thermometer, although the patient experiences a very distinct and distressing sense of coldness in one limb.

The *heart* will often continue to beat in a violent or tumultuous manner for many months after the receipt of a severe nervous shock, the pulse however being feeble. This disproportion between the force of the heart's action and that of the pulse is very marked in many of these cases, and is a proof of the important part played by the sympathetic in these cases, as is further indicated by the flushings, sensations of heat and cold and excessive sweating, which are common symptoms.

The condition of the *genito-urinary organs* is seldom much deranged in the cases under consideration. Sometimes there is suppression of urine more or less complete for two or three days; retention very rarely occurs except in the cases of profound shock at the time of the accident. Page draws attention to the subsequent trouble which may result if the distension of the bladder thus produced be left long unrelieved. Some weakness in the action of the bladder and inability to empty it completely may be the result of the general impairment of muscular power.

The progressive development of the various symptoms that have just been enumerated often extends over a lengthened period. In the early stages, the chief complaint is a sensation of lassitude, weariness and inability for mental and physical exertion. These are followed by motor and vaso-motor disturbances, and affections of the special senses. With appropriate treatment complete recovery may usually be anticipated, but permanent impairment of nervous power may undoubtedly be the result in some cases. Page records two cases in which death occurred after symptoms of general nervous shock had persisted for several weeks; in both cases the brain and spinal cord presented no signs of structural disease.

Traumatic Hysteria.—In the last section it has been shown how seriously the whole central nervous system may suffer as the result of an injury to the spine, being in fact left in a state of exhaustion. Other symptoms of a functional nature may however be produced which are more local in character and usually manifest themselves as definite impairments of motion and sensation; they are by no means necessarily accompanied by the emotional and psychical phenomena which are frequently associated with hysteria. Of late years no subject in the whole range of medical science has received more attention than that relating to the phenomena and symptoms of hysteria and the neuroses generally. Amongst the many writers upon the subject must be specially mentioned the late J. M. Charcot, to whom more than any other we are indebted for a clear recognition of the true nature of hysteria. In speaking of the occurrence of hysteria in the male sex Charcot says: "One can conceive that it may be possible for a young effeminate man, after excesses, disappointments, profound emotions, to present hysterical phenomena, but that a vigorous artizan, well-built, not enervated by high culture—the stoker of an engine for example—should, after an accident to the train by a collision or running off the rails, become hysterical for the same reason as a woman, is what passes our imagination." Charcot further shows that the symptoms of hysteria in the male may manifest a permanence and obstinacy in marked contrast to the instability which so often characterizes the symptoms in the female. For the right appreciation of the class of cases now under consideration it must be assumed as definitively proved: first, that

hysterical phenomena may be the result of an injury; secondly, that such phenomena may occur in men and in individuals who have shown no signs of the so-called "hysterical" or "neurotic" temperament; thirdly, that the emotional symptoms of hysteria may be altogether absent; and lastly, that the symptoms may be of a remarkably obstinate and permanent character.

It may here be pointed out that the reason for considering the subject of traumatic hysteria in this place, is that, not only does it frequently occur as the result of spinal injuries, but the local motor and sensory phenomena produced frequently closely imitate the paralyses and defects of sensation which result from gross lesions of the spinal cord and the nerve-roots.

It would be beyond the scope of this work to enter into a full consideration of the highly-interesting subject of Traumatic Hysteria, and the reader who wishes for further information may consult the works of Charcot, Oppenheim, Page, Thorburn and others. It will be sufficient here to indicate the chief characters of some of the more important phenomena.

Symptoms.—The condition of acute hysteria which may follow an injury to the spine, especially such as occurs in a railway accident, merely needs mention. In a chronic case the true nature of the affection is easily recognizable if it is accompanied by the emotional symptoms and "hysterical seizures" which are so common in hysteria in the female. The purely local phenomena need further consideration.

1. *Motor.*—The most common local effect is paralysis, although spasmodic contraction may occur. The paralysis may assume the monoplegic, hemiplegic or paraplegic form. It is in those cases in which one limb only is affected, or in which paraplegia exists that difficulty may arise in distinguishing it from the paralyses due to damage to the spinal cord by hæmorrhage and bruising. It is an important fact that if the paralysis of a limb be partial the muscles affected in hysteria are usually those which are associated in their action and thus the patient is unable to perform one or more particular movements; whereas we have already seen that in cases of organic lesion of the cord by hæmorrhage or later by myelitis the paralysed muscles can be grouped according to the spinal nerve-roots by which they are supplied. Charcot also insists upon the important fact that in a case of traumatic hysteria the muscles often do not atrophy and do not exhibit the reaction of degeneration.

2. *Sensory.*—Varying degrees of anæsthesia are frequently associated with hysterical paralysis. The presence of hemianæsthesia associated with any form of paralysis after a spinal injury may be taken as strong evidence that the paralysis is functional and not due to any gross lesion. In such cases the anæsthesia is usually more marked in the paralysed limb than elsewhere. Complete flaccid paralysis with anæsthesia of one limb constitutes another type of an hysterical condition. The loss of sensation is deep and superficial, and the muscular sense may be totally lost. Patches of hyperæsthesia are often present. The tendon-reflexes may be diminished.

We thus see that a careful study of the extent and character of the paralysis and anæsthesia may often lead to a recognition of their true nature. Amongst other conditions which may be present, and which will greatly assist in the diagnosis, may be mentioned:—Contraction of the field of vision for white light; diminution or loss of the sense of hearing, smell or taste; and insensibility of the pharynx.

Affections of the Eye after Spinal Injury.—In the various forms of spinal injury it has been seen that some affection of the eyes is not uncommon; it will be convenient now briefly to consider these effects in a more detailed manner. The following conditions need separate attention:—*Asthenopia*, *Photophobia*, *Alterations in the Pupil*, *Changes in the Field of Vision*, and *Congestive and Inflammatory Affections of the Optic Nerve*.

Asthenopia.—This occurs as a symptom of general nervous shock resulting from spinal injuries. We have already seen that it is an evidence of nervous exhaustion, and is due to failure of accommodation. The patient complains of dimness and weakness of sight, so that he cannot define the outlines of small objects; the letters of small print are often seen clearly for a few seconds, but soon they run into one another, and become obscured and blurred. If the eyes were free from errors of accommodation before the accident the asthenopia will disappear with restoration to health; but in many cases the defect is merely an exaggeration of a condition of hypermetropia or presbyopia previously existing.

Photophobia.—The condition of nervous exhaustion may be accompanied by an irritable condition of the eyes. They cannot bear a strong light, even that of an ordinary window, in the daytime, or unshaded gas or lamplight. In consequence of this irritability of the eyes, the brows become involuntarily contracted, and the patient acquires a peculiar frown so as to exclude light as much as possible. This intolerance of light may amount to perfect photophobia, and is then associated with congestion of the conjunctiva accompanied by lachrymation. One or both eyes may be thus affected. The condition is usually accompanied by *muscæ volitantes* and spectra, rings, stars, spots, flashes, and sparks, or an appearance of white-coloured flame. The appearance of a fixed luminous spectrum, a line, circle, or coloured bar across the field of vision, is sometimes complained of. There is an undue retention of the image in many cases; and where the patient has looked at any fixed object, such as the sun or the fire, complementary spectral colours, often of the most beautiful character, of varying degrees of intensity, will develop themselves in succession. The patient is in some cases conscious of the circulation in his own eye, which becomes distinctly visible to him, even in its pulsatory character.

Alterations in the Pupil.—A dilated pupil with sluggish movements is commonly met with in general nervous shock. In cases of damage to the cervical and upper dorsal regions of the spinal cord by hæmorrhage or laceration, or by the subsequent inflammation, contraction of the pupil has been observed. This may be unilateral or bilateral, and results from paralysis of the pupil-dilating fibres. Irritation of this part of the cord, on the other hand, as by compression, is followed by irritative dilatation of the pupil. Budge and Waller, in 1851, first demonstrated that the filaments of the sympathetic, which supply the eye, take their origin from that part of the spinal cord which is contiguous to the origin of the first pair of dorsal nerves. Hence, by these physiologists the part of the cord from which these fibres arise has been called the "*cilio-spinal region*." The pupil-dilating fibres leave the cord by the anterior nerve-roots from the fifth cervical to the fifth thoracic, and pass to the last cervical and first thoracic ganglia of the sympathetic; thence they pass through the cervical sympathetic to the Gasserian ganglion, and reach the iris in the ciliary branches of the ophthalmic

division of the fifth nerve. The contraction of the pupil which is produced by a destructive lesion of the cilio-spinal region may be accompanied by narrowing of the palpebral fissure from paralysis of the involuntary muscular tissue which is present in both the upper and lower lids.

Changes in the Field of Vision.—Charcot has drawn especial attention to the retraction of the field of vision which is frequently present in cases of hysteria, and it has already been mentioned incidentally that the detection of this symptom by the use of the perimeter may be of assistance in distinguishing between a paralysis of hysterical origin, and one resulting from a lesion of the spinal cord. The retraction may be bilateral, but in cases of unilateral affections of sensation the change in the field of vision may exist on the affected side only. In association with this retraction of the field of vision for white light may be found a retraction of the visual fields for all colours, passing on in some cases to complete loss of colour vision. The normal relation of the fields of perception of red and blue light may be reversed, the field for red remaining larger than that for blue.

Changes in the Optic Nerve.—The changes in the ophthalmoscopic appearances of the fundus after injuries of the spine were carefully studied by Wharton Jones and Allbutt, but more recent investigations seem to shew that changes in the optic disc in this class of injuries are not so common as was formerly supposed. The subject has recently been inquired into by William Thorburn, who has studied the visible optical changes in definite organic lesions of the cord, in slight injuries of the back not implicating the cord, and lastly, in injuries complicated by severe general shock. Thorburn concludes that in severe injuries to the spinal cord below the third dorsal roots, no changes occur in the optic disc; whilst "in four cases of crush of the upper part of the spinal cord (third cervical to second dorsal) when frequent examinations were made, ophthalmoscopic changes were found in three, being absent in one only." The changes consisted of haziness, want of definition of the disc, and slight distension of the retinal veins. In the slighter forms of spinal injury, Thorburn concludes that no changes occur in the optic disc, although the chronic myelitis or meningitis which very rarely follows, may perhaps give rise to it. Lastly, there is some evidence that vascular changes in the disc may follow injuries to the spine in which general nervous shock is produced, probably of the same nature as the vasomotor changes which occur elsewhere in this condition. In the light of our present knowledge of the subject it must be concluded that optic neuritis after spinal injuries is a rare occurrence.

Diagnosis.—The differential diagnosis between the various conditions above described must often be a matter of the greatest difficulty, especially when it is remembered that the symptoms in any particular case may be produced by two or more of these conditions combined. The symptoms of uncomplicated concussion are immediate in their onset and transient in character; those due to hæmorrhage appear early, rapidly reach their maximum, and according to the amount of damage produced, they may gradually pass away entirely or leave permanent impairment of function. Symptoms of meningitis and myelitis come on after an interval, and are often progressive. Enough has already been said to enable the Surgeon to recognise such cases as are "functional" in character. The detection of *malingering* in the subjects of supposed spinal injury may severely test the Surgeon's

knowledge, and he must endeavour alike to avoid the serious errors of too quickly assigning base motives to a genuine sufferer or of being misled by the plausible story and clever deceit of the malingerer. *Syphilitic affections of the cord and its membranes* may be confounded with the after-effects of spinal injury, whilst the disease may itself be called into activity by the injury. The antecedent history, and perhaps the concomitant evidence of constitutional syphilis in one of its minor forms, will determine the diagnosis.

The PROGNOSIS of spinal injuries is a question of extreme interest from a medico-legal point of view and is often involved in much difficulty.

So far as life is concerned it is only in cases of severe and direct blows upon the spine, causing intraspinal hæmorrhage or actual laceration of the cord, that a speedy fatal termination is to be feared. Death may rarely occur at a later date from inflammation of the cord and its membranes, or still more rarely at a remote period from progressive development of structural changes. In considering the probability of complete recovery it may be said that this is looked for after simple concussion and in cases of spinal sprain however severe. The subsequent development of diseased conditions of the cord in these cases is extremely rare, but should they occur the prognosis will always be very unfavourable. In forming an opinion as to the patient's probable future state, it is of far less importance to look to the early severity of the symptoms than to their progressive and insidious development. In all cases in which the symptoms produced are recognized as "functional" and unconnected with structural changes in the cord or its membranes, a hopeful prognosis may be given if suitable treatment is carried out faithfully by the patient and his friends. It does undoubtedly happen that in certain cases, happily few, the general nervous shock to which a patient has been exposed to a railway accident may leave permanent traces in an alteration of the temperament and the nervous state generally.

TREATMENT.—In the **Early Stages of a case of Injury of the Spine**, the injured part must be given complete and absolute rest. The importance of rest cannot be over-estimated. Without it, no other treatment is of the slightest avail; and it would be as irrational to attempt to treat an injured brain or a sprained ankle without rest, as to try to benefit a patient suffering from a severe concussion or wrench of the spine unless he be kept quiet.

In order to secure rest efficiently, the patient should be made to lie prone on a couch. In the prone position, the spine is the highest part of the body; thus passive venous congestion and determination of blood, which are favoured when the patient lies on his back, are entirely prevented. Again, the absence of pressure upon the back is a great comfort when that part is unduly sensitive and tender, and is a source of additional safety to the patient, if he be paraplegic, by lessening the liability to the formation of bed-sores. Lastly, the prone position presents this advantage over the supine, that it allows the ready application of local treatment to the spine. In some instances complete and absolute rest may be secured to the injured spine by the application of a gutta-percha case to the back, embracing the shoulders, nape of the neck and back of the head; or by letting the patient wear a stiff collar, so as to give support to the neck. In these cases Sayre's plaster of Paris jacket will be found of the utmost service. It secures more perfect and continuous rest than any other apparatus.

In cases of simple concussion a period of complete rest is the only treat-

ment required. Rest is essential in the treatment of a sprain of the spine, but it is difficult to decide how long the patient should keep his bed. Page finds that this is rarely required for longer than three weeks, and the restoration of free mobility may be greatly hastened by systematic massage, and in some cases by faradisation of the spinal muscles.

If the symptoms are indicative of intraspinal hæmorrhage, prolonged rest may be necessary, and the nutrition of paralyzed muscles must be maintained by the use of electricity. Retention of urine must not escape notice (see p. 810). The question of operative interference is considered at the end of this chapter.

The onset of symptoms of myelitis or meningitis indicates the use of counter-irritation: the actual cautery, mustard poultices, blisters, &c. Dry cupping may be of service. Under these circumstances perchloride of mercury in tincture of quinine or of bark may be given internally. At a more advanced period, and in some constitutions in which mercury is not well borne, the iodide or the bromide of potassium in full doses will be found highly beneficial, more especially when there are indications of the presence of inflammatory effusion causing pressure.

In the treatment of the condition of general nervous shock one of the most important indications is to procure sleep. For this purpose chloral sulphonal and morphia may each be found most efficacious in different cases. Bromide of potassium or ammonium may be useful, but Page has clearly shown how much harm may result from the persistent use of the drug in large doses. The other indications are a period of freedom from the anxieties of business, the assurance that no serious injury of the spine has occurred, and general attention to diet with a course of tonics. Hysterical paralyses and other purely functional disorders must be treated on general principles.

WOUNDS OF THE SPINAL CORD.

These injuries may occur from stabs with pointed instruments: from gunshot violence: or, most frequently, from the pressure of fractured vertebrae. In the latter form of injury there is an association of wound and compression, giving rise essentially to the same symptoms as if the cord were divided.

Symptoms.—When the spinal cord is *completely divided* or crushed subcutaneously, certain symptoms occur that are common to all cases, at whatever part of the cord the injury has been inflicted, provided it be not so high as to cause instant death. In the first place, there is *complete paralysis of sensation and motion* in all the parts below the seat of injury, though the mental state of the patient continues intact. The seat of injury may be diagnosed by the extent of the paralysis. Thus, there may be paralysis of all the parts supplied by the nerves of the sacral plexus, while those from the lumbar are not affected; thus leading to the inference that the injury has been inflicted above the one and below the other set of nerves.

When the continuity of the cord is completely interrupted there is, at first, vaso-motor paralysis of the parts below the injury. Owing to the feebleness of the heart's action consequent on the shock of the injury, and to the want of movement in the paralyzed muscles, there is soon some degree of venous stagnation, and the temperature of parts below the injury soon falls considerably, so as to give a distinct sensation of coldness to the hand. After a

days the vessels gradually recover their tone, and the congestion becomes marked. The condition of the reflexes in the parts below the injury is a point of great interest. It is universally agreed that during the period of shock the superficial and deep reflexes are completely abolished. It has usually been supposed that after the period of shock has passed, the reflexes return and become exaggerated. The matter has, however, recently been brought forward by Bastian and Bowlby in separate communications read before the Royal Medical and Chirurgical Society. Bastian finds that in cases of complete transverse destruction of the cord by disease, the tendon reflexes are permanently abolished. Bowlby has investigated the subject in numerous cases of transverse lesion of the cord by injury; he finds that the deep reflexes do not return, whilst the condition of the superficial reflexes varies, being in some instances permanently abolished and in others returning in a few weeks. The conclusion drawn from these observations is that permanent abolition of the tendon reflexes is evidence that the transverse lesion is complete, and that return of these reflexes in an exaggerated form proves that the lesion is only partial. Bastian suggests that the exaggeration of the reflexes in partial transverse lesions is the result of the action of the cerebellum unrestrained by cerebral influence, and not, as has usually been supposed, of degenerative changes in the motor tracts below the injury. After a time visible diminution takes place in the nutritive activity of the limbs, the circulation becoming feeble, with a tendency to stasis. The muscles waste to a certain extent, the skin assumes a livid, cadaverous hue, and the cuticle usually exfoliates in branny flakes. Even, however, as the parts are in connection with a healthy portion of spinal cord, the graver trophic lesions, such as acute bed-sore, do not manifest themselves. Bed-sores, no doubt, commonly occur in these cases, they are due to the irritating effects of the urine and faeces involuntarily voided by the patient, together with his want of mobility, and can usually be prevented by skillful nursing.

Open wounds of the spinal cord, such as result from gunshot injuries or from stabs, the patient is exposed to the dangers of **septic meningitis** and **myelitis**. These complications are commonly fatal. They are characterized by high temperature with pain in the back, and sometimes spasm or rigidity of the muscles of the trunk and limbs. The mischief may extend upwards to the base of the brain, and cerebral symptoms may then manifest themselves before death. Inflammatory softening of the cord in the neighborhood of the wound is indicated by the paralysis extending upwards. It is following the injury is very commonly complicated by the formation of acute bed-sores, which are rapidly fatal. This is due to the parts no longer being in connection with a healthy nerve-centre.

The general symptoms of paralysis following injury present important variations, according to the height at which the cord is divided.

Injuries in the Lumbar and Lower Dorsal Region.—The cord terminates at the lower border of the first lumbar vertebra, consequently injuries at that point will affect only the spinal nerves forming the cauda equina. All the nerves entering into the lumbar and sacral plexuses arise from the part of the cord below the lower border of the eleventh dorsal vertebra. Injuries in this region consequently often cause complete paralysis of the parts supplied from both the sacral and the lumbar plexuses; some-

times, however, the sacral alone is affected. When the injury affects the sacral plexus only, all the muscles below the knee, the flexors of the leg, the rotators, abductors, and extensors of the thigh are paralyzed; but the extensors of the leg and the flexors and adductors retain their power. The muscles of the perinæum, the sphincter ani, and the bladder are also paralyzed. Sensation is lost in the gluteal region, the back of the thigh, the outer side of the leg and foot, the genital organs, and the perinæum. When the lumbar plexus is also affected, the whole lower limb is deprived of sensation and motion, and there is some loss of sensation about the lower part of the abdomen in the part supplied by the ilio-hypogastric, but the abdominal muscles retain their power of contraction. In some cases we find complete paralysis of the parts supplied by the sacral plexus, and irregular paralysis and loss of sensation in those supplied by the lumbar plexus. This is due to injury of that part of the cord from which the sacral plexus arises, with damage to some of the lumbar nerves which lie by the side of it, before they leave the vertebral canal. In an injury completely paralyzing the sacral plexus, there is always relaxation of the sphincter ani, with consequent incontinence of flatus and, to a great extent, of feces. In these cases the feces are brought down into the rectum by the peristaltic action of the intestines, which is not suspended, being under the control of the sympathetic system, which communicates with the cord at a much higher level. The power of voluntary micturition and the sensation of fulness of the bladder are of course abolished. The act of micturition is supposed to be controlled by three centres in the lumbar region of the cord: an automatic centre maintaining the contraction of the sphincter, a motor centre in connection with the muscular coat of the bladder, and a sensory centre receiving the afferent nerves from the mucous membrane. These are in communication with the brain and with each other. In the normal act of micturition the sensation of fulness of the bladder is conveyed to the brain, from which an efferent impulse is sent to the motor centres, which inhibits the action of the automatic centre controlling the sphincter and stimulates the motor centre connected with the muscular coat of the bladder. In an injury of the cord it is possible that these centres may be destroyed. The bladder then becomes an inert bag, and the urine will dribble from it as soon as it has accumulated in sufficient quantity to overcome the mechanical resistance at the neck of the bladder and along the urethra. When the injury is at a higher level the urine is retained during the period of shock, but as this passes off the bladder usually empties itself periodically without the patient being conscious of what has occurred. This is due to communication between the centres controlling micturition. As soon as the bladder reaches a certain degree of distension the centre controlling the sphincter is inhibited in its action, and that connected with the muscular coat is stimulated through the direct communications between these and the sensory centre. In these cases, therefore, the patient would not die from rupture of the bladder if no catheter were passed, but he would be constantly wet from the involuntary escape of urine, and thus the danger of fatal tetanos would arise. A catheter is, therefore, usually passed at regular intervals, and as a consequence of this it often happens that after the first few days the urine becomes ammoniacal in odour and alkaline in reaction, from the formation of ammonium carbonate from the urea. This fermentation is believed always to be due to the introduction of micro-organisms into the

bladder from without either by means of the catheter or by direct extension up the paralysed urethra, which cannot perfectly empty itself of urine and mucus during the act of micturition as in a state of health. The decomposing urine soon sets up severe cystitis. The first effect of this is that, owing to the irritation of the sensory nerves, the act of automatic micturition is repeated at very short intervals till it amounts to almost constant dribbling. The urine becomes very foul, and is mixed with an abundant secretion of mucus and often some blood. Finally, it may lead to ulceration of the bladder, followed by septic poisoning by absorption from the raw surfaces: or the mischief may extend to the kidneys and terminate fatally by septic nephritis. Later in the case the bladder often becomes contracted, and constant dribbling of urine follows. In the early stages of these injuries to the cord, the penis will usually be observed to be in a state of semi-erection.

Patients who have met with injuries of this portion of the spinal cord may live on for many months, or even for a year or two, in a cachectic state; death then occurs usually from the formation of bed-sores, or from the effects of the diseased condition of the bladder.

2. When the cord is divided in the **Upper Dorsal Region**, about the level of the third dorsal vertebra, we have not only the train of symptoms that has just been mentioned as characteristic of this injury lower down, but respiration also is interfered with in consequence of paralysis of the greater portion of the expiratory muscles. The intercostal muscles, and those constituting the abdominal wall, no longer acting, the imperfect expiration is effected solely by the elasticity of the walls of the chest; and the purely muscular expiratory movements, such as sneezing and coughing, cannot be accomplished. In these cases, during inspiration, which is effected chiefly by the diaphragm, the ribs are depressed instead of being expanded and raised; and the abdominal wall, which is soft and flaccid, is protruded far beyond its normal limits. In consequence of the impediment to respiration the blood is not properly arterialized: and hypostatic pneumonia often causes death in two or three weeks.

3. When the injury is situated in the **Lower Cervical Region**, not only do all the preceding symptoms occur, but there is paralysis of the upper extremities as well; and, inspiration being entirely diaphragmatic, the circulation is speedily affected, the lungs become congested and oedematous, and the countenance suffused and purplish. If the cord have been crushed or divided immediately above the brachial plexus, there will be complete paralysis of the whole of the upper extremities; but if the injury be lower, the paralysis of the upper limbs may be only partial, those muscles which have their nerve origin above the lesion more or less escaping (see p. 791). There is this remarkable fact connected with injuries of the lower portion of the cervical spinal cord, that the temperature frequently presents a marked deviation from the normal standard. In some cases it rises very considerably, in fact to a higher point than has been noticed in any other surgical affection. Brodie found in one case that the thermometer marked 111° F. But in other cases again the temperature has been found greatly reduced, even to 81° or 82° F. No explanation of these extraordinary differences has as yet been discovered. In cases of injury of the cord in this situation, the patient, being unable to expel mucus from his lungs, usually dies from asphyxia in from forty-eight hours to a week.

When the division of the spinal cord takes place **above the Origin of the Phrenic Nerves** opposite to or above the third cervical vertebra, instantaneous death results from the paralysis of the diaphragm, as well as of the rest of the respiratory muscles, inducing sudden asphyxia.

It necessarily happens in **partial division of the cord** that the symptoms are less clearly marked. In many of these cases resulting from fracture or dislocation, the symptoms due to actual injury of the cord are complicated with those of pressure on one or more nerves in the intervertebral foramina. When this occurs there is often pain in the line of the nerve, and, if it be in the dorsal region, a sensation like a painful girdle round the waist. The most definite of these injuries are met with in partial division of the cord by a stab. In these cases it has occasionally happened that the weapon has divided one of the lateral halves of the cord. Under these circumstances the parts on the same side of the body below the seat of the lesion are paralyzed; this necessarily follows from the fact that the motor fibres have their decussation chiefly in the medulla, although to a minor extent in the cord. Brown-Sequard was one of the first to lay down the rule that in such cases sensation is lost on the side opposite to the section, and that hyperæsthesia exists on the paralyzed side. This distribution of the anæsthesia was explained by the then generally accepted view that the decussation of the sensory fibres took place along the whole length of the cord. At the present day, however, there is an increasing tendency towards the belief that the chief decussation of the sensory fibres takes place in the bulb, and that sensory impulses are carried up the cord chiefly on the same side as that upon which the posterior roots enter. This view is supported by the recent experiments of Mott and of Horsley and Gotch, and is not altogether without clinical evidence in its favour. It thus appears that there is good reason to believe that the condition following hemisection of the cord is not so clearly defined as was formerly supposed, and detailed investigation of these unusual cases must prove of the greatest value.

FRACTURE AND FRACTURE-DISLOCATION OF THE SPINE.

Fracture of the spine may occur without displacement, and very rarely dislocation occurs without fracture, but in the large majority of cases the two conditions are associated and a **Fracture-dislocation** is the result.

This injury may occur either by the application of direct violence, or by a violent twist or bend of the body forwards. Direct violence, as a blow, fall, or gunshot injury, may of course fracture the spine at any part and almost to any extent, in some cases merely detaching a spinous process, in others splintering and comminuting several vertebrae and lacerating or dividing the spinal cord. Fracture of the spine from a violent but forcible bend of the body forwards occurs chiefly in the cervical region. It is usually produced by a person falling from a height on the head, the body being bent forward so as to drive the chin against the sternum. This accident often happens in falls from horseback, or in taking a "header" into shallow water. In some cases it has occurred from a person sitting on the top of a vehicle having his head forcibly bent down whilst passing under an archway. In these accidents there is usually extensive rupture of the spinal ligaments with displacement of the bones, as well as fracture.

In some cases of even very extensive fracture there may be no appreciable

displacement; usually, however, some change of position ensues, in many cases to such an extent as to compress or lacerate the spinal cord. The mode of occurrence of the fracture will influence the amount of displacement. If the fracture be through the arch, or consist in a simple detachment of the spinous process by a fall or a blow on the back, there may be no displacement. If it occur from a fall upon the head, or by a forcible flexure of the neck and body forwards, as when the body is compressed between the top of a van and an archway, there will probably be great displacement and perhaps separation of the articulating surfaces of contiguous vertebræ. In these cases the upper part of the spine is almost invariably displaced forwards.

The **Signs** of this injury vary very greatly, and depend in a great degree upon the extent of the displacement. If this be inconsiderable, it may be extremely difficult, and even impossible in some instances, to pronounce with certainty whether the spine has been broken or not; the more so if the fracture do not implicate the body of the vertebra. If, on the other hand, the displacement affect the axis of the column or compress the cord, the symptoms are so marked that diagnosis is easy. They are of two kinds: those due to injury of the bone, and those dependent on injury by compression or laceration, or both, of the spinal cord.

The **Local Signs** are usually pain at the seat of injury, greatly increased by pressure on, or motion of the part; inequality of the line of the spinous processes, with depression of the upper portion of the spine, and corresponding prominence of the lower. There is an inability to support the body in the erect position, and to move the spine in any way; hence, when the upper portion of the column is injured, the patient holds his head in a stiff and constrained attitude, fearing to turn it to either side.

The **General Symptoms** of fracture of the spine are dependent upon the injury which the cord has received. If the fracture have not implicated the spinal canal, as when only the tip of a spinous process has been broken off, or if it be unattended with displacement, although it may traverse the body and arches, no symptoms depending upon injury of the cord need exist. But even in these cases there may be transitory paralysis, owing perhaps to the concussion to which the cord has been subjected at the moment of injury; and occasionally a sudden movement by the patient will bring on displacement, by which the cord is compressed and all the parts below the injured spot are paralysed. A woman was admitted into University College Hospital with an injury of the neck, the nature of which could not be accurately ascertained. She was in no way paralysed, but kept her head immovable in one position. A few days after admission, whilst making a movement in bed, by which she turned her head, she fell back dead. On examination, it was found that the spinous process of the fifth cervical vertebra had been broken off short, and was impacted in such a way between the arches of this and the fourth as to compress the cord. This impaction and consequent compression probably occurred at the time of the incautious movement, thus causing immediate death. When there is only partial displacement, there may be but incomplete paralysis of the parts below the injury—of one arm, one leg, &c. In these cases there is usually great pain at the seat of fracture, and extending from it along the line of junction between the paralysed and the sound parts round the body or along the limb. This symptom, which is of great importance as exactly defining the seat of injury, is due,

as I found in dissecting a case of fracture of the sixth cervical vertebra under my care, to the fractured bone compressing and irritating the nerve that issues from the vertebral notch opposite the seat of injury.

When the cord is implicated, the symptoms will vary according to the seat of the injury and the extent of the damage. For a detailed account of the symptoms presented by injuries of the different portions of the cord, the reader is referred to the sections on "Intraspinal Hæmorrhage" (p. 789) and "Wounds of the Spinal Cord" (p. 802).

If the spine be fractured by indirect violence, as by the head being forcibly bent down on to the chest as the patient is driving under an archway, and a fracture be thus occasioned through the lower cervical or upper dorsal portion of the column, we shall find that the cord being lacerated, and compressed transversely in one part only, the ordinary symptoms of division of the cord at that part will be presented, the patient being paralysed below the seat of injury (see p. 791).

In a large proportion of cases of fracture of the spine, there is such displacement of the bone as to compress the whole thickness of the cord, and thus to occasion complete paralysis of motion and sensation in the parts below the seat of injury. This paralysis resembles that which arises from simple division of the cord, but is followed by greater impairment of nutrition, as shown in wasting, cachexy, and a tendency to sloughing. The reason of this difference is, that in fracture the cord is not simply compressed or divided, but is continuously irritated by the edges of broken bone, and thus not only becomes incapable of healing, but is kept in a state of chronic irritation and inflammation. If the fracture be above the origin of the phrenic nerve, respiration will be arrested and the patient will die instantaneously.

Prognosis.—The danger from fracture of the spine depends on the amount of injury sustained by the cord, and the situation of the injury. Thus, if there is no displacement of the broken vertebra or injury to the cord, union will take place, and the patient recover perfectly; but fractures of the spine through the bodies of the vertebræ, with displacement and compression of the cord, are most commonly fatal.

When the fracture occurs in the middle or lower dorsal regions, so that the lower portion only of the cord is injured, the patient may live for many years, even though the cord is completely severed and the spinal canal obliterated by the displacement, and by the new bone formed in the process of repair. There is a specimen in University College Museum which well illustrates this fact (Fig. 313). The patient was a man who, at the age of thirty-two, fell fifty feet from a tree. He sustained a fracture of the spine, with the unusual displacement of the upper fragment backwards. The fracture became firmly consolidated, and he lived for nine and a-half years, completely paralysed below the middle of his body. There was no sloughing of the hips or back, and the vesication caused by blisters, which were for some reason applied to the paralysed parts, healed without difficulty. After repeated attacks of cystitis inflammation spread to the kidney, and he died of septic pyelo-nephritis. The specimen shows ossification of the dura mater below the seat of fracture.

Even when the injury is in the cervical region, recovery may take place, although the case may appear most unpromising. I have known at least four cases in which recovery has occurred after fracture of the lower cervical vertebræ, with paralysis more or less complete from the neck downwards. In

one of these the neck was broken by a fall in kangaroo-hunting, and the patient, who was young and active, after being paralysed for eleven months, made a fair though not complete recovery—some paralysis, with wasting, of the extensors of the hands being left.

When *death* takes place, it may occur in three different ways. It happens primarily as the immediate result of the injury, in all those cases in which the fracture is above the origin of the phrenic nerve. It occurs secondarily and indirectly, at a more or less remote period, as the result of changes in the body dependent on permanent separation of the parts below the injury from the nervous centres above. At the seat of injury, compression, or crushing, inflammation is necessarily developed; thence it may spread along the membranes, giving rise to effusion into the canal, and into the cord itself, causing softening. It is, doubtless, by the gradual extension upwards of this secondary inflammatory softening that death is ultimately occasioned in many

Fig. 313.—Fracture through the lower dorsal and first lumbar vertebrae, with displacement backwards of upper fragment.

Fig. 314.—Crush of Cord. The result of a Fracture of the Spine.

cases. Thus, an injury in the cervical region, which was not immediately fatal, may ultimately prove so by the mischief extending to the origins of the phrenic nerves, and so arresting respiration. Many also perish from bed-sores, and a very large proportion of cases prove fatal from pyelo-nephritis secondary to cystitis, with decomposition of the urine.

The **Treatment** is simple enough when the patient escapes without implication of the cord. It is evident that in such cases no attempt at reduction should be made, lest by dislodgment of the fragments the cord be injured. The patient must be placed flat upon his back, and the strictest possible rest maintained. König of Gottingen has recommended, in cases of fracture in the dorsal or lumbar region without damage to the cord, that Sayre's plaster of Paris jacket should be applied as early as possible. He has himself applied it on the fourth day, and Berkeley Hill at the end of thirty hours. In these cases the patient was suspended by the arm-pits, and at the same time supported by assistants, care being taken not to lift him sufficiently high to raise

the feet from the ground. Extension under these circumstances, however, cannot be devoid of danger, and the better plan would be to apply the apparatus in the way recommended by Walker of Peterborough. He first puts on the patient a flannel vest without sleeves, or if there is any difficulty in doing this, a piece of soft flannel wide enough to reach from the axilla to the hip may be passed under the back, and carefully sewn down the front, so as to leave no creases. A number of strips of muslin bandage, cut of the proper length to encircle the body, and to overlap for a few inches, are then prepared. These are dipped in a mixture of plaster of Paris, 1 lb., water, 3vi., with 3j of mucilage of gum acacia added, to delay the setting. They are then quickly spread on a bed covered with a mackintosh sheet, each overlapping that above for two-thirds of its width. They must be thus arranged till a sufficient width is reached to extend from the patient's axilla to midway between the crest of the ilium and the trochanter; and a sufficient number of strips should be used to make the whole about six layers thick. The patient is then carefully lifted and laid on the bandages, which are folded over and rubbed smooth, as in an ordinary plaster of Paris bandage. A pad should be put over the epigastrium, which can be withdrawn when the splint is firm. In the cases treated by König, and in Hill's case, the results were most satisfactory. Two cases have, however, been recorded in which the patient could not bear the bandage, but no harm was done by the attempt to use it.

Another plan of treatment, originally recommended by Wornall, is to raise the patient carefully up, and place beneath him a large sheet of softened gutta-percha, and so to mould a splint to the back.

In cases in which the cord is injured, attempts at the reduction of the fractured and displaced spine must not be lightly undertaken. It may prove unsuccessful, greatly increase the sufferings of the patient, or hasten his death. In cases of injury to the lower cervical vertebrae, it would rarely, if ever, be proper to make such attempts. In the upper and middle dorsal they would not be likely to succeed, owing to the want of mobility of this part of the column. In the lower dorsal and lumbar regions they would be less dangerous, and more likely to prove advantageous.

All our efforts must be directed to prolonging life, if the fracture be in such a situation (at any point below the upper dorsal vertebrae) as to hold out a prospect of continuance of life for a few weeks or months. Means must be taken to prevent the occurrence of sloughing of the nates, an accident that is commonly fatal. The patient should be laid on a water-bed, cushion, or mattress, and must be kept scrupulously clean. If possible, a mattress should be obtained, with a segment that will pull out to admit the bed-pan, or some such arrangement to avoid disturbance of the spine. Every precaution should be taken to prevent the supervention of cystitis. For this purpose the urine must be drawn off with a catheter, regularly, at least twice in the day. The catheter should, before being used, be dipped in a vessel containing a 1 in 20 solution of carbolic acid and lubricated with carbolic oil (1 in 10). If, in spite of these precautions, ammoniacal decomposition of the urine should take place, the bladder must be washed out with an antiseptic solution every time the water is drawn off. Solution of permanganate of potash, or three grains of quinine, with three minims of dilute sulphuric acid to the ounce of water, will be found the most efficient preparations. (See Cystitis.) If, as usually happens after a time, the bowels become confined, relief must be afforded by

castor-oil or turpentine enemata. A nonrishing diet must be administered and perfect rest in one position enjoined. In this way life may be maintained for a considerable length of time, and bony union of the fracture may take place, though the patient may not recover from the paralysis, and may die eventually from the effects of the injury. But in some cases a much more satisfactory result is obtained; the patient gradually gains power in the paralysed parts. Much assistance will then be afforded by making him wear, as soon as the fracture is sufficiently consolidated, the apparatus shewn in Fig. 315, consisting of a firm pelvic band, with a strong iron rod shaped to the spine, and running as high as the vertex, having padded transverse arms to support the head and shoulders, and the whole attached to a stout leather case moulded to the back and shoulders. If not applied primarily the plaster of Paris jacket will always be found of great service in the later stages of the case.

Fig. 315. Apparatus for Fracture of the spine.

DISLOCATIONS OF THE SPINE.—On looking at the arrangement of the articular surfaces of the vertebrae, the very limited motion of which they are susceptible, and the way in which they are closely knit together by strong ligaments and short and powerful muscles, it is obvious that dislocations of these bones must be excessively rare. So seldom, indeed, do they occur that their existence has been denied by many Surgeons. Yet there are several instances on record which prove that such accidents may happen. The cases that have been met with have usually been associated with partial fracture, but this complication is not necessary. In all, the displacement was incomplete; and, indeed, a complete dislocation cannot occur. Fracture may occur anywhere in the spine, but dislocation without, or with very slight, fracture is met with only in certain situations. Dislocation of the spine may occur in the following parts:—1. Between the occiput and atlas. This is very rare. 2. Between the atlas and axis. This, though rare, is much less so than the preceding, and may occur with or without fracture of the odontoid process; when the odontoid process is broken, death at once ensues. 3. Dislocation between the second and third cervical vertebrae is very rare—as rare as dislocation between the atlas and axis. 4. Dislocation generally happens somewhere between the fifth and seventh cervical vertebrae. Dislocation without fracture can scarcely occur in the dorsal region, and there is no recorded case of a pure dislocation in the lumbar region.

In Fig. 316 we have an example of dislocation of the fifth from the sixth cervical vertebra, with the separation only of a scale of bone which was adherent to the intervertebral fibro-cartilage. The patient had fallen on his head from a van and died of asphyxia in twenty-four hours.

The spine may be so seriously injured that dislocation is at any moment imminent, and yet the patient may live for some days before the displacement, by which the cord is compressed, occurs. A man was admitted into University College Hospital, who had been crushed by falling between the platform and a train in motion. Amongst other severe injuries he had paralysis of the circumflex and musculo-spiral nerves of the left arm, but no hyperaesthesia. On the third day, whilst being moved in bed, his head fell to one side, and he

suddenly died. On examination after death, it was found that the second cervical vertebra, carrying the atlas and head with it, had been dislocated from the third (Fig. 317); the connecting ligaments being completely torn through on the left side, so that the head falling to one side had caused fatal compression of the cord.

Dislocation of the Occipital Bone from the Atlas has been described by Lassus, Paletta, and Bouisson. In the case by Lassus death ensued in six hours, and the right vertebral artery was found to be ruptured. In Paletta's case, the patient is said to have lived for five days, but the report is so incomplete that little value can be attached to it.

Dislocation of the Atlas from the Axis is of more frequent occurrence. It may happen with or without fracture of the odontoid process. In either case, the atlas is carried forwards and the spinal cord thus compressed.

Fig. 316.—Dislocation between the Fifth and Sixth Cervical Vertebra.

Fig. 317.—Dislocation of the Axis from the Third Cervical Vertebra.

This accident is said to have been caused by a person in play lifting a child off the ground by its head; the combination of rotation and traction in this movement being especially likely to occasion the accident. For the same reason, it has been met with in those who have been executed by hanging. Death would probably be instantaneous in these circumstances. It has, however, been stated that, in dislocations of this kind, life has been saved by the Surgeon placing his knees against the patient's shoulders, and drawing or twisting the head into position. This, however, I cannot believe possible if the displacement has been complete, as death must be instantaneous; the cases of supposed dislocation and reduction have probably been instances of concussion of the cord with sprain of the neck.

Dislocation of any one of the five Lower Cervical Vertebra may occur. The third vertebra is least frequently dislocated; the fifth is more commonly displaced (Fig. 316). These injuries are usually associated with fracture; sometimes, though rarely, they happen without this complication. In these dislocations, as in those that have already been described, the dis-

placed bone carries with it the whole of that portion of the vertebral column which is above it.

In dislocations, the articulations between the two vertebræ are torn open. The supraspinous and interspinous ligaments, the ligamenta subflava, and the common posterior ligament, are torn through, so that the spinal canal is opened. The intervertebral fibro-cartilage may be torn, or it may be entire, a scale of the body of the subjacent vertebra being detached with it. When the spine above the dislocated part is bent forwards, a wide gap is visible posteriorly, at the seat of injury.

Causes.—The causes of dislocation are numerous, and the following may be given as examples. A person standing in a cart and driving under an archway finds, too late, that he is too tall to clear the arch: he bends forwards, but miscalculating the distance, his head is pressed violently downwards. A person takes a "header" into shallow water: his head comes against the bottom, is forcibly flexed, and his spine is broken or dislocated. Such accidents are not very unfrequent. I have seen several cases of paralysis and death resulting from this kind of injury.

These accidents most commonly happen from forcible flexion of the neck, though traction and rotation conjoined have occasioned them. In a case of luxation of the sixth and seventh cervical vertebræ, recorded by J. Roux, the accident happened to a sailor plunging into the sea for the purpose of bathing, and coming head foremost against a sail which had been spread out to prevent the attack of sharks: he died on the fourth day. In a patient of mine, who fell out of a window in such a way that the head was doubled forwards upon the chest, and who was brought to the Hospital with supposed fracture of the spine, we found after death, which occurred on the fifth day, that the seventh cervical vertebra, carrying with it the upper portion of the spine and the head, had been dislocated forwards from the first dorsal, the intervertebral substance detaching with it an extremely thin and small layer of bone from the body of the seventh vertebra. There was a wide gap posteriorly between the laminae. There was no fracture about the articular processes, which were completely separated from one another. In the instance already referred to, in which a man fell on his head from a van, and death resulted in twenty-four hours, a similar displacement was found of the fifth from the sixth cervical vertebra, with compression of and hæmorrhage into the substance of the medulla, and disorganization of it to the extent of nearly an inch opposite the seat of dislocation, where it had been injured by the forward pressure of the dislocated vertebra.

In the **Dorsal Region**, dislocation of the spine, though excessively rare, may occur; seldom, however, without being accompanied by fracture. The last dorsal vertebra has several times been found dislocated from the first lumbar with rupture of the intervertebral fibro-cartilage. In these cases, however, there has usually been found fracture of the transverse processes of the first lumbar vertebra, or, as in an instance recorded by Charles Bell, fracture of its body.

The **Symptoms** caused by dislocations of the spine are, like those of fracture, dependent on the degree and seat of the injury inflicted on the spinal cord. And death will ensue at varying periods, according to whether the dislocation is above or below the origin of the phrenic nerves, in accordance with the rules laid down at p. 809.

The **Diagnosis** between a dislocation and a fracture of the cervical spine is not easily made. But there is one symptom which, according as it is present or not, may throw much light on this point. This is the occurrence of pain, amounting to hyperæsthesia, along the line of junction between the paralysed and the unparalysed parts. In fracture this will commonly be found to be present (p. 807). In dislocation, where the nerves are not irritated or lacerated in their exit through the spinal column, it is absent.

The **Treatment** of dislocation of the spine resembles in all important respects that of fracture of the vertebral column. *Reduction* has, however, been effected in a sufficient number of cases to justify the attempt being made when the danger is imminent.

Dislocation of the Transverse Processes of the Cervical Vertebra occasionally occurs. The patient, after a sudden movement, or a fall on the head, feels great pain and stiffness in the neck, the head being fixed immovably, and turned to the side opposite to that on which the displacement has occurred. In these cases I have known *Reduction* effected by the Surgeon placing his knee against the patient's shoulder, drawing on the head, and then turning it into position, the return being effected with a distinct snap.

Wound of the Theca Vertebralis.—Holmes has recorded two cases in which this accident happened from the stab of a penknife in the lumbar region; in one of them the patient died. The only characteristic sign was the escape of cerebro-spinal fluid in large quantities from the wound.

Operation in Injuries of the Spine.—As the fatal result of fracture of the spine, with compression of the cord by the broken vertebra, or by extravasated blood, is almost inevitable, the idea has naturally suggested itself to Surgeons that life might be prolonged, and health perhaps restored, if the same operation were extended to the spine which is successfully employed in analogous cases of injury of the head: viz., the elevation and removal, if necessary, of the depressed portion of bone. This operation, originally proposed by Heister, was first performed by Louis and Cline. In all cases of compound fracture the wound must be enlarged and any fragments removed. The results of operation in cases of fracture have not been very encouraging; but, as fracture of the spine with serious lesion of the cord is almost invariably fatal, and as the evil consequences of the fracture are occasionally dependent not only upon the primary lesion of the cord, but on the secondary inflammatory processes set up in it by the continued irritation of the fractured fragments, the Surgeon is surely justified in attempting the removal of this source of certain misery and impending death by the only means in his power—operative procedure; the more so as the operation is not necessarily dangerous, does not appear often to have hastened death, and has certainly, in some cases, afforded relief, the paralytic symptoms disappearing to a great extent, and the patient being able to move limbs that were previously motionless.

Unfortunately in the great majority of cases the fracture of a vertebra is through the body and not through the arches. Little more than temporary relief can be expected from the removal of the pressure from behind by cutting away the arches, when the cord is partially divided and lacerated by a rough and jagged edge of the broken body of a vertebra thrust back against it. It is when the arches only are fractured and displaced—a rare

condition it is true—that permanent good may be expected to follow the operation.

We have already seen that in some cases of fractured spine the symptoms are due to hæmorrhage within the spinal canal, and that such hæmorrhage may occur independently of fracture. Under these circumstances, operation may be undertaken for the relief of pressure. The same remark applies to those rare cases in which symptoms arise at a later date from the occurrence of meningitis with inflammatory effusion. Thorburn strongly advocates operation in injuries of the cauda equina, that is, injuries below the first lumbar vertebra, if spontaneous recovery have not occurred after about six weeks. From the study of some two hundred cases in which operation has been undertaken for injury of the spine, Thorburn concludes that little good is likely to result, except in the three conditions already mentioned—fractures of the spines and laminae, intraspinal hæmorrhage, and injuries of the cauda equina. The fact that recovery is rare, even when the displacement of the bones which damages the cord is momentary, will readily explain the unfavourable results which usually follow the relief of pressure on the cord by operation, for the cord itself has usually been damaged beyond hope of repair.

The operation of **laminectomy** is performed as follows:—The patient is turned on to the side, or slightly on to the face. An incision, from three to five inches in length, is made over the spines, and the soft structures are separated from the spines, neural arches and articular processes with a scalpel and periosteal elevator. Additional room may be obtained by making short transverse cuts in the vertebral aponeurosis. All bleeding vessels are tied, and the free general oozing is arrested by plugging the wound with cotton wool soaked in a hot solution of perchloride of mercury (1 in 1,000). Each of the exposed spines is now tested to ascertain if any fracture exists, and any completely or partly separated bone is removed. Should a fracture be detected, one or more spines must be cut away with strong bone forceps, and the ligamenta subflava very carefully divided with a scalpel and forceps. The pin of a trephine is now applied to the surface left by removing a spine, and the lamina on each side notched. The lamina is now cut away very carefully with bone forceps, and others are similarly removed if necessary. The theca is thus exposed, and bleeding is arrested by gentle sponge pressure.

If no cause of the compression be found outside the theca, the latter must be carefully opened in the middle line. In cases of fracture a bent probe or searcher may be passed beneath the cord to see if any fragments lie in front of it. The theca may be closed with fine catgut sutures; deep sutures are inserted through the muscles and skin. A small drainage tube should be placed in the superficial part of the wound for 24 hours, and the deepest part of the dressing should consist of a longitudinal pad on either side of the incision. It is scarcely necessary to insist upon the strict antiseptic precautions which must be observed in all operations upon the spinal canal; otherwise a fatal complication may be added in the form of septic meningitis and myelitis.

CHAPTER XXVI.

INJURIES OF THE FACE AND ADJACENT PARTS.

FACE.—Cuts about the *Cheeks and Forehead* are of common occurrence. These injuries present nothing peculiar, except that the structures of the face show the same ready disposition to repair that characterizes the scalp when injured.

In the *Treatment* of these wounds, it is of much consequence to have as little scarring as possible. The edges, after being well cleaned, should be brought neatly into apposition by one or more wire or catgut sutures deeply applied to take the chief strain, and a number of fine horsehair interrupted sutures to bring the edges in accurate apposition. If the wound penetrate to the nose or mouth, so that there will be sufficient drainage from the mucous surface, the skin may be covered with collodion; if not, a dry wool dressing is the best.

When the wound is in the neighbourhood of the eyelids, especial care must be taken to prevent suppuration, lest the contraction of the cicatrix produce eversion of the lid. In those cases in which a portion of the nose or lip has been lost, much may be done to repair the deformity by properly conducted plastic operations, such as will be described in Chapter LVIII. The bleeding, which is usually very free in wounds of the face, is easily arrested by ordinary means.

If the *Lip be cut from within*, by being struck against the teeth, the coronary artery may be divided, the patient swallowing the blood that flows into the mouth. Some years ago, a man was brought to the Hospital, drunk, and much bruised about the face. Shortly after his admission he vomited a large quantity of blood, which was at first supposed to proceed from some internal injury; but, on examining his mouth, it was found that the blood came from a wound of the coronary artery of the lip.

PAROTID DUCT.—It occasionally happens in wounds of the cheek that the parotid duct is divided, in consequence of which the wound does not close, and a trickling of saliva takes place upon the outside of the cheek; a **Salivary Fistula**, which is a source of great disfigurement and inconvenience, being established. The surface surrounding it is puckered and somewhat excoriated, and the fistula opens by a granulating aperture.

If from its anatomical situation a wound is known to have divided the parotid duct, the formation of a fistula may be prevented by bringing the skin surface accurately together, leaving the mucous aspect of the wound freely open and covering the surface with a piece of lint dipped in collodion. If the divided ends of the duct can be seen in the wound it has been recommended to pass one end of a fine piece of silver wire down into the mouth and the other up the duct towards the parotid for a short distance and then through the mucous membrane into the mouth; the two ends are then knotted together

inside the mouth and the external wound closed. By this means the continuity of the duct is maintained while the wound heals, and at the end of a week the silver wire may be withdrawn by dividing the loop in the mouth. Should a fistula form it must be treated as described in Chapter LV.

Besides fistula of the Stenonian duct, other fistulous apertures may be formed in the cheek, as the result of injury or disease, allowing the escape of a small quantity of saliva. These openings are always closed with difficulty; the edges becoming callons, and not readily taking on reparative action. Closure may be effected in some cases by canterization with nitrate of silver, or with a red-hot wire. In other cases, the electric cautery may prove successful. If, however, the opening is free, with much indurated structure about it, it may be necessary to excise a portion of the edges before bringing them together.

Nose.—**Foreign Bodies**, such as pebbles, beads, dried peas, &c., are occasionally met with in the nostrils of children, having been stuffed up in play and become so firmly fixed as to require extraction by the Surgeon. In most cases a bent probe or an ear-scoop will remove the impacted body most easily. If it be large and soft it may often be easily removed with a pair of forceps, but a hard smooth body is almost sure to be pushed further up with these instruments. It is always best to administer an anæsthetic, otherwise the involuntary movements of the child will greatly add to the difficulties of the Surgeon. If the body be not removed it may give rise to chronic purulent catarrh or even to disease of the bones.

The **EARS** are not unfrequently wounded in injuries of the head and scalp; a portion of the external ear being sometimes torn down and hanging over the side of the face. In these cases, as in scalp injuries, the part should never be removed, but, however lacerated and contused, should be cleaned and replaced by means of a few points of suture. When the cartilaginous portion of the ear is divided, nice management is usually required in effecting perfect union.

Foreign Bodies are often pushed into the ears of children. When pointed or angular, such as pieces of stick, they may readily be extracted with forceps provided they can be clearly seen; but when round and small, such as pebbles or beads, they are not so easily removed.

The foreign body may occasionally be removed by passing the bent ear-scoop round it. In some cases I have found an instrument (Fig. 318) made by Coxeter on the model of Civiale's urethral scoop, useful in extracting a foreign body from the ear. It can be introduced straight and passed beyond the body, when, by the action of a screw in the handle, the scoop is curved forwards, and so enables extraction to be readily effected. But, as a rule, it is bad practice to attempt to extract foreign bodies from the ear by means of instruments; in the majority of cases the offending body is best removed by syringing the ear with tepid water, injected in a full stream by means of a large brass syringe, the pinna being drawn up so as to straighten the external meatus. In this way the bead or pebble is soon washed out by the reflux of the water striking against the tympanum. It may be laid down

Fig. 318.—Ear-Scoop.

as a good general rule, that if a round or oval body cannot be dislodged by syringing it will not be removed by instruments: and if the proper use of the syringe do not suffice, it is better to leave matters alone, and to allow the foreign body to become loosened, when it can be easily syringed out, than to poke instruments into the ear with the view of forcibly extracting it. These attempts are ill-advised; and I have known death, from inflammation and suppuration in the middle ear extending to the meninges of the brain, to follow from prolonged and unsuccessful efforts at the extraction of a pebble from the ear.

ORBIT.—*Injuries of the Orbit* may be dangerous, either to the brain or to the eye. Deep wounds are usually directed upwards, so that the roof of the orbit is the part most likely to suffer. The gravity of such a wound may not be recognized until meningitis sets in, for the small skin wound may rapidly heal, or may even be wanting if the penetrating weapon have passed between the lid and the eye. The optic nerve may be divided without damage to the globe itself, and thus immediate and permanent blindness may result. Foreign bodies in the orbit are easily overlooked and may cause trouble for months before their presence is suspected.

Orbital abscess is sometimes the result of a wound, with or without the retention of a foreign body. It may run an acute course, or it may be extremely chronic and strictly localized, thus simulating a tumour. In the acute form there is swelling of the lids, almost erysipelatous in character, with protrusion of the eye, loss of movement and intense widespread throbbing pain. The eye may also be displaced vertically or laterally according to the position of the pus. The widest interval between the globe and the orbital margin is therefore the point at which an incision should be made. A narrow-bladed knife, held with its back towards the globe, should be passed deeply into the orbit. The early evacuation of the pus is very essential lest blindness result from the prolonged pressure upon the optic nerve, or lest the inflammation spread backwards and set up purulent meningitis.

EYE-LIDS.—These may be extensively cut or lacerated without damage to the eye itself, but a careful examination of the eye should always be made when there is any fear of the lid having been penetrated. Wounds of the lids unite readily if sutured, but great care must be taken that the margin of the lid be brought into accurate apposition. For this purpose a fine suture should first be inserted in the free border of the lid, and then a row of others placed in the skin. If there be much gaping of the wound, a deeper suture or a fine pin with a figure-of-8 turn of silk may be used.

EYE.—*Injuries of the Conjunctiva.*—The most common minor injury of the eye is the impaction of a minute fragment of some foreign body in the cornea or conjunctiva. The foreign body will most often be found imbedded in the lower half of the cornea, as this part is most exposed in the palpebral fissure. There is usually much pain and discomfort, aggravated each time that the patient closes the eye when the upper lid is scratched by the offending particle. The eye waters freely and is intolerant of bright light; the pupil may be smaller than the other (congestion myosis). The removal of a foreign body from the eye may be effected as follows. The patient should be seated. The Surgeon stands behind, with the patient's head resting against his chest. After dropping some 2 per cent. solution of cocaine into the eye, the Surgeon concentrates the light of a lamp on to the

cornea with a convex lens held with the thumb and index finger of the left hand, the lids being steadied and held gently apart with the other finger of the same hand. The best instrument is a fine needle such as is used for the dissection of cataract membranes, as this causes less injury to the corneal epithelium than the ordinary "spud." The patient is directed to look with both eyes at some fixed object, and the foreign body is removed by inserting the point of the needle beneath its edge and gently lifting it out of its bed. Should no foreign body be found on the cornea, the patient should be directed to look downwards whilst the upper lid is everted over a probe. The foreign body most usually adheres to the lid about an eighth of an inch from the margin. Some castor oil or simple ointment should be put between the lids and the eye kept bandaged for a day. If much irritation has already been produced it is advisable to use atropine drops once or twice.

Burns by acid, caustic alkalies, lime, and molten metal are amongst the most disastrous injuries to which the conjunctiva is liable. The ultimate damage to the edge is often much greater than would seem probable immediately after the injury. A fresh burn of the cornea often appears only as a clear slightly depressed area interfering little with vision, whilst the resulting leucoma may be so dense as to render the eye practically useless. Burns of the conjunctiva may lead to extensive adhesion of the lids to the globe—*symblepharon*. The immediate treatment of an eye injured by escharotics should be to alleviate the pain and orbicular spasm by the use of a 2 per cent. solution of cocaine, and after carefully removing all solid particles, to wash out the conjunctival sac. The chemical action of an acid or alkali may be arrested by the use of a weak neutralizing solution if the case be seen immediately after the accident. After washing out the conjunctival sac, a few drops of castor oil, or better, some simple ointment with lanolin as a basis, should be put inside the lids to lessen the friction of the raw surfaces on one another. Opium in some form will probably be needed at night, as the pain is always severe. A pad of absorbent wool should be kept lightly applied over the eye with a bandage. Frequent irrigation with warm boracic lotion and the use of a simple ointment will be required. Any attempt to prevent the formation of adhesions between the globe and lids by breaking them down frequently is quite futile, and only delays the healing. When cicatrization is complete, much may often be done by plastic operations to remedy the deformity produced by cicatrices.

Contusions of the Eyeball.—A severe blow upon the eye, as by a racket ball or the cork of a soda-water bottle, may, without injuring the outer tunic, cause serious damage to the deeper structures. Temporary paralysis of the sphincter muscle of the iris may cause a dilated inactive pupil, whilst partial or complete paralysis of the ciliary muscle may be evidenced by loss of power of accommodation for near vision. The iris may be torn away from some part of its peripheral attachment, leaving a spindle-shaped gap, or it may be fissured radially at its pupillary margin. *Hæmorrhage* may take place into the anterior chamber, the vitreous, or the retina. Hæmorrhage into the anterior chamber (*hyphema*) is often, but not always, associated with rupture of the iris; the blood may come from the ciliary processes, and finding its way through the pupil, settles in the lower part of the anterior chamber. Absorption of the effused blood usually occurs rapidly. Hæmorrhage into the vitreous may be so profuse as to cause immediate blindness. If the pupil be

dilated and light focussed on to the eye with a convex glass, a red mass is seen behind the lens, whilst on ophthalmoscopic examination there is found to be complete absence of the normal red fundus reflex. If the amount of effused blood be small, it will be recognized with the ophthalmoscope as fine webs floating in the vitreous. Blood effused into the vitreous is usually absorbed slowly, and some permanent opacity may result. Hæmorrhages into the retina are, as a rule, multiple, and rarely of large size; they usually disappear quickly.

Dislocation of the lens may follow a blow on the eye, as the result of tearing of the suspensory ligament, the amount of displacement varying with the extent of the rupture of the ligament. In the slighter cases in which one edge of the lens is tilted forwards, the nature of the injury is recognized by the pushing forwards of the iris at this spot, whilst in its opposite part the iris is tremulous on account of the loss of the support of the lens; pendulum-like oscillations of the lens may be observed when the head is moved.

Complete displacement of the lens may occur, forwards into the anterior chamber, or backwards into the vitreous; in the latter case the whole iris is tremulous, when the eye is sharply moved from side to side. After complete displacement, the lens may remain clear for a long period, but more often it sooner or later becomes opaque. Dislocation of the lens forwards is especially likely to be followed by acute glaucoma. If the case can be kept under observation, it is probably better not to attempt to remove the dislocated lens so long as the eye remains quiet, but if the eye becomes painful and injected, or if the tension rises, the removal of the lens must be attempted. The operation may be very difficult, especially if the lens lie in the vitreous; it should be performed only in case of necessity, and excision of the globe is often ultimately required.

Concussion cataract is an occasional result of a blow on the eye, not accompanied by a penetrating wound, and not causing dislocation of the lens. The condition has been shown, in some cases at least, to be due to rupture of the posterior part of the lens capsule.

Detachment of the retina may result from hæmorrhage between the retina and the choroid. More frequently it comes on slowly after an interval of some weeks, and is then probably due to shrinkage of the vitreous. The treatment of this condition is very unsatisfactory. Perfect rest in bed for some weeks with both eyes bandaged is sometimes followed by improvement, but this is rarely permanent.

Rupture of the choroid is accompanied by hæmorrhage into the vitreous, and it is only after the vitreous has cleared that the nature of the injury can be recognized by ophthalmoscopic examination. The clefts in the choroid are then seen as white lines over which the retinal vessels pass. They are generally near the optic disc, and arranged concentrically to it. The prognosis as regards useful vision is not good.

Rupture of the Globe is most common in aged people in whom the sclerotic is rigid, and usually results from a severe blow, as with the closed fist. The rupture is most common at the thinnest part of the sclerotic, that is, about four millimetres from the corneal margin. Through the opening any or all of the contents of the globe may escape, and total disorganization of the eye is an almost constant result. Should the conjunctiva remain intact, the lens or iris may escape into the subconjunctival tissue, and the prospect is

slightly more favourable as the interior of the eye is not opened to the air. In the large majority of cases immediate enucleation of the globe is the only treatment. If the rupture be subconjunctival, the case is rather less hopeless, but excision may be required if the eye become shrunken or irritable. If the lens be lying under the conjunctiva, no attempt should be made to remove it until the wound in the sclerotic is firmly healed, and in some cases it causes no discomfort, and may be left to undergo slow absorption.

Penetrating Wounds of the eye-ball are all dangerous to sight, but their severity varies with the size and position of the wound, and the implication of deep structures, and is much increased by the retention of a foreign body and the introduction of septic matter into the interior of the globe. If the wound be large, escape of the contents and hæmorrhage into the eye may render the case scarcely more favourable than one of rupture. A small wound also may be rendered very serious on account of its position. The "dangerous area" is a zone about a quarter of an inch in width behind the corneal margin. This area corresponds to the position of the ciliary body, and wounds of the latter are especially liable to be followed by shrinkage of the globe or by sympathetic ophthalmia. The simplest form of penetrating wound is one in which the cornea only is involved, and which heals without further complication after the escape of the aqueous.

More often the iris becomes entangled in the wound. When such a case is seen within a few hours of the accident and the iris appears to be uninjured, an attempt should be made to replace it with a fine probe. The eye should first be bathed with a weak solution of perchloride of mercury (1 in 3,000), and the previous use of eserine for half an hour will aid reduction by putting traction on the iris and retaining it in position when reduced. If some days have elapsed since the accident no attempt should be made to reduce the prolapsed iris. The latter must then be gently drawn out with fine forceps to free it from its adhesion to the corneal wound and cut off with scissors. Wound of the iris considerably increases the gravity of the injury, for it almost necessarily involves wound of the lens, with resulting swelling and opacity of the latter.

The severity of a penetrating wound may be much increased by the retention of a foreign body in the eye, an accident especially frequent among fitters, riveters, and other workers in metal. Careful examination of the eye should be made as soon as possible after the injury, before the occurrence of iritis or opacity of the lens has perhaps rendered examination difficult. After having carefully examined the iris for a wound, the pupil should be dilated with atropine. The relation of the corneal wound to that in the iris or lens may serve to indicate the direction which the foreign body has taken. The vitreous and the fundus must be successively investigated with the ophthalmoscope. The lower part of the vitreous should be examined with great care, whilst the presence of a retinal hæmorrhage may indicate the position at which the foreign body has struck the back of the globe.

The chemical properties of any substance retained within the eye will in some measure determine the amount of irritation which it causes. Metals are less likely to be tolerated than inert substances, such as glass or stone, whilst an eye containing a fragment of copper has an even worse prospect than one containing a piece of iron of the same size, the salts of the former

being more irritating than those of the latter. Before the introduction of breech-loading guns many eyes were lost from injuries with fragments of copper percussion caps.

The highly albuminous contents of the eye form a very favourable soil for the growth of pyogenic organisms, which have been carried in by a penetrating body or have subsequently gained entrance through the wound. Acute general suppuration (*panophthalmitis*) may follow any penetrating wound of the eye, but occurs most commonly after perforation with some obviously foul instrument, such as a steel dinner fork—a not uncommon accident among children who use a fork to unpick a knotted boot-lace.

The suppurative process extends with great rapidity, appearing first as a yellowish infiltration along the track of the wound, and soon spreading into the vitreous. The aqueous becomes turbid, and the wounded cornea may necrose. Iritis is always present, often with hypopyon. If there is an open wound the pus may drain away from it; under other circumstances the sclerotic may give way, to the great relief of the patient. Complete shrinkage of the globe subsequently occurs.

Treatment.—When there is no probability that the eye contains a foreign body, and when the injury is not so severe as to necessitate excision, the wound and the conjunctival sac should be thoroughly cleansed with a weak solution of perchloride of mercury (1 in 3,000), and a compress applied. Atropine should be used twice a day, and leeches applied to the temple if there is pain. If the wound is in the sclerotic, the conjunctiva should be sutured over it, and any protruding vitreous cut off close with scissors. The treatment of prolapsed iris has been described on p. 821. Any case in which the lens is wounded should be carefully watched, lest the swelling of the lens result in glaucoma. The increase of tension will be accompanied by great pain, and often by frequent vomiting. Prompt operation is required in such a case, and should consist in a free incision through the cornea, and the evacuation of the softened lens with a curette.

When a fragment of metal remains imbedded in the cornea or sclerotic, considerable difficulty may be experienced in removing it; if in the sclerotic it is sometimes necessary to enlarge the wound. If the foreign body be adherent to the iris, iridectomy is generally the best treatment, the foreign body being removed together with the damaged portion of iris. A particle of metal lodged in the lens causes less irritation than in any other part of the eye, the lens can sometimes be removed when it has become opaque with the foreign body *in situ*. When the fragment lodges in the vitreous the electro-magnet has been successfully used for its removal, but the case is always very serious and subsequent excision is often required.

Non-penetrating Wounds.—These are of importance only when the cornea is involved, for wounds of the conjunctiva heal readily enough and seldom require the use of sutures unless there is obvious gaping. Corneal wounds assume a special importance from the pain and discomfort which they cause, and from the possibility of local infective processes starting in them. Vision may be impaired by those which encroach on the central region or by those which cause irregularity in the curve of the cornea. The resulting scar tissue may occasion a more or less dense nebula, which may, however, in the case of children, completely disappear in the course of time.

The treatment of these simple corneal wounds consists in bathing the eye

with hot boric lotion, and the use of atropine and cocaine drops. A bandage should be worn until the repair of the wound is complete.

Occasionally a small corneal wound or abrasion becomes infected and takes on an unhealthy action. An ulcer results, which tends to spread on the cornea, first in one direction and then in another (serpiginous ulcer). Pus in the anterior chamber (hypopyon) and iritis are very frequent accompaniments of this form of ulceration. Treatment must be directed to the arrest of the process of ulceration, and this can as a rule be best done by the application of the actual cautery to the spreading margin.

Sympathetic Ophthalmia.—A perforation of one eye by wound or ulceration is occasionally followed by a destructive form of inflammation in the other eye. This so-called "sympathetic ophthalmia" affects primarily the ciliary body and iris, and though often insidious in its onset, tends to cause severe damage or destruction of sight. It is especially likely to follow perforating wounds of the "dangerous area" or those involving the iris (p. 821). The interval which may elapse between the injury of one eye and the onset of inflammation in the other varies greatly, but is probably never less than two weeks. The pathology of sympathetic ophthalmia is doubtful, but the condition probably results from the extension of some specific micro-organism from one eye to the other along the lymph channels of the optic nerves. It is the possibility of its occurrence which gives such a grave importance to the decision whether to preserve or excise a wounded eye; and for the same reason, an eye containing a foreign body can seldom be left with safety. Sympathetic inflammation is sometimes preceded by a condition known as *sympathetic irritation*; the eye is the seat of neuralgic pain, is intolerant of light and tires readily in attempts to read or do near work. Amongst the earliest signs of sympathetic ophthalmia are turbidity of the aqueous with the deposit of fine dots on the posterior surface of the cornea (keratitis punctata); alteration in the colour of the iris and defective action of the pupil; deep injection of the ciliary region of the sclerotic; haziness of the vitreous; and neuro-retinitis. These conditions may be recovered from, but as a rule the inflammation of the iris and other structures progresses until sight is destroyed.

Treatment.—The onset of *sympathetic irritation* is an indication for the immediate excision of the exciting eye. If the signs of *sympathetic ophthalmia* are present the exciting eye, if blind, should be excised, but if it still retains any power of useful vision, this should not be done as this eye may eventually prove the better of the two. In any case excision of the exciting eye seldom has any marked effect upon the inflammation of the sympathising eye; and this in spite of the fact that if done sufficiently early the operation would have altogether prevented it.

The constitutional treatment usually adopted consists in the administration of mercury, which is known to be of undoubted utility in other forms of iritis. Atropine should be used locally, and the application of leeches to the temple relieves the pain. Both eyes should be kept bandaged.

EXCISION OF THE EYE-BALL.—This is under favourable conditions a simple operation, but some difficulty may be met with if the globe is collapsed, or if the surrounding tissue is adherent from previous inflammation.

The instruments required are a speculum, fixation forceps, strabismus hook, a pair of small blunt-pointed scissors for dividing the conjunctiva and muscles,

and a stronger pair of scissors, curved on the flat, for cutting the optic nerve (Fig. 319).

Having inserted the speculum, the Surgeon picks up the conjunctiva with forceps close to the corneal margin, and often cutting a small opening in it with the scissors, divides it completely round as near the cornea as possible. The capsule of Tenon is next opened by cutting back between the position of any two of the recti muscles, keeping close to the globe. By now passing the strabismus hook along the track of the scissors and sweeping it gently over the surface of the sclerotic, the muscles can be picked up in succession and divided on the hook close to the sclerotic. It is immaterial where the opening in the capsule is made, but a convenient spot is to one side or other of the inferior rectus, and from this opening the operator divides the muscles in whichever

Fig. 319.—a. Wire Speculum. b. Toothed Forceps with Fine Points. c. Straight Scissors. d. Strabismus Hook. e. Scissors for Dividing Optic Nerve in Exstirpation of the Eye.

order is most convenient. The optic nerve is next cut through with the curved scissors, which are passed backwards with the blades closed until the optic nerve is felt. Any remaining structures may be divided close to the globe.

A compress should be firmly applied with a bandage for a few hours, after which a light pad of antiseptic gauze or wool is sufficient. At each dressing the lids should be separated and the orbit irrigated with tepid mercurial or boric lotion.

MOUTH.—Wounds of the mouth are seldom met with, except as the result of gunshot violence. The amount of injury done to the soft structures, however great, is usually only secondary to the mischief that results to the brain, spinal cord, jaws, and skull, and must of course be dealt with on the ordinary principles of treatment of gunshot and lacerated wounds.

TONGUE.—Wounds of the tongue usually occur from its tip or sides being caught between the teeth during an epileptic fit. They have been known to be inflicted by insane patients, in attempts to excise or to bite off this organ. Should the hæmorrhage be free, it can be restrained by the application of a

ligature, or by torsion. The raw surface should then be well dusted with iodoform. These wounds often assume a sloughy appearance for a few days; they then clean up, and granulate healthily. It is useless to bring the edges together by sutures, which readily cut out. If, however, a large portion of the tip be nearly detached, it must be supported in this way; but the sutures, which should be of silkworm-gut or silver wire, must be thick and passed deeply. Pieces of tobacco-pipe are occasionally driven into and broken off in the substance of the tongue, and they either give rise to very free hæmorrhage, or the wound may close and heal over the foreign body, the existence of which may not be known to the patient. In a case of this kind, in which a man complained of much pain and stiffness in the tongue, with difficulty in deglutition, I found a hard swelling towards the base of the organ; on cutting down upon this I extracted three inches of the stem of a clay pipe, which had been lodged there for several months.

THE PALATE and the PHARYNX are sometimes lacerated by gunshot injuries of the mouth; or the wound may result from something that the patient happens to have between his lips being driven forcibly backwards into his mouth. Thus, a tobacco-pipe may, by a blow on the face, be driven deeply into the substance of the tonsil, or perhaps into the pharynx, wounding and lodging behind the arches of the palate; it generally breaks off short, and the fragment that is left in gives rise to an abscess, and perhaps to ulceration of vessels, and fatal secondary hæmorrhage. In a case that was under my care some time ago, the soft palate was nearly detached from the palate bones by a deep transverse wound, caused by the end of a spoon having been forcibly driven into the mouth; good union took place eventually, the parts having been stitched together by a few points of suture. In some rare cases the internal carotid has been wounded from inside the mouth.

CHAPTER XXVII.

INJURIES OF THE THROAT. ASPHYXIA.

INJURIES OF THE LARYNX AND TRACHEA.

FRACTURE OF THE CARILAGES OF THE LARYNX.—The cartilages of the larynx may be broken and displaced by violent blows or by a squeeze, the fracture in some cases taking place transversely, in others longitudinally. Digital examination will at once detect the nature of the injury. There is superficial extravasation of blood, with pain and difficulty in breathing, speaking, and swallowing. In some cases there is spitting of blood with cough. Fracture of the larynx is an extremely dangerous injury. Durham has collected 69 cases of which 53 died. The great danger is from asphyxia, which may occur immediately as a direct consequence of the displacement due to the fracture, or may come on at a later period as the result of inflammatory swelling. In some cases, simple concussion of the larynx without fracture has been known to prove fatal, apparently from shock. Should symptoms of serious dyspnoea appear, tracheotomy must be performed without delay; if not, attention to position and support of the injured parts will suffice.

WOUNDS OF THE THROAT.—These are of great frequency and importance, implicating, as they do, some of the most important organs in the body. They may be divided into three categories:—

1. Those that do not extend into the Air- or Food-passages.
2. Those that implicate the Air-passage, with or without injury of the (Esophagus.
3. Those that are accompanied by injury of the Spinal Cord.

These injuries are most commonly suicidal, and may be inflicted with every variety of cutting instrument; except where the spinal cord is injured, which must, in cases of suicide, be the result of gunshot wound, and is necessarily fatal. Though incised, they are often jagged, and partake somewhat of the character of lacerated wounds, with great gaping of the edges.

1. **Wounds not extending into the Air- or Food-passages.**—In these there is very free and even fatal hæmorrhage, and this sometimes though none of the larger arterial or venous trunks have been divided; the blood flowing abundantly from the venous plexuses or from the thyroid body when the wound is low down. If the larger arteries be wounded, as the carotid and its primary branches, the hæmorrhage may be so abundant as to cause almost instantaneous death. Another source of danger in these cases proceeds from the admission of air into the veins of the so-called "dangerous region" of the neck. For this a free wound is by no means necessary, as is proved by a remarkable case that occurred some years ago near London, in which the introduction of a seton into the fore part of the neck was followed by death from this cause.

Wounds of the internal jugular vein are necessarily very dangerous. There is not only the ordinary risk of primary hæmorrhage from a vessel of such large size, but the special danger of the introduction of air into it; should these evils be safely passed, the secondary ones of recurrent hæmorrhage, diffuse inflammation, and pyæmia, may still have to be encountered. Ligation of the vessel above and below the wound in it, exactly as if it were an artery that had been opened, is the only course that can safely be pursued, unless the opening be merely a puncture, when it may be picked up and tied without occluding the lumen of the vessel. In one case, I saw and heard air enter the vein as it was being raised for the passage of the ligature, but the patient made a quick recovery.

The large nerves, such as the vagus and phrenic, can scarcely, in a suicidal wound, be divided without fatal injury to the neighbouring vessels, but they may be injured by stabs or gunshot wounds. The division of the nerves on one side only, or even of one of them, may be fatal in man, by interfering with the proper performance of the respiratory act. In a case with which I am acquainted, in which the phrenic nerve was divided during ligation of the subclavian artery, death resulted in a few days from congestion of the lungs. Sadler has however recorded a case of division of one pneumogastric in a punctured wound in which recovery took place without serious symptoms.

In the **Treatment** of wounds of the neck of this category, the principal points to be attended to are, in the first place, the arrest of hæmorrhage by the ligation of all bleeding vessels, whether arterial or venous; and, secondly, bringing together the lips of the wound. This is best done by the use of sutures and by position. A recent clean-cut wound of the throat of this class may as a rule be safely closed with sutures, and thus primary union obtained. If the wound is transverse, the head should be fixed, with the chin almost touching the sternum, and retained in this posture by tapes passing from a nightcap to a piece of bandage fixed round the chest. I have had under my care one case in which, owing to the projection and mobility of the larynx, the wound did not unite, a large and deep gap being left, which required a series of plastic operations in order to effect its closure.

2. Wounds implicating the Air-passage.—Wound of the air-passage is common, and is revealed in suicidal attempts by the air being heard and seen to bubble in and out of the wound during respiration. These wounds vary much in extent, from a small puncture with the point of a penknife to a cut extending completely across the throat, and even notching the vertebrae. They are frequently complicated with injuries of the larger vessels and nerves, and sometimes with wound of the œsophagus. Most commonly the cut is made high up in the neck; for the suicide, thinking that it is the opening into the air-passage that destroys life, draws the razor across that part of the throat where this is most prominent and easily reached; and thus, through not wounding the larger vessels, which are saved by the projection of the larynx, he frequently fails in accomplishing his object.

These wounds occur in four situations: above the Hyoid Bone; in the Thyro-hyoid Space; through the Larynx; and through the Trachea.

The wound may be made **above the Hyoid Bone**, the cut extending into the mouth and wounding the root of the tongue. A wound in this situation is usually attended with much hæmorrhage; and there is great trouble in feeding the patient, as the power of swallowing is completely lost.

The wound may be inflicted in the **Thyro-hyoid Space**, laying the pharynx open, but being altogether above the larynx. This is the most common situation for suicidal attempts. In many cases, the incision is carried so low as to shave off or partly detach the epiglottis and the folds of mucous membrane around it. In other cases, the edges of the glottis or the arytenoid cartilages are injured, the cut extending back to the bodies of the vertebrae. Here also there is great difficulty in swallowing and great risk of the sudden supervention of oedema of the glottis, and consequent suffocation.

When the **Larynx** is wounded the incision is usually transverse; but I have seen a longitudinal cut made through the larynx, splitting the thyroid and cricoid cartilages perpendicularly. In these cases of wounded larynx, there is great danger of the blood from the superficial parts trickling into the air-passage and asphyxiating the patient, and of inflammation of the bronchi and lungs supervening at a later period.

Wounds of the **Trachea** are not so common as those of the larynx, from which they differ but little in the attendant dangers.

The **Œsophagus** is seldom wounded, and such wounds still more rarely come under the care of the Surgeon, as the part can be reached only through the trachea by a deep cut, which will probably implicate the large vessels. The Œsophagus has also been wounded from within in performing the feat of "sword-swallowing."

Effects.—There are various sources of danger in wounds of the neck implicating the air-passage. The *hemorrhage*, whether it proceed from any of the larger trunks, or consist of general oozing from a vascular surface, may prove fatal either directly by the amount of blood lost, or indirectly in consequence of the blood trickling into the air-tube, and producing suffocation.

Asphyria may supervene, either in the way already mentioned, or, when the wound has been inflicted above the larynx, from the occurrence of oedema of the glottis. It may likewise occur when the external opening is very small, and occasionally happens suddenly when the wound is nearly closed.

Another source of danger is the *loss of the natural sensibility of the glottis*, in consequence of which it no longer contracts on the application of a stimulus. Hence food taken in by the mouth may pass into the larynx and appear at the external wound, though neither the pharynx nor the Œsophagus has been wounded. This I have observed in many cases of cut throat; hence the presence of food in the wound cannot in all cases be considered an evidence of injury to the food passage. In some cases this may be due to wound of the superior laryngeal nerve, but it quite as frequently occurs in cases in which it is certain that this nerve is uninjured. It is then a bad sign, and is never met with until a semi-asphyxial condition has come on, by which nervous irritability is blunted, or until inflammation has been set up about the rima glottidis, giving rise to so much swelling as to interfere with the natural action of the muscles, and to deaden the perception of the part to the contact of a foreign body. In these cases also the sensibility of the air-passage generally is much lowered, so that mucus accumulates in the bronchi, even to a dangerous extent, the patient not feeling the necessity for expectoration, and often, indeed, having much difficulty in emptying his chest; his efforts at clearing the bronchi being reduced to a forced expiration, as a true cough is impossible while the wound is open below the glottis.

The occurrence of *bronchitis* and *septic broncho-pneumonia* is a frequent

cause of death in patients who survive the immediate effects of the wound. This is due in many cases partly to the direct admission of cold air, without its being warmed by passing through the nasal cavities, but much more often it results from the inhalation of the septic discharges from the wound. At the *post-mortem* examination of these cases the bronchi are found intensely injected; the lungs are as a rule swollen and oedematous throughout, and here and there patches of consolidation will be felt. On cutting into these they will be breaking down and softening in the centre, sometimes forming cavities almost like abscesses. They differ, however, from the secondary abscesses of pyæmia in being scattered through the lung and not specially on the surface; and if a patch be found in an early stage, it will be seen that there is no hæmorrhagic infarct preceding the softening, but that the air-vesicles are distended with opaque puriform secretion, and that the cavities are formed by the coalescence of the distended air-vesicles through destruction of their walls. The pathology of the process seems to be that septic matter from the wound is inhaled and lodges in the smaller bronchi where it sets up acute purulent catarrh with decomposition of the secretions. The decomposing secretions excite inflammation terminating in gangrene of the surrounding tissue of the lung. In some cases extensive areas of the lung may thus become gangrenous.

The *depressed mental condition* of the patient also is usually unfavourable to recovery when the wound is suicidal.

Treatment.—The same general principles apply as in the management of these wounds of the throat that do not open up the mucous canals in this region. Hæmorrhage must be arrested by ligature of all the bleeding vessels, whether arteries or veins, so that no oozing or trickling into the wound may take place. In some cases the hæmorrhage consists principally of general venous oozing which cannot be stopped by ligature, the patient drawing a large quantity of blood into the air-passage through the wound. In these circumstances I have found it useful to introduce a large silver tube into the aperture in the windpipe, and to plug the wound around it. As soon as the bleeding has fairly ceased, the plugs and the tube must be removed.

It has long been a recognized rule not to close wounds of the throat of this category with sutures, except, perhaps, at the angles. In this way the risks of an accumulation of coagula in the wound, and more especially the burrowing of septic matter between the deep cervical fascia, are effectually prevented. With improved methods of the treatment of wounds this rule cannot now be considered an absolute one. Morris, Pollard, and others have recorded cases which show that with efficient antiseptic precautions even an extensive wound of the throat may be accurately closed with sutures, and thus primary union obtained. The wound in the air-tube must first be carefully united with fine silk sutures, and it may be advisable to bring together the divided muscles and fascia with buried sutures before finally closing the skin wound. Provision for drainage will usually be required. This mode of treatment is, however, justified only when the Surgeon is able to carry out all the details of the antiseptic method; under other circumstances, the rule of leaving the wound widely open should be followed. If the trachea has been completely cut across it is always advisable to insert a stitch in each side of the tube, in order to prevent the wide separation of the two portions that would otherwise take place, owing to the great mobility of the larynx and upper end of the

windpipe. The head must be kept in a flexed position by the use of tapes, as described on p. 827.

In order to lessen the liability to inflammation of the lungs, the patient should be put into a room, the temperature of which is raised to about 70° Fahr. A piece of lightly folded gauze, acting as a filter, should be laid over the wound if this has been left open, and as soon as the cut surfaces begin to granulate, the edges of the wound may be brought into apposition by strips of plaster, and a compress if necessary. During the treatment, the principal danger proceeds from inflammatory affections of the chest: these must accordingly be counteracted by the temperature in which the patient is placed, and by making every effort to prevent as far as possible the accumulation of decomposing discharges about the wound, for which purpose iodoform is most useful. It must be remembered that the mental depression, and the bodily exhaustion from loss of blood, that are common in these cases, do not allow of any lowering treatment.

The **administration of food** always requires much attention. As a general rule, the patient should be kept on a nourishing diet, with a moderate allowance of stimulants. If, as not uncommonly happens, the food-passage be opened in consequence of the wound extending into the mouth, the pharynx, or the œsophagus, it is of course impossible for the patient to swallow, and the administration of nourishment becomes very difficult. It is best accomplished by means of a gum-elastic catheter passed through the mouth into the gullet or stomach. This is easier than passing the instrument through the nose, and much better than introducing it through the wound. In this way a pint or more of the strongest beef-tea or soup, mixed with two or three eggs, and having an ounce or two of brandy added to it, should be injected regularly night and morning, until the patient is able to swallow. In those cases in which the wound is above the larynx, there is occasional danger of the supervention of œdema of the glottis; should this occur, tracheotomy may be necessary.

As consequences of wounds of the throat, we occasionally find stricture of the trachea, or aërial fistula. If the vocal cords have been injured, loss of voice may follow.

Aërial Fistula may sometimes form owing to the skin doubling in and becoming adherent to the edges of the wound in the air-tube, and most frequently occurs when the cut is in the thyro-hyoid space; adhesion taking place between the inverted integuments and the os hyoides above, and the surface of the thyroid cartilage below. The same may occur in the crico-thyroid space, and indeed at any part of the larynx that has been opened. When this happens, the fistula tends to remain patent. In these circumstances, I have found the following operation successful.

The edges of the fistulous opening having been freely pared, and the knife passed under them for some distance, so as to detach them from the subjacent parts, a vertical incision is made through the lower lip of the opening, so as to split it downwards. Two points of suture are then inserted into each side of the horizontal incisions, bringing their edges into contact, *but the vertical cut is left free* for discharges and mucus to drain through, and for the expired air to escape, lest emphysema occur. Unless this outlet be afforded, the fluids will burst through the sutures, and thus destroy union of the edges.

It is not in every case that an aërial fistula can safely be closed. In some instances the larynx becomes contracted either by drawing in of the wound, or by thickening of the mucous membrane above the artificial opening to such an extent that the fistula becomes essential, for the purposes of respiration. In such circumstances, any attempt at closing it will be followed by symptoms of impending asphyxia; and it may be necessary to leave the opening free, or even, as happened in a case under my care, in which an opening was left in the crico-thyroid membrane of a girl who had attempted suicide by cutting her throat, to enlarge the opening and introduce a silver tube. Intubation of the larynx (see Chap. LVIII.) is a mode of treatment which should be given a trial in such cases.

FOREIGN BODIES IN THE AIR-PASSAGE.—A great variety of substances have been found in the air-passage: such as nut-shells, beans, cherry-stones, teeth, meat, money, buttons, pins, fish-bones, bullets, pills, pebbles, and pieces of wood. These foreign bodies are not introduced into the air-passage by any effort of deglutition, for no substance can be *swallowed* through the glottis. They are *inhaled*; thus, if a person, whilst holding anything in his mouth, make a sudden inspiration, the current of air may draw it between the lips of the dilated glottis into the larynx.

The symptoms vary, according to the situation in which the foreign body is lodged, its nature, and the time that has elapsed since the occurrence of the accident. The foreign body may lodge in one of the ventricles of the larynx; if light, it may remain in the trachea, and be carried up and down by the movement of the air in expiration and inspiration; if too heavy for this, it will fall into one or other of the primary divisions of the trachea, and, as Aston Key has observed, will most commonly be found in the right bronchus. The explanation of this has been pointed out by Gray, who states that on making a transverse section of the trachea, and taking a bird's-eye view of the bifurcation, the septum will be seen to be considerably to the left of the middle line; and further it has been shewn by Acby that the right bronchus is in a more direct line with the trachea than the left. The greater size of the right bronchus would also favour the entrance of a foreign body into it. If the substance be small, it may pass into one of the secondary divisions of the bronchi; and, if it continue lodged here for a sufficient length of time, it may make a kind of cavity for itself in the substance of the lung, where it may either excite suppuration round it or become encysted.

The *Symptoms* may be divided into three stages: 1. Obstruction, immediately following the introduction of the substance; 2. Irritation, produced by its presence; and 3. Inflammation, coming on at a later period.

1. Symptoms of Obstruction.—The immediate symptoms vary somewhat according to the size and nature of the foreign body, and the part of the air-tube that it reaches. In all cases there is a feeling of intense suffocation, with great difficulty of breathing, and violent fits of spasmodic coughing, often attended by vomiting, during which the foreign body may be expelled. Indeed, its partial entry and immediate extrusion by coughing are not uncommon. In some cases immediate death may ensue at this period from obstruction of the glottis. If the body have entered the air-passage fully, there is violent coughing, with a feeling of suffocation for an hour or two, accompanied by lividity of the face, great anxiety, and a sense of impending death. There is

also usually pain about the episternal notch. The symptoms then gradually subside, but any movement on the part of the patient brings them on again with renewed violence. All these symptoms are most severe if the foreign body remain in the larynx; the voice being then croupy, irregular in tone, or altogether lost. If it be lodged elsewhere, as often as it is coughed up and strikes against the interior of the larynx, an intense feeling of suffocation is produced; and if it happen to become impacted there, sudden death may result, even though it be not of sufficient size to block up the air-passage, apparently by the spasm that is induced. Many years ago I saw a boy die before tracheotomy could be performed, in consequence of a flat piece of walnut-shell that had entered the trachea being suddenly coughed up, and becoming impacted in one of the ventricles of the larynx. The symptoms, during this period, are much less severe when the foreign body is in the trachea or bronchi.

When there is a suspicion that the foreign body is lodged in the larynx, a laryngoscopic examination should be made, when it may, perhaps, if large—as a plate with false teeth—be seen between the vocal cords. Small bodies also have several times been detected in this way lodging in one of the ventricles of the larynx.

2. Symptoms of Irritation.—When the foreign body has passed into the air-passage, and the immediate effects produced by its introduction have subsided, another set of symptoms, dependent on the irritation produced by it, is met with; and it is during the occurrence of these that the patient is most generally brought under the Surgeon's observation.

The **General Symptoms** consist of occasional fits of spasmodic cough accompanied by much difficulty of breathing, a feeling of suffocation, and an appearance of urgent distress in the countenance. These attacks do not occur when the patient is tranquil, but come on whenever the foreign body is coughed up so as to strike the larynx, and the upper and more sensitive parts of the air-passage. In children the spasmodic cough caused by the presence in the air-passages of a small irritating body, such as a blade of grass, has been mistaken for whooping cough. As a general rule, the distress is less the lower the substance is lodged; the sensibility of the lower portion of the trachea and that of the bronchi being much less acute than that of the larynx and of the upper part of the trachea. In consequence of the irritation, there is usually abundant expectoration of frothy mucus. These symptoms often remit for a time, more particularly if the foreign body become fixed. In some cases, indeed, there appears to be so little distress some days after the accident, that considerable doubt may exist whether any foreign body really be lodged in the air-passage or in the lungs; and much valuable time is often lost by the indisposition of the Surgeon to adopt active measures.

The **Physical Signs** depend necessarily upon the situation of the foreign body. If this be loose and floating, it may be heard, on applying the ear to the chest, moving up and down, and occasionally striking against the side of the trachea. If it be fixed, it will necessarily give rise to a certain degree of obstruction to the admission of the air beyond it, perhaps occasioning sibilant or sonorous rhonchi during either inspiration or expiration or both. If it be impacted in the larynx, the voice will be hoarse and croupy, and there will be a loud rough sound in respiration, with much spasmodic cough and distress in breathing. If the foreign body be impacted in one bronchus, the physical

signs will vary according to circumstances. If it be angular or perforated a peculiar whistling noise may be heard as the air passes over or through it. A piece of broken tracheotomy tube has been known to become impacted in one bronchus without the production of any abnormal physical signs, the position of the foreign body being unsuspected until the occurrence of signs of inflammation in the affected lung. If the foreign body completely obstructs the bronchus, the respiratory murmur will be wanting on the side on which it is lodged. As a rule the obstruction is somewhat valvular in character, allowing a little air to be forced out during expiration but none to enter in inspiration, and extreme collapse of the affected lung may thus arise. There will then be absolute dulness on percussion, with deficiency on measurement and a want of expansion during inspiration. In other cases in which the form of the foreign body is such as not to obstruct the bronchus, the physical signs will be much less marked. If one of the subdivisions of either bronchus be occupied by the foreign body, the entrance of air will be prevented in the corresponding lobe of that lung, though it enter freely every other part of the chest.

3. Inflammation.—After a foreign body has been lodged for a day or two, inflammation of the bronchi or lungs is apt to be set up; in some cases, however, this occurs only after a considerable time has elapsed, or, perhaps, not at all—much depending, of course, on the shape and character of the irritant. In some cases an acute destructive inflammation of the lung occurs and proves fatal in a few weeks. If the foreign body completely obstruct one bronchus, the corresponding lung gradually becomes collapsed; and after a time abscesses form in it, apparently in consequence of the retention of the natural secretion in the smaller bronchi and air-vesicles. This condition of bronchiectasis usually proves fatal eventually either by the supervention of altemenoid disease or of acute inflammation of the lung. Godlee points out that unilateral bronchiectasis in a child is suggestive of the presence of a foreign body. In some cases a cavity forms in the substance of the lung around the foreign body, whence purulent matter is continually expectorated. Death in such cases may result after many months, or a year or two, from tuberculous phthisis. In very rare cases a foreign body has spontaneously escaped from the lung through an abscess pointing in the chest wall.

Should any of the above-mentioned changes have occurred in the lung, the expulsion of the foreign body is by no means necessarily followed by a cure.

Prognosis.—This depends more upon the nature of the foreign body and its size than on any other circumstance. If it be rough, angular, and hard, there is necessarily much more risk than if it be soluble in, or capable of disintegration by, the mucus of the air-passage. So long as the foreign body is allowed to remain, the patient is in imminent danger, either from immediate and sudden suffocation, or from inflammation at a more remote period.

The danger depends greatly upon the length of time during which the body is allowed to lodge. Of 62 cases which I collected in 1850 (4 of which had fallen under my own observation), I found the time that the foreign body was allowed to remain in, and the result of the case, stated in 49 instances.

PERIOD OF RETENTION	SUMMER OF CASES.	RE- COVERED.	DIED.
Less than 24 hours	8	6	2
Between 24 and 48 hours	4	3	1
Between 48 hours and 1 week	13	6	7
Between 1 week and 1 month	8	4	4
Between 1 month and 3 months	3	3	0
Between 3 months and 1 year	6	4	2
More than 1 year	7	4	3
Total	49	30	19

From this it would appear that, if the patient escaped the danger of the immediate introduction, the greatest risk occurred between the second day and the end of the first month, no fewer than 11 patients out of 21 dying during this period; and then that the mortality diminished until the third month, from which time it again increased.

The cause of death varies also according to the period at which the fatal result takes place. During the first twenty-four, and, indeed, forty-eight hours, it takes place from sudden asphyxia and convulsions. During the first few weeks it is apt to occur from inflammatory mischief within the chest; and after some months the patient will be carried off by the gradual exhaustion consequent upon the formation of abscesses in the lung.

Spontaneous expulsion of the foreign body occasionally occurs, usually in a violent fit of coughing. Gross of Philadelphia found that there are 49 cases on record, in which the body was spontaneously expelled, the patient recovering. In 37 of these, it was expelled during a fit of coughing. The period during which a foreign substance may remain in the air-passage before it is spontaneously expelled varies from a few minutes to many months or years; in one case a piece of bone, introduced at the age of three, was not ejected until sixty years had elapsed. Tulpus relates a case in which a nut-shell was coughed up after being lodged for seven years; and Heister one in which a ducat was thus brought up after a lapse of two years and a half; the patients, in both instances, recovering. In other cases death may ensue, although the foreign body is coughed up; thus Sue relates an instance in which a pigeon-bone was spat up seventeen years after its introduction, the patient, however, dying in little more than a year from marasmus. In eight of the cases collected by Gross, death followed the spontaneous expulsion.

Treatment.—This accident is always very serious, and hence requires the use of prompt and energetic means in order to save the patient; and fortunately the means at our disposal, consisting of the simple operation of opening the trachea and thus facilitating the expulsion of a foreign body, are usually highly successful. Of 60 cases in which the result was noted, I found that 37 lived, and 23 died; but on analysing these cases more closely, it appeared that in 39 no operation was performed, the expulsion of the foreign body being effected by the efforts of nature. Of these 23 died, and 16 lived. In the remaining 21 cases, tabulated below, tracheotomy was performed; of these 18 lived, and only 3 died, showing a remarkable success attendant on this operation.

PERIOD OF RETENTION.	NUMBER OF CASES.	CURED.	DIED.
Less than 24 hours	3	2	1
Between 24 and 48 hours	2	2	0
Between 48 hours and 1 week	9	8	1
Between 1 week and 1 month	5	4	1
Between 1 month and 3 months	2	2	0
Total	21	18	3

The statistics as to the result of operations for the removal of foreign bodies from the air-passages have been worked out chiefly by Gross, Durham, and West (U. S. A.). Gross has collected the particulars of 85 cases not operated on. Of these 56 recovered and 29 died, the deaths amounting to 34·11 per cent. Tracheotomy was done in 98 cases: of these 83 recovered and 15, or 15·30 per cent., died. Durham collected 271 cases not operated on. Of these 156 recovered and 115, or 42·2 per cent., died; whilst of 283 cases operated on, 213 recovered and 70, or 24·2 per cent., died. West (U. S. A.) has collected 1000 cases. Of these, in 63 cases the foreign body was removed by forceps, with or without the aid of the laryngoscope. Of the remaining 937 cases, 599 were not operated on. Of these 460 recovered and 139, or 29·70 per cent., died. In 398 cases the air-passages were opened. Of these 245 recovered and 93, or 23·42 per cent., died.

Taking the combined results of these three tables and comparing them in reference to the particular operation performed, we find that the results are as follows: of laryngotomy there were 70 cases, in all of which probably the foreign body was impacted in the glottis, with 56 recoveries and 14, or 20 per cent., of deaths; laryngo-tracheotomy, 59 cases, with 44 recoveries and 15, or 25·42 per cent., deaths; tracheotomy was performed in 605 cases, with 449 recoveries and 156, or 25·78 per cent., deaths.

The Surgeon may be hurriedly summoned to a patient, probably a child, who has "swallowed" a foreign body and is *in extremis* from asphyxia. Under these circumstances he should pass his finger to the back of the throat, where the foreign body may be felt and possibly extracted by using the index fingers of the two hands. Failing this, *laryngotomy* should at once be performed. Every moment is of consequence, and the Surgeon who is probably single-handed, and possibly provided with no instruments beyond a penknife, is little prepared for the far more troublesome operation of tracheotomy.

In the treatment of less urgent cases, emetics, sternutatories, and succussion of the body, are all either useless or dangerous. Inversion of the body has succeeded in several instances, and might be tried before operation is had recourse to, more particularly if the foreign body is heavy, as a coin, and is movable in the air-passages. Padley caused the ejection of a sixpenny-piece in this way from the trachea of a man, and he recommends the supine as a safer and better position than the prone. There is undoubtedly danger, in inversion, of the supervention of laryngeal spasm, but statistics do not prove that any fatal consequences have resulted from this cause. Should, however, the attempt at expulsion by inversion of the body bring on an attack of laryngeal spasm, it should be abandoned, as not only useless but in the highest degree dangerous.

When the foreign body is lodged in the larynx, it can be detected by laryngo-

scopic examination, and may be removed with forceps or by such other means as the ingenuity of the Surgeon may suggest. This may sometimes be done a considerable length of time after its impaction. Thus in a case recorded by Petrie of Liverpool, a coin was successfully removed with forceps after having been impacted six years in the larynx of a boy.

Should it, however, not be possible to extract the foreign body through the mouth, tracheotomy must be performed, and an attempt made to dislodge it from below by means of a feather passed up into the mouth, or it may possibly be seized and brought out by the wound. Should this fail, the operation of **Thyro-chondrotomy**, more often, but incorrectly, called **Thyrotomy**, should be performed. The operation is the same as that for intralaryngeal tumours, and will be described in the Chapter on Diseases of the Throat. It is of importance that it should not be delayed, for the foreign body, more especially if rough or irregular, as a piece of bone, will shortly excite inflammation and ulceration of the mucous membrane and possibly entail permanent impairment of voice or of respiration.

When the foreign body has passed beyond the larynx, or is not to be recognised by means of the laryngoscope, inversion may perhaps be tried in some cases, but, as a rule, tracheotomy ought to be performed at once. Tracheotomy is in all cases preferable to laryngotomy, as the opening can be made more freely and left open more easily, and moreover, being further removed from the glottis there is no possibility of both openings being blocked by the foreign body if it be coughed up. The operation should be performed even though the symptoms be not urgent. There is often a remission in the symptoms, a period of deceptive security, by which the Surgeon must not be put off his guard. But, it may be asked, for what purpose is the trachea opened? Why should not the foreign body be expelled through the same aperture by which it has entered? The opening in the trachea serves a double purpose: it not only affords a ready and passive outlet for the expulsion of the foreign body, but serves as a second breathing aperture in the event of its escaping through the glottis. The advantage of the opening in the trachea as a ready aperture of expulsion is evident from the statistics given by Durham of 212 cases in which tracheotomy was performed for a foreign body in the air-passages. One hundred and fifty-seven recovered: in 64 of these spontaneous expulsion took place through the tracheal opening: in 35 spontaneous expulsion occurred from the mouth, and in 58 the foreign body was removed with forceps or other instruments. Fifty-five died: in 48 of these the body was retained till death, in 2 it was expelled from the mouth, and in 2 from the wound immediately after the operation, and in 3 it was removed with forceps.

The reason why the foreign body usually passes out of the artificial opening instead of escaping by the glottis, is, that the sides of the former aperture are passive, whereas those of the latter are highly sensitive and contractile. Before the operation is performed, it will be found that the great obstacle to expulsion is the spasmodic contraction of the glottis, by the closure of which not only is the passage of the foreign body prevented, but respiration is impeded. Every time the foreign body is coughed up so as to touch the interior of the larynx, intense dyspnoea is produced, owing to sudden and involuntary closure of the glottis, by which respiration is entirely prevented and suffocation threatened; the expulsion of the body is consequently

arrested, unless it by chance take the glottis by surprise, and pass through it at once in the same way that it has entered it, without touching its sides. If it be arrested by the spasm in the glottis it is inevitably drawn down into the trachea again by the deep inspiration that follows the relaxation of the spasm. If there be a second breathing aperture, though the larynx is equally irritated by the foreign body, yet this dyspnoea cannot occur, respiration being carried on uninterruptedly by one opening whilst the foreign body escapes through the other; and thus, in these circumstances, it may pass through the glottis with but little inconvenience. In performing tracheotomy for a foreign body in the air passages, the opening must be made freely: no tube must be introduced, but the edges of the wound must be kept open by blunt hooks, made of bent wire, and secured behind the neck by a piece of tape.

In some cases, the foreign body is expelled at once after the trachea has been opened; in others, not until some hours, days, or even weeks, have elapsed. Thus, in Houston's case, a piece of stick was not coughed up until ninety-seven days after the operation; and in Brodie's case, in which the celebrated engineer, Brunel, was the patient, sixteen days elapsed before the half-sovereign came away.

The expulsion has in some instances been facilitated by inverting the patient, shaking him, or striking him on the back. In cases in which the foreign body has not readily been expelled, forceps and other instruments have been introduced through the wound to extract it. But, although in many instances this has succeeded, these proceedings should not be lightly undertaken. It is better always to wait some time, as in a large number of successful cases expulsion has not taken place spontaneously till more than twenty-four hours after the operation. If the body does not come up spontaneously by the end of the second day, the Surgeon is not justified in further delay, as the mischief set up in the lung may soon become irreparable. The patient must be put fully under an anæsthetic, and even then the introduction of the instrument will cause a violent spasmodic cough. If the nature of the foreign body be known, the instrument must be adapted to it. If it be of metal, glass, or china, its position can first be detected by means of a probe. If it be of the form most easily to be seized with forceps, Gross's tracheal forceps, or Durham's flexible forceps may be used. It is difficult, however, in using forceps to avoid passing the blades down two separate bronchial tubes and thus seizing the septum between them. A loop of stiff wire, bent at its extremity to an angle so that it can be directed into either bronchus, will be found very useful in dislodging a round body impacted in a bronchus. In this way a plum-stone was easily dislodged and removed in a case which occurred in University College Hospital some years ago, and the child rapidly recovered. During these operations the opening in the trachea may be kept open, as suggested by Thomas Smith, by temporarily suturing together the edges of the tracheal and skin incisions. Should the attempt fail, the wound should be kept open by means of blunt hooks for a week or ten days longer, when perhaps the foreign body may be ejected. After its escape, the opening in the trachea must be allowed to close.

SCALDS OF THE MOUTH, THE PHARYNX, AND THE GLOTTIS, occasionally occur from attempts to swallow boiling water; or these parts are scorched by the inhalation of hot air or flame. The scalding happens chiefly to the

children of the poor, who, being in the habit of drinking cold water from the spout of a kettle, inadvertently attempt to take a draught from the same source when the water is boiling. The hot liquor is not swallowed, but, though immediately ejected, it scalds the inside of the mouth and pharynx, giving rise to great inflammation, which, extending to the glottis, will produce oedema of it, and thus speedily destroy life by suffocation. In three cases which I examined after death, there was no sign of inflammation below the glottis, though the lips of this aperture were greatly swollen: and this I believe to be invariably the case. The accident always reveals itself by very evident signs: the interior of the mouth looks white and scalded, the child complains of great pain, and difficulty of breathing soon sets in, expiration being comparatively easy, while inspiration is obstructed by the swollen aryteno-epiglottidean folds falling together over the glottis in a valve-like manner. This condition, unless efficiently relieved, may terminate in speedy suffocation. In those cases in which these parts have been similarly injured by the flame produced by the explosion of gas or of fire-damp being sucked into the mouth, the same conditions present themselves.

In the **Treatment** of this injury, the main point to attend to is to subside the inflammation before it involves the glottis to a dangerous extent. With this view, leeches should be freely applied to the neck, and hot fomentations put on. If symptoms of dyspnoea have set in, the cedematous parts should be freely scarified with a curved bistoury, sheathed by wrapping adhesive plaster round it nearly to its point. If this be not at hand, much may be done by means of the finger nail, notched so that it may tear the mucous membrane. The child should be placed in a tent-bed, and the steam-spray used. Should these measures fail to give relief, intubation or tracheotomy must be performed without delay. Intubation is likely to be attended with some difficulty, owing to the swollen condition of the part, so that the Surgeon who is not skilled in this procedure had better resort at once to tracheotomy. A tube must be inserted and retained until the swelling about the glottis has subsided. In the majority of the cases, however, that have fallen under my observation, in which this operation has been performed, the issue has been a fatal one, from the speedy supervention of broncho-pneumonia. Bernard Pitts has collected seventy-eight cases of this injury, treated in St. Thomas's Hospital. Of these sixty-three recovered—seven after tracheotomy, one after intubation followed by tracheotomy, and three after intubation alone. In twelve of the fifteen fatal cases tracheotomy was performed, the operation having been preceded by intubation in three.

ASPHYXIA.

ASPHYXIA may arise from various causes. The following classification is derived from a table by Harley:—

I. **Mechanical Impediment to the Entrance of Air into the Lungs.**

A. From **Accident**: either (1) *external*, as in pressure on the trunk preventing expansion of the chest; pressure on the throat; smothering; injury of the spinal cord causing paralysis of the respiratory muscles; penetrating wound of the chest, admitting air; or (2) *internal*, as in obstruction of the fauces or larynx by foreign bodies, or in constriction of these parts from the application of irritating fluids. B. From **Disease**: as in pressure on the

trachea by an aneurism or other tumour ; oedema of the glottis ; obstruction of the air-passage by tumour ; accumulated mucus, &c.

2. **Drowning.**

3. **Absence of Oxygen**,—nitrogen, hydrogen, or some other harmless gas being inhaled.

4. **Accumulation of Carbonic Acid Gas in the Blood.**

5. **Inhalation of Toxic Gas or Vapour.**

Several of the conditions above enumerated as producing asphyxia have been described in the preceding pages ; and others will be considered when we speak of diseases of, and operations on, the Air-passage. In this place we will speak of the Surgical management of cases in which respiration has been suspended by Drowning, Hanging, and the respiration of Noxious Gases.

The general subject of Suspended Animation from these various causes cannot be discussed here, but we must briefly consider some points of practical importance in its treatment.

In cases of **Drowning**, life can often be restored, although the sufferer may have been in the water for a considerable time ; for, though *immersed*, he may very probably not have been *submersed* during the whole time. The period after which life ceases to be recoverable cannot be very accurately estimated. The officers of the Royal Humane Society, who have great experience, state that generally persons are not recoverable who have been more than four or five minutes under water. In these cases, however, although submersion may not continue for a longer period than this, the process of asphyxia does ; for it does not cease on the withdrawal of the body from the water, but continues until the blood in the pulmonary vessels is aerated, either by the spontaneous or artificial inflation of the lungs. As several minutes are commonly consumed in withdrawing the body from the water and conveying it to land, during which time no means can be taken to introduce air into the lungs, we must regard the asphyxia as continuing during the whole of the period that intervenes between the last inspiration before complete submersion, and the first inspiration, whether artificial or spontaneous, after the removal of the body from the water. The latest time at which life can be recalled, during this period, is the measure of the duration of life in asphyxia. If, during this period, the action of the heart should cease entirely, I believe that the circulation can never be restored. But although we may put out of consideration those marvellous cases of restoration of life that are recorded by the older writers, and which are evidently unworthy of belief, are we to reject, as apocryphal, cases such as that related by Smethurst, in which recovery took place after ten minutes' submersion ; that by Douglas of Havre, in which the patient was not only submersed, but had actually sunk into, and was fixed in the mud at the bottom of the harbour for from twelve to fourteen minutes ; or that by Weeks, in which the submersion, on the testimony of the most credible witnesses, exceeded half an hour ? I think that it would be unphilosophical in the extreme to deny the facts clearly stated by these observers ; the more so that in these, as in many other instances of apparent death from drowning, life appears to have been prolonged by the patient falling into a state of syncope at the moment of immersion. We must therefore not despair of recovery, but should employ means of resuscitation, even though the body had been actually under water a considerable time.

There are certain minor means often employed in the case of persons who

have been immersed in water, and are apparently drowned, which appear to be well adapted for the treatment of the less severe forms of asphyxia, or rather cases of syncope from fright and immersion in cold water. These consist, after the nose and mouth have been cleared of mucus, in the application of heat by means of a bath at about the temperature of 100° Fahr. until the natural warmth is restored; in the employment of brisk friction; and in passing ammonia to and fro under the nostrils. It is evident that these measures can have no direct influence upon the heart and lungs, but can only act as general stimuli to the system, equalizing the circulation if it be still going on; and, by determining the flow of blood to the surface, tending to remove those congestions that are the consequences not so much of the asphyxia as of the sojourn of the body for several minutes in cold water; they would therefore be of especial service during the colder seasons of the year. A hot bath may also, by the shock it gives, excite the reflex respiratory movements. With the view of doing this with a greater degree of certainty, cold water should be sprinkled or dashed upon the face at the time when the body is immersed in the hot bath, as in this way a most powerful exciting influence can be communicated to the respiratory muscles, and the first object of treatment in all cases of asphyxia—the re-establishment of respiration—would more rapidly and effectually be accomplished; deep gaspings ensuing, by which the air would be sucked into the remote ramifications of the air-cells, aerating the blood that had accumulated in the pulmonary vessels, and enabling it to find its way to the left cavities of the heart, and thus to excite that organ to increased activity. These means, then, are useful in those cases of asphyxia in which the sufferer has been but a short time submersed, and in which the heart is still acting and the respiratory movements have either begun of their own accord on the patient being removed from the water, or in which they are capable of being excited by the shock of a hot bath, aided by the dashing of cold water on the face. At the same time the lungs may be filled with pure air, by compressing the chest and abdomen, so as to expel the vitiated air, and then allowing them to recover their usual dimensions by the natural resiliency of their parietes. A small quantity of air will, in this way, be sucked in each time the chest is allowed to expand, and thus the re-establishment of the natural process of respiration may be greatly hastened. This simple mode of restoring the vital actions should never be omitted, as it is not attended with the least danger, and does not in any way interfere with the other measures employed. Marshall Hall has recommended that the patient be turned prone, so that the tongue may hang forwards, and the larynx thus be opened; and that respiration be then set up by gentle pressure along the back, and by turning the patient on his side at regular intervals. This position is very valuable in draining away the water from the bronchial tubes, which is very necessary in cases of drowning before any attempt is made to introduce air into the lungs. If, by these means, we succeed in rapidly restoring the proper action of the respiratory movements, it will be necessary merely to pay attention to the after-treatment. Should we, however, fail in restoring respiration, we should have recourse to other and more active measures.

In the more severe cases of asphyxia, the most direct and efficient means that we possess for the re-establishment of the circulation is **Artificial Respiration**, which should be resorted to without delay. The whole value of artificial respiration, however, depends upon the way in which it is

employed. Inflation from the mouth of an assistant into the nostrils or mouth of the sufferer is not very effectual, as air once respired is not well fitted for the rekindling of the few sparks of life that may be left, but it is in many instances the readiest and indeed the only mode by which respiration can be set up, especially if water or other fluids have found their way into the mouth.

The bellows, if properly constructed for artificial inflation, so that the quantity of air injected may be measured, are no doubt very useful; and if furnished with Leroy's trachea-pipes, or, what is better, with nostril tubes, may safely be employed. About fifteen cubic inches of air may be introduced at each stroke of the bellows, and these should be worked ten or a dozen times in a minute. The lungs should be emptied by compression of the chest before beginning to inflate, and, after each inflation, by compressing the chest and abdomen; but care must also be taken not to employ much force, lest the air-cells be ruptured. Richardson has devised a pocket-bellows for artificial respiration, consisting of two elastic hand-bellows with a single tube for

Fig. 320. —Sylvester's Method—Inspiration.

introduction into the nostril. A very efficient mode of introducing pure air into the lungs, especially in children and young persons, is, by the elastic expansion of the walls of the chest. This may be effected by alternately compressing the chest and abdomen with the hand, and then removing the pressure so as to enable the thorax to expand by the natural resiliency of its parietes, and thus, each time it expands, to allow a certain quantity of air to be sucked into the bronchi. A much more efficient method, however, is that recommended by Sylvester, and adopted by the Royal Humane Society. It is carried out in the following way. The patient is laid on a flat surface on his back, with the head and shoulders slightly raised on a pillow. The tongue should be drawn out and held forwards. The arms are then to be grasped just above the elbows, and to be drawn gently and steadily upwards above the head and pulled upon slightly, so as to drag on the great pectoral muscles (Fig. 320). In this position they are kept for two seconds; they are then to be brought downwards, and to be pressed for two seconds firmly against the sides of the

chest (Fig. 321); at the same time an assistant may compress the lower ribs and push up the liver and diaphragm. These movements are to be repeated deliberately about fifteen times in the minute, until natural efforts at respiration are induced, when they are to be discontinued and the ordinary means to promote circulation and warmth employed. The quantity of air introduced need not be large; for, by the law of the diffusion of gases, if oxygen be introduced only into the larger divisions of the bronchi, it will rapidly find its way into the ultimate ramifications of these tubes. This last means of inflation has the additional advantage of closely resembling the natural process of respiration, which is one of expansion from without inwards, and not, as when the mouth or bellows are used, of pressure from within outwards. In the one case the lungs are, as it were, drawn outwards, the air merely rushing in to fill up the vacuum that would otherwise be produced within the thorax, by the expansion of its parietes; in the other they are forcibly pressed up from within, and hence there is a danger of rupture of the air-cells. Care must be taken not to use too much violence in compressing the chest. I have

Fig. 321. Silvester's Method - Expiration.

known a case in which the sternum and several ribs were broken in an old man during the employment of this method. Laborde has recently recommended rhythmic tractions of the tongue at the rate of fifteen to twenty times a minute, as an efficient means of exciting respiratory movements. It is by no means certain, however, that the method acts in any other way than in removing the blockage of the pharynx by the tongue, which falls back in the supine position. In case a battery be at hand, faradization of the phrenic nerve forms a valuable adjunct to the method of artificial respiration. It is thus carried out. It must first be ascertained that the current is of sufficient strength to cause vigorous contraction of the muscles of the ball of the Surgeon's thumb. The person in charge of the battery should stand on the right side of the patient and press one rheophore well down on the phrenic nerve at the outer border of the sterno-mastoid, where the nerve lies on the scalenus anticus, and, while the person in charge of the Silvester method of artificial respiration raises the arms he should press the other rheophore on

the right side of the thorax in the sixth intercostal space : when the arms are depressed he should remove the rheophore. If it is successfully carried out, a distinct rush of air will be heard to enter the mouth as the rheophore is applied to the side.

Inflation of the Lungs with Oxygen Gas is likely to be of great service in extreme cases of asphyxia. I have found by experiment that the contractions of the heart can be excited by inflating the lungs with this gas when the introduction of atmospheric air fails to do so ; and there are cases on record in which resuscitation was effected by inflating the lungs with oxygen, when in all probability it could not have been accomplished by any other means. In my Essay on "Asphyxia" will be found a case of resuscitation, in which oxygen was successfully administered by Weeks after the asphyxia had continued three-quarters of an hour.

Whatever means of resuscitation are adopted, they should be continued for at least three or four hours, even though no signs of life show themselves; and after ordinary respiration has been re-established, the patient should be kept quiet in bed some hours. The danger of the supervention of **Secondary Asphyxia** after recovery has apparently taken place is much increased, and indeed is usually brought about, by some effort on the part of the patient that tends to embarrass the partially restored action of the heart and lungs. The patient, being to all appearance resuscitated, is allowed to get up and walk home, when the symptoms of asphyxia speedily return. Should symptoms of secondary asphyxia, such as stupor, laborious respiration, dilatation of the pupils, and convulsions, manifest themselves, artificial respiration should immediately be set up, and maintained until the action of the heart has been fully restored.

Asphyxia from the **Respiration of Noxious Gases**, such as carbonic acid, is best treated by exposing the surface of the body to cold air, by dashing cold water on the face, and by setting up artificial respiration without delay, if the impression of cold upon the surface do not excite these actions. There is a peculiar variety of this kind of asphyxia, which is occasionally met with among infants, the true nature of which was pointed out to me by Wakley, who, as coroner, had abundant opportunities of witnessing it, as it is not an uncommon cause of accidental death amongst the children of the poor. It is that condition in which a child is said to have been *overlain* ; the child, sleeping with its mother or nurse, being found in the morning suffocated in the bed. On examination no marks of pressure will be found ; but the right cavities of the heart and the lungs are gorged with blood, and the surface is livid, clearly indicating death by Asphyxia. That this accident is not the result of the mother lying upon her child, is not only evident from the *post mortem* appearances, but was clearly proved by a melancholy case to which I was called several years ago, in which a mother, on waking in the morning, found her twin infants lying dead, one on each side of her. Here it was evident, from the position of the bodies, that she could not have overlain both. The true cause of death is partly the inhalation of, and slow suffocation by, the vitiated air which accumulates under the bed-clothes that have been drawn, for the sake of warmth, over the child's head, and partly the diminished supply of oxygen. In such cases, resuscitation by artificial respiration should always be attempted if any signs of life remain.

Asphyxia from the respiration of **carbonic oxide** is more frequent than

Surgeons are apt to imagine. As has already been stated in the chapter on Burns, death often takes place, in cases where buildings are on fire, from poisoning by the respiration of carbonic oxide. According to Leblanc, it is this gas that is the poisonous agent given off in the fumes of charcoal. The effect of the respiration of carbonic oxide gas is to deprive the red corpuscles of their power to carry oxygen, and death takes place rather from the want of oxygen than from the poisonous action of carbonic oxide itself.

The inhalation of oxygen is of service in such cases; but it must be borne in mind that death is generally very rapid.

In cases of **Hanging**, death seldom results from pure asphyxia, but is usually the consequence, to a certain degree at least, of apoplexy, and possibly of simultaneous injury of the spinal cord. In these cases, bleeding from the jugular vein may be combined with artificial respiration.

If there should be a difficulty in setting up artificial respiration through the mouth or nose, as is more especially likely to happen when the patient has been suffocated by breathing noxious gases, or in cases of hanging, tracheotomy or laryngotomy should at once be performed, and the lungs inflated through the opening thus made in the neck.

INJURIES OF THE PHARYNX AND OESOPHAGUS.

WOUNDS OF THE OESOPHAGUS are met with chiefly in cases of cut-throat, in which, as already stated, they occasion much difficulty by interfering with deglutition.

RUPTURE OF THE OESOPHAGUS during vomiting is a very rare accident, of which a few cases have been recorded. The patient has in almost every case been an habitual drunkard, and the accident has occurred after a debauch or over-eating. The rupture always occurs near the cardiac orifice, and may extend into the stomach. In a case recorded by Adams the contents of the stomach passed into the left pleura. The symptoms are sudden severe pain, and a sense of impending death and collapse. Emphysema of the mediastinum extending into the root of the neck has been observed. Death has in most cases followed in less than twenty-four hours; but Meyer has recorded a case in which the patient survived fifty hours, and Pitz one in which death did not occur till the eighth day.

FOREIGN BODIES not uncommonly become impacted in the pharynx and oesophagus, and may produce great inconvenience by their size or shape. If large, as a lump of meat, the substance may lodge in the lower part of the pharynx and occlude the orifice of the glottis, thus at once suffocating the patient. If of smaller size, as a gold plate with false teeth or a coin, it may lodge at the lower end of the pharynx where it is narrowed by the projection of the larynx backwards. Any flat body, such as a coin, if it lodge in this situation, will almost invariably lie with its surfaces looking backwards and forwards. If the foreign body be arrested beyond this point, it will usually be near the termination of the oesophagus. When it is small or pointed, as a fish-bone, pin, or bristle, it may become entangled in the folds of mucous membrane that stretch from the root of the tongue to the epiglottis, or that lie along the sides of the pharynx. In some cases it may even perforate these, penetrating the substance of the larynx, and thus producing intense local irritation, cough, dyspnoea, and suffocation. The foreign body, by transfixing

the coats of the œsophagus, may seriously injure neighbouring parts of importance. Thus, in a case admitted into University College Hospital, a juggler, in attempting to push a blunted sword down his throat, perforated the œsophagus and wounded the pericardium; death resulted in a few days.

The **Symptoms** occasioned by the impaction of a foreign body in the food-passages are sufficiently evident. The sensations of the patient, who usually complains of uneasiness about the top of the sternum, difficulty in swallowing solids, and perhaps an urgent sense of suffocation, lead to the detection of the accident. Should any doubt exist, the Surgeon may, by introducing his finger, explore nearly the whole of the pharynx, and may examine the œsophagus by the cautious introduction of a well-oiled probang.

If the impaction be allowed to continue unrelieved, not only may deglutition and respiration be seriously interfered with, but ulceration of the œsophagus will take place, and an abscess form either behind it or between it and the trachea; or fatal hæmorrhage may ensue by perforation or ulceration of neighbouring blood-vessels.

The **Treatment** must depend upon the nature of the foreign body and its situation. Should it be large, blocking up the pharynx so as to render respiration impracticable, it may be hooked out by the Surgeon's fingers. Should asphyxia have been induced, it may be necessary to perform laryngotomy at once, and to keep up artificial respiration until breathing is fully re-established, when the foreign body can be removed. If it be small or pointed, as a fish-bone or pin, though it have lodged high up, the Surgeon will usually experience great difficulty in its removal, as it becomes entangled between, and is covered in by, the folds of the mucous membrane, where from its small size it may escape detection. In these cases an expanding probang will be found useful. Emetics have been recommended and have been used with success; but it would not be safe to employ them if the foreign body was of any size or firmly impacted, lest the œsophagus should be ruptured during the act of vomiting. After the foreign body has been removed, the patient will for some time experience a pricking sensation, as if it were still fixed. If the impacted body have passed low down into the œsophagus, the Surgeon must deal with it according to its nature. A coin can usually be caught by the instrument known as a "coin-catcher," and removed without difficulty. If the body be smooth and soft, as a piece of meat for instance, it may be pushed down into the stomach by the gentle pressure of the probang. If, however, it be rough, hard, or sharp-pointed, as a piece of earthenware or bone, or a metallic plate with false teeth attached, such a procedure would certainly cause perforation of the œsophagus, and serious mischief to the parts around: in these circumstances, therefore, an attempt at extraction should be made by means of long slightly-curved forceps, constructed for the purpose.

The foreign body occasionally becomes so firmly impacted in the pharynx or œsophagus, that the employment of any force for the purpose of extracting it would be attended with danger of perforating the œsophagus or transfixing the large vessels of the neck; in these circumstances it may become necessary to open the tube and thus remove it. The operation of **Pharyngotomy** or **Œsophagotomy** is seldom called for; if required, it may be performed by making an incision about four inches in length along the anterior border of the left sterno-mastoid muscle, the œsophagus naturally curving somewhat towards

the left side. The dissection must then be carried with great caution between the carotid sheath and the larynx and trachea in a direction backwards, the omohyoid muscle having been divided in order to afford room. Care must be taken in this deep dissection not to wound either of the thyroid arteries, more especially the inferior, which will be endangered by carrying the incisions too low. When the pharynx or the œsophagus has been reached, the foreign body may be felt and directly cut down upon. If it cannot be felt a sound should be passed through the mouth, and pushed forwards so that its point may cause the walls of the œsophagus to project, and thus serve as a guide to the Surgeon. This must then be cut upon, and the aperture thus made in the gullet enlarged, by means of a probe-pointed bistoury, to a sufficient size to allow the removal of the extraneous substance. The opening in the œsophagus should then be closed by catgut sutures, not including the mucous membrane, and the external wound should be left freely open to heal by granulation in case the œsophageal incision should fail to unite. The same operation is occasionally performed for stricture of the œsophagus high up, and then a tube is introduced and the wound allowed to close round it. The operation has been attended with considerable success. Agnew gives a table of 36 cases, 27 of which recovered; 31 of these were for the removal of foreign bodies, and of these only four died. When the foreign body is impacted near the cardiac orifice and can neither be pushed down nor drawn up, Richardson, of the Massachusetts Hospital, has shown that it can be removed from below through an opening in the stomach. This operation he successfully performed on a man aged 37, who had accidentally swallowed a plate containing four false teeth eleven months before. It was impacted about two inches above the diaphragm, and was dislodged and removed after considerable manipulation with the index and middle fingers of the right hand, the whole of which was introduced into the stomach. The wound was closed with Lambert's suture, and the patient rapidly recovered. There was some difficulty in finding the cardiac orifice, but experiments on the dead body showed that this may be overcome by putting the small curvature on the stretch, so that it makes a straight line to the œsophageal opening. By doing this forceps can be passed with certainty into the orifice without introducing the hand. The stomach is best exposed by an incision parallel to the left costal margin.

Jacobson has performed a similar operation, but was unable to dislodge a tooth-plate which was impacted $1\frac{1}{2}$ inch above the cardiac orifice; whilst Ball, of New York, extracted a peach-stone which was fixed in a similar position by passing a bougie, with a sponge attached, along the œsophagus from the opening in the stomach and withdrawing it through the mouth.

A hard and perfectly indigestible foreign body may pass through the œsophagus into the stomach. Should it be small, as a coin, or even angular and sharp-pointed, as a plate with artificial teeth, it will, in the great majority of cases, pass safely through the intestines, and may, therefore, be left alone. When it is thus left, the patient should take neither purgatives nor opiates. Both are injurious: the purgatives by increasing the irritation of the bowels and the chance of their being wounded by sharp and projecting points from the plate; the opiates by arresting its progress. The better plan is to keep the patient in bed, perfectly quiet, and to give him an abundance of pulsatious food. By adopting this plan I have succeeded in getting a gold plate, with three molar teeth and a sharp curved

clasping hook at each end, to pass without the slightest difficulty or pain four days after it was swallowed by a gentleman about 25 years of age. No attempt need ever be made to extract small coins from the stomach, as they will always easily pass through the intestinal canal. If the foreign body lodges in the stomach, producing irritation with continued efforts at vomiting, an attempt may be made to remove it through the gullet, but the chances of success are very small. If the attempt be made, an ivory-balled probang should first be passed in to ascertain the situation of the foreign body. After this has been heard and felt, we may try the plan successfully employed by Little—who removed a hooked plate containing five artificial teeth from the stomach of a woman—of introducing a “coin-catcher” so as to search for, secure, and then extract it. In doing this, there is of course a great probability that the mass will be drawn up sideways; and that it may, if broad, hitch in the pharynx, whence it must be detached as well as the Surgeon can manage by a judicious combination of force and skill.

If the body be of such a nature that it is impossible to remove it through the œsophagus, and it is equally unlikely that it can pass safely through the intestines, the operation of **Gastrotomy** must be performed. This is seldom required except in the case of the swallowing of a fork or knife, or some such instrument, either intentionally by a lunatic, or accidentally during drunkenness, or while performing a trick. The foreign body when of this size can usually be felt without difficulty through the abdominal wall. The operation of gastrotomy for the removal of foreign bodies has been singularly successful. Durham states that of ten recorded cases only one died, and in that one œsophagotomy had previously been performed. The operation will be described in the chapter on stricture of the œsophagus.

CHAPTER XXVIII.

INJURIES OF THE CHEST.

WOUNDS OF THE CHEST-WALLS are not of such frequent occurrence now as in the days of duelling. The soft tissues may, however, be contused, torn, or cut. The thoracic muscles, especially the pectorals, are sometimes ruptured by force applied to the arms when abducted or raised above the head. The great pectoral muscle has been torn in a boy who attempted to drop from hand to hand three rungs of a ladder at a time. Extravasation of blood, and even inflammation and suppuration, may result from such injury. Subpectoral abscess may occur from injury of the pectoral muscles, or of the areolar tissue beneath them, or it may form without any apparent cause. The pus must be evacuated early. This may be done by making an incision through the skin and then tearing through the fibres of the muscles, after the manner recommended by Hilton for the emptying of submuscular or deep-seated abscesses.

Wounds of the chest derive their principal interest and importance from the accompanying injury of the lungs, heart, or larger blood-vessels. When the soft parietes alone are wounded, the injury differs in nothing from similar lesions in other parts of the body ; except that it is usually slower in healing, in consequence of the want of rest caused by the movements of respiration. This is especially the case when the muscular parietes are furrowed by bullets. If the Surgeon be in doubt whether the cavity of the chest have been penetrated or not, he may endeavour to ascertain this point by careful examination with the finger, but he should never introduce a probe ; it is better for him to wait and to be guided in his opinion by the symptoms that manifest themselves, rather than, by probing the wound, to run the risk of converting it into what he dreads—a penetrating wound of the chest.

FRACTURES OF THE BONES OF THE CHEST.

FRACTURE OF THE RIBS AND COSTAL CARTILAGES.—These injuries may occur in two ways : 1st, from direct violence, the part that is struck being driven in towards the thoracic cavity, and thus broken ; 2nd, from indirect violence, the fore part of the chest being forcibly compressed, so that the rib is bent outward, and snaps. When the injury is the result of direct violence, and the broken fragments are forced in, the pleura, lung, liver, or diaphragm, may be wounded, thus giving rise to the most serious and fatal consequences, such as hæmorrhage, emphysema, and inflammation of the parts injured. When it is occasioned by indirect violence, as the fracture takes place in an outward direction, the thoracic organs may be contused, but they are not likely to be punctured by the fragments. In some rare cases, the ribs have been known to be broken by the violent contraction of the abdominal muscles during labour.

Fracture of the ribs may be *single*; *multiple* when several, or even all the ribs on one side, or several on both sides, are fractured; *simple*, as in ordinary violence; and *compound*, as in gunshot injuries.

Any one of the ribs may be broken, and frequently several are fractured at the same time. The middle ribs, from the fourth to the eighth, are those that oftenest give way, being most exposed, and at the same time fixed. The first and second ribs are seldom broken, being protected by the clavicle and shoulder. When they are fractured it is usually the result of gunshot violence, or, if from some of the ordinary accidents of civil life, the clavicle will be broken as well. But this is not an invariable complication. I have seen fractures of the first two ribs from a fall, without any injury to neighbouring bones. This fracture is always very dangerous, on account of the liability to injury of important subjacent structures. The lower ribs, being less firmly fixed than the others, commonly escape, unless very great and direct violence be inflicted upon them. Any part of a rib may be broken by direct violence; but when the fracture is the result of compression of the chest, it is usually the point of greatest convexity or the neighbourhood of the angle of the rib that gives way. These indirect fractures commonly occur in elderly people, in whom the elasticity of the thoracic parietes has lessened as the result of age, and they are peculiarly liable to occur in some cases of general paralysis of the insane, in which the bones are weakened by atrophy.

Symptoms.—The chief symptom is a sharp pricking and catching pain at the seat of injury, increased by breathing deeply, or by coughing. In order to avoid this, the inspirations are shallow, and the breathing is principally diaphragmatic. On placing one hand on the sternum, and the other on the spine, and pressing gently, the patient will complain of pain at the seat of fracture. This is often a valuable means of diagnosis. On laying the hand over the seat of injury, and desiring the patient to cough, crepitus may often be felt; and in most cases this is audible on applying the ear to the chest. The diagnosis of the fracture is necessarily more easily made where the ribs are thinly covered, than where they lie under the muscles of the back. Occasionally the outline of the rib will be found to be irregular; and in some instances, where several ribs are broken, the whole side of the chest is flattened and depressed. Besides these local symptoms, special complications resulting from laceration of the pleura and lung, such as hæmoptysis, pneumothorax, or emphysema, may occur. These complications are much less frequent than might *a priori* be supposed, owing to the fracturing force being usually indirect, causing the rib to bend outwards, and thus to break away from, instead of into, the chest. The danger of fractured ribs, indeed, depends wholly on the thoracic complications, and these will be occasioned chiefly by one of two conditions: either by the forcible driving in of the fractured ends, as from the kick of a horse, so that the pleura and lung are wounded by the sharp and ragged fragments; or else by a large number of ribs being broken by a severe squeeze of the chest, and the thoracic organs injured by the general compression. It is surprising, however, what an extent of injury of this kind may take place without serious consequences. I have had under my care a young man, who, in consequence of a crush of the chest, in a railway accident, had the upper seven ribs broken on the right side, and the lower five on the left, the chest, especially on the right side, being greatly flattened; he recovered without a bad symptom. In gunshot injuries of the chest, with

splintering of the ribs, there is always wound of the contained organs, which becomes the main source of danger to the patient and the chief point to which the attention of the Surgeon has to be directed.

Treatment.—In treating fractured ribs, the Surgeon need not concern himself so much about the union of the fracture, as about the prevention of pain to the patient in breathing, and of the subsequent occurrence of serious inflammation or other mischief within the chest.

Any displacement that may exist usually remedies itself. The chest-wall, even when extensively flattened, gradually expands under the influence of the respiratory movements. If, however, a portion of the rib continue depressed, it had most certainly better be left so; the suggestions that have been made for elevating these fractures by means of sharp hooks and screw-probes being more likely than the continuance of the depression to occasion serious mischief to the contents of the thorax. In order to prevent undue motion of the broken bone and the consequent irritation produced by its puncturing the pleura or lung, the movements of the injured part of the chest must be restrained. If one or more ribs be broken on one side, this can usually be accomplished by applying strapping to the injured side only. A sufficient number of strips, two inches broad and long enough to reach two inches beyond the middle line in front and behind, may be firmly applied, overlapping each other in fully half their width. The strips should be applied from above downwards, and each should be adjusted at the end of the movement of expiration. A broad flannel roller may now be carried circularly round the chest, but not so firmly as seriously to hamper the movements of the undamaged side. When the fractures have occurred on both sides of the chest, a broad strip of plaster may sometimes with advantage be carried completely around it. In some cases, however, more particularly in those in which the fragments are driven inwards, it will be found that the constriction of the chest by bandage or plaster becomes unbearable, producing great pain and dyspnoea. In these circumstances, all constriction must be removed, and the patient allowed to breathe easily, but he must be confined to bed. If the lower ribs be broken, the diaphragm may become irritated by the projection inwards of the fractured bone; and if the plaster and bandage be applied too tightly, spasmodic action of that muscle may ensue, occasioning distressing hiccup and dyspnoea.

The **average period of union** of a fractured rib is three weeks. There is always a considerable amount of callus thrown out in the repair, on account of the constant movement that necessarily takes place between the broken ends in respiration.

In **gunshot injuries of the chest, with splintering of the ribs**, all broken spicula of bone must be carefully picked out, and the wound cleaned with an antiseptic lotion when possible. It must then be covered with carbolie gauze, iodoform, salicylic wool, or some other efficient antiseptic application. In such cases, the grave injuries usually inflicted on the intrathoracic organs will absorb the Surgeon's attention.

It occasionally happens that fracture of one or more of the **Costal Cartilages**, especially the fifth, sixth, seventh, or eighth, is produced by direct violence. They may be separated from their junction with the rib, or broken across the middle. The existence of fracture may be determined by the pain on pressure, mobility, and irregularity at the seat of injury. The same treat-

ment is required for this fracture as for a broken rib; the broken cartilage most commonly uniting by a bony callus which surrounds the fractured ends.

FRACTURE OF THE STERNUM.—The sternum is not often broken. The accident occurs usually from very severe and direct violence; and when this is applied on the fore part of the chest, the ribs or costal cartilages are more likely to suffer. The elastic support furnished to the sternum by these structures explains in a great measure the rarity of its fracture. It may also be produced by violent bending forward of the body after the spine has been broken. The bone has been known to be broken, though very rarely, by violent straining muscular efforts during parturition. Its fractures are always transverse, usually single, but sometimes multiple. I have seen it broken into three nearly equal fragments by a fall from a scaffold. The displacement of one of the fragments is sometimes considerable, the upper fragment being almost invariably behind the lower; but even if there be but little deformity, the very superficial situation of the bone will always enable the Surgeon to judge of the exact nature of the injury it has suffered, the signs of which resemble those of a fractured rib.

The **Treatment** must be conducted on the same principles as that of a broken rib, and presents nothing special. Indeed, when fracture of the sternum occurs from external violence, it is commonly associated with fracture of the ribs, near the angles; and then the chest-bandage or plaster answers equally for both injuries. Should the sternum be broken during parturition, the patient should be made to sit up in bed, with the shoulders supported and leaning slightly forwards, so as to take off the tension of the abdominal muscles. If a portion of broken sternum be depressed, it should be left undisturbed, unless it can be readily got into position by placing a firm pillow under the back and allowing the shoulders to fall backwards. If this fails, the displacement will probably give rise to no serious inconvenience, while any attempt to remove it by surgical interference might be attended with the greatest danger.

INJURIES OF THE LUNG.

CONTUSION OF THE LUNG without injury to the pleura covering it may happen from severe blows on the chest, as from falls from horseback or kicks on the side. It may be complicated with fracture of one or more ribs; but this is not necessarily a concomitant of the injury. The symptoms are as follows. After the receipt of the blow, the patient is seized with difficulty in breathing, which is apt to become paroxysmal, so as to resemble asthma. There is expectoration, at first of mucus untinged with blood. On listening at the chest, coarse crepitation, with some dulness on percussion, will be found over the injured part of the lung. After some days, the patient coughs up a small quantity of dark, coagulated, viscid fluid; and the sputa may be tinged for some time afterwards. The dyspnoea and cough are greatly relieved, and recovery gradually takes place.

It is probable that in these cases the lung is ecchymosed at the time of the injury, and that the blood extravasated in its tissue gradually breaks down, being then discharged by coughing in the viscous, semi-coagulated state above described—very different from the florid frothy sputum of a recent lung wound.

RUPTURE OF THE LUNG, that is to say, a contused wound with laceration of the visceral pleura, has occasionally been observed as the result of violent compression in some cases without fracture of the ribs. Thus, a young woman was brought into University College Hospital a few years ago, who had thrown herself from a first-floor window, and had fallen with her chest against an iron bar. She died soon after admission, and it was found that death had resulted from hæmorrhage from a laceration of the root of the right lung. The chest walls were extremely elastic, and no fracture of the ribs had taken place. The symptoms are identical with those of a wound of the lung. Rupture of the lung is a dangerous accident, but not necessarily fatal.

WOUND OF THE LUNG is the most common, and one of the most serious complications of injuries of the chest. Wounds of the lung may be divided into those which communicate with the external air by a wound penetrating the walls of the thorax, and those which do not. In an organ like the lung which contains air, this distinction might seem to be of little importance; but as has already been pointed out, it is the dust of the air, and not the gases, which gives rise to decomposition of extravasated blood or inflammatory effusions. The well-known experiment of Tyndall, by which he showed that the residual air—that is to say, the last part of the air driven out from the smaller bronchial tubes and the air-vesicles by forced expiration—contains no dust, proves that all the solid particles floating in the atmosphere are deposited in the larger tubes; and, consequently, unless the wound of the lung be of sufficient depth to open these, there is no reason to fear that decomposition will take place in the cavity of the pleura, even though a considerable quantity of air may escape into it. Wounds of the lung also vary greatly in severity—from the superficial puncture produced by the pointed fragment of a broken rib, to a deep stab by a sword-thrust, or the wound produced by a fragment of shell or a bullet. The general constitutional effects will necessarily vary in accordance with the nature and extent of the injury.

The pleura may be opened at any part, and it is important to remember its anatomical relations. Its upper part extends into the root of the neck from one to two inches above the anterior end of the first rib, or, according to Pansch, from half an inch to one and a half inches above the clavicle. Below, the limits of the pleura are as follows: behind they both reach to the twelfth rib, and sometimes a little below it; in the axillary line the right pleura extends to the lower border of the ninth rib, and the left to the lower edge of the tenth; in front the right pleura reaches to the junction of the seventh rib with its cartilage, and the left a little lower. Thus, a stab in the neck one inch and a half above the clavicle may reach it, and a shot in the back that shatters the twelfth rib will wound it in its inferior pouch, where it is reflected off the last rib on to the diaphragm. In a penetrating wound of the chest, so low down as this, the diaphragm comes into such close contact with its posterior walls that it could scarcely escape injury. The abdominal cavity would thus be opened, and some of its viscera probably injured. As the lung does not descend below the tenth rib, it could be wounded only as low as the ninth intercostal space in the back, unless the tenth rib itself were penetrated.

The **Symptoms** of a wound of the lung are usually sufficiently well marked, though they necessarily vary with the extent of the injury. There is, in the first place, the immediate shock that usually accompanies the infliction of an

injury on an important internal organ, in severe cases amounting to extreme collapse. The patient is at the same time seized with considerable difficulty of breathing, and in consequence of the injury to the parietes, the respiration is as a rule chiefly abdominal; this is followed by much tickling and irritating cough, and the expectoration of frothy bloody mucus; or, if a large vessel is wounded, great quantities of pure blood may be brought up. On auscultating the chest immediately after the infliction of the injury, loud coarse *râles* will be heard, caused by the presence of blood in the smaller bronchial tubes. In the least severe cases, in which the surface of the lung is merely pricked by a fragment of a broken rib, the occurrence of subcutaneous emphysema may be the only certain indication of the injury.

Complications.—In order to save repetition and to make the subject more clear, it will be better first to describe the complications that may attend wounds of the lung. The principal dangers arise from bleeding, both external and internal, the occurrence of *Hæmothorax*, *Pneumothorax*, *Emphysema*, *Pneumonia*, and *Empyema*.

1. The **Hæmorrhage** varies with the part of the lung wounded, and the extent of the wound. If the large vessels near the root are implicated, death occurs almost instantaneously from loss of blood and suffocation. If the surface only is injured, the bleeding may be very slight. When it is abundant the patient spits up large quantities of florid frothy blood, a considerable amount of which may be swallowed and subsequently vomited. If it do not prove fatal, this bloody expectoration generally ceases in a great measure in the course of forty-eight hours, giving way to sputa of a rusty character. If there be a free external wound, there may also be copious bleeding from it; but not unfrequently the blood finds its way into the pleural sac rather than through the external aperture and accumulates in it. If there is no external wound, such blood as is poured out from the surface of the lung must necessarily find its way into the pleura. Death may arise either from the exhausting effects of this internal and concealed hæmorrhage, or from suffocation through the pressure exercised on the lungs by the blood in the pleura. Although bloody expectoration, to some extent at least, is an almost necessary and invariable accompaniment of a wounded lung, yet I have seen a laceration in that organ three inches in length, occasioned by the projection of broken ribs, which proved fatal on the seventh day from hæmothorax and pleuritic effusion, unattended with any expectoration of blood, or other positive sign of wound of the lung. The blood in these cases would probably be infiltrated into the loose tissue of the lung around and above the wound, where it would coagulate so as to offer a barrier against its escape into the bronchi, while it was being poured out where least resistance was offered to it—viz., at the point of injury in the pleura. The symptoms of this internal hæmorrhage, **Hæmothorax**, are those that generally characterize loss of blood, such as coldness and pallor of the surface, small weak pulse, and a tendency to collapse with increasing dyspnoea. The more special signs consist in an inability to lie on the uninjured side, with, in extreme cases, some bulging of the intercostal spaces, and an ecchymosed condition of the posterior part of the wounded side of the chest. If there is an open wound there will be occasional gushes of blood from it when the patient coughs. The most important signs are furnished by physical examination of the chest. As the blood gravitates towards the back of the chest, between the posterior wall and the diaphragm, there will be gradually

increasing dulness on percussion in this situation, with absence of respiratory murmur and of vocal fremitus. In the upper and anterior part of the lung air continues to enter, but as the pressure increases and the lung becomes more completely collapsed, the vesicular murmur will be lost, and the breath-sounds become tubular in character.

An ecchymosis of the loins described by Valentin, and noticed by Larrey and others, occasioned by the filtration of blood through the wound or rent in the pleura costalis into the areolar tissue of the chest, has been looked upon by some Surgeons as pathognomonic of hæmothorax; its importance, however, is secondary to that of the auscultatory signs, as in many cases it has not been met with, and in others of non-penetrating wounds of the chest it has occurred.

2. **Emphysema**, or the infiltration of air into the areolar tissue of the body, and **Pneumothorax**, or the accumulation of air in the cavity of the pleura, are occasional complications of a wounded lung. Emphysema of a limited character without pneumothorax is a very common complication of superficial wounds of the lung from simple fracture of the ribs, and is of no importance. In such cases the two layers of the pleura remain closely applied to each other and the air passes through these without filling the pleural cavity. More extensive emphysema is almost always associated with air in the pleural cavity. These accidents occur more commonly when the external wound is small and oblique than when it is large and direct, and often happen in those cases in which the lung is punctured by a fractured rib, without there being any external wound. The mechanism of traumatic emphysema in such cases is as follows. The two layers of the pleura, being punctured and torn, and the lung wounded, a quantity of air is sucked into the pleural sac at every inspiration, either through the external wound, or, if none exist, from a hole in the lung, thus giving rise to pneumothorax. At each expiration, the air that thus accumulates in the pleural sac, being compressed by the descent of the walls of the chest, is pumped into the areolar tissue around the edges of the wound; and if this be oblique and valvular, or if no external wound exist, the air being unable to escape wholly through it, finds its way at each succeeding respiration further into the large areolar planes, first about the trunk and neck, and eventually, perhaps, into those of the body generally. Under no circumstances can any air find its way back into the bronchial tubes, for although a wound in the lung allows air to pass readily in the direction of the pleura, it offers a valve-like resistance to its passage in the opposite direction. Though this is the way in which the most marked cases of emphysema occur, it may be occasioned otherwise. Thus, for instance, I once had under my care a woman who had extensive emphysema of the areolar tissue of the trunk from fractured ribs, but without any pneumothorax, the lung having been wounded at a spot where it was attached to the walls of the chest by old adhesions, and the air having passed through them into the areolar tissue of the body, without first entering the cavity of the pleura. I have also seen extensive emphysema occasioned by the apex of the lung being wounded by the fragments of a comminuted clavicle. Hilton has described another form of traumatic emphysema that arises without any external wound. The air passes along the root of the lung into the middle, and thence into the superior mediastinum; running up along the great vessels and the œsophagus, it passes into the neck between the layers of cervical fascia which enter the thorax

in front of the great vessels and behind the œsophagus respectively. From these the carotid and subclavian vessels, with their nerves, derive sheaths, so the air now runs along these structures into the limbs and neck.

The air which escapes from a wound of the lung is, as before stated, thoroughly filtered, and has no tendency to give rise to putrefaction of the extravasated blood or inflammatory effusions in the parts about the wound, and in the vast majority of cases of simple fracture of the ribs, complicated by a slight wound of the lung and subcutaneous emphysema, no suppuration follows the accident. I have, however, seen extensive suppuration in the areolar tissue, so that the broken parts of the fractured ribs lay bathed in pus, when the emphysema was the result of puncture of the lung by the broken rib, without any wound in the skin.

The *Symptoms of Emphysema* are very distinct. There is a puffy diffused swelling, pale in colour, and crackling when pressed upon, at first confined to the neighbourhood of the wound, if there be one externally; if not, making its appearance opposite the fractured ribs, and gradually extending over the upper part of the trunk and neck. To these parts it is usually limited; in some cases, however, which are happily rare, the swelling becomes more general, the body being blown up to an enormous size, the features effaced, movement of the limbs interfered with, respiration arrested, and suffocation consequently induced; after death, air has been found in all the tissues, even under the serous coverings of the abdominal organs. The rapidity with which the emphysema diffuses itself will depend largely upon the nature of the opening in the chest-wall, whether valvular or direct, and upon whether the patient coughs or not—coughing, if violent, causing very rapid and extensive infiltration of air over the body. I have seen in such a case the scrotum blown up to the size of a coco-nut five minutes after the chest had been punctured. In *traumatic pneumothorax* the auscultatory phenomena are very distinctly marked; there is a diminution or complete absence of the respiratory murmur and of vocal fremitus on the affected side, with loud tympanitic resonance on percussion, displacement of viscera, and considerable distress in breathing. If the pressure in the pleura becomes very great, respiration may be completely arrested by pressure on the opposite lung.

3. Pneumonia.—Every wound of the lung is necessarily followed by a localised traumatic inflammation, limited to the parts actually injured. The inflammatory exudation fills the air-vesicles, and thus causes a consolidation of the lung at the injured spot. This is a necessary stage in the process of repair, and in subcutaneous injuries has little or no tendency to spread. In cases complicated by the admission of unpurified air from without, decomposition of the extravasated blood and inflammatory effusion frequently occur, and the presence of the irritating products of putrefaction in the track of the wound may lead to an extension of the inflammation, with suppuration, and occasionally gangrene of a portion of the lung. More commonly the lung collapses, in consequence of the pressure of blood and inflammatory effusion in the pleura, and at the *post-mortem* examination, if the patient should die, the consolidation of the lung is found to extend scarcely beyond the parts actually injured by the missile or weapon by which the wound was inflicted. The comparative rarity of spreading pneumonia in cases of gunshot wound of the lung is specially commented on in the Reports of the Civil War in America, and was noted also by Klebs and Socin in the Franco-German War of 1870.

The simple localized traumatic inflammation consequent on an injury causes but slight constitutional disturbance, and it is only in exceptional cases that it could give rise to definite physical signs. There may be a little fine crepitation, and possibly recognizable dullness; but more commonly the physical signs are obscured by hæmorrhage into the lung substance, and into the cavity of the pleura. The rusty sputa are more the consequence of the hæmorrhage into the air-vesicles than of inflammatory hyperemia. Should spreading septic inflammation set in, the constitutional symptoms are much more grave, very high fever being caused by absorption of the products of putrefaction, the temperature reaching 104° F. or 105° F. It may then occasionally be possible to recognize the ordinary signs of pneumonia—hurried respiration, fine crepitation, dullness on percussion, increased vocal fremitus, tubular or bronchial breathing, and increased vocal resonance,—but far more commonly all these signs are wanting in consequence of the simultaneous inflammation of the pleura, with effusion into its cavity. The pneumonia that occurs as a consequence of injury differs essentially from acute croupous pneumonia. The disease has of course no fixed locality, starting as it does from the wound, and it has much less tendency to spread. Moreover it occurs most frequently in a collapsed or partially collapsed lung, and consequently there is not the same distension of the air-vesicles with inflammatory exudation. It is a most dangerous complication but not a hopeless one. If free drainage be provided from the pleura, the mischief may cease to spread, granulations may spring up, and the wound in the lung may gradually close.

Foreign bodies are frequently carried into the substance of the lung in gunshot wounds of the chest. If these are metallic, they may become encysted; if non-metallic, as pieces of clothing, they more commonly give rise to suppuration; and should the patient recover, they may ultimately find their way into the bronchi, and be coughed up.

4. **Plourisy and Empyema.**—Whenever the pleura is wounded, whether it be by a fractured rib or by a direct open wound, and whether the lung be injured or not, localized traumatic inflammation necessarily results, and the first stage in the repair of the injury in the serous membrane is adhesion of the two opposed surfaces by means of the inflammatory exudation. Afterward firm fibrous adhesions are formed between the parietal and the visceral pleura at the injured spot, thus to a certain extent obliterating the serous sac. Subcutaneous injuries of the pleura, such as are made by the ends of a broken rib, rarely give rise to any serious trouble. The inflammation remains strictly limited to the injured spot, and shows little tendency to spread. Even when the physical signs have shown that some amount of blood has been extravasated into the cavity of the pleura, the inflammation rarely reaches the stage of suppuration unless there is an external wound. If there is an external wound, the condition is always one of considerable danger. The cavity of the pleura is partly filled with extravasated blood and inflammatory exudation, that is to say, with putrescible matter, to which the air has free access through the external wound; at the same time, in most cases, the drainage by the wound is very imperfect. Decomposition naturally follows, and the decomposing matter sets up the most intense inflammation of the pleura, rapidly reaching the stage of suppuration. The lodgment of a foreign body in the pleural cavity or an unhealthy constitutional condition of the patient necessarily favours the formation of pus in the pleura. In wounds of

the pleural cavity which follow this course, the effused fluid is at first serum, with some flakes of lymph floating in it, and it is generally mixed with blood from the wounded lung. The effusion takes place very rapidly, so as to half fill one side of the chest in two or three days. By about the third day it becomes turbid, and before the end of a week it assumes the character of pus. The discharge from the wound is often abundant, offensive, and extremely irritating to the skin. The constitutional symptoms are most severe, the temperature rising to 104° F. or 105° F. The patient may die during the first week from absorption of the products of putrefaction. Should he survive till suppuration is fully established, the intensity of the symptoms subsides, the cavity may gradually close, and recovery take place; or death may ensue from hectic or exhaustion from prolonged suppuration.

The presence of fluid in the pleura may be recognized by the physical signs; dulness on percussion and absence of respiratory murmur at the lower and posterior parts of the chest, up to a level which has a gradual tendency to ascend, and which varies according as the patient is upright or recumbent; vocal fremitus is abolished over the fluid, and vocal resonance is muffled. At the border of the fluid there is occasionally ægophony. In cases in which there is no external wound, or in which it has been closed, the whole side of the chest may be filled with fluid. There is then complete absence of all breath and voice sounds and of vocal fremitus, with increase of size on measurement, bulging of the intercostal spaces, and compression of the lung against the spine; and, if the left pleura be filled, displacement of the heart towards the right side—if the right pleura, descent of the liver below its normal level, and displacement of the heart to the left. When the pleuritic effusion and extravasation reach such a degree as this, there is necessarily great dyspnoea, and death will usually speedily ensue. If there be air as well as fluid in the cavity of the pleura, it can be recognized by the combination of the signs of pneumothorax at the upper part of the chest, with those of fluid at the lower. Occasionally distinct splashing sounds may be produced by gently shaking the patient. If it is desired to ascertain the nature of the fluid in the pleural cavity, a small quantity may be drawn off by means of an exploring syringe.

Collapse of the Lung.—In wounds of the chest, as soon as air is admitted to the cavity of the pleura the atmospheric pressure on the surface of the lung and within the air-vesicles becomes equal and it would naturally be supposed that the lung would at once collapse by virtue of its own elasticity. This, however, is not always the case. The chest may be largely opened and yet no collapse may take place. This seems most probably to be due to the adhesion of the two smooth moist pleural surfaces to each other. When collapse of the lung occurs early it is often due to air entering the pleura during inspiration, either from the lung or from without, and in consequence of the valve-like action of the wounded lung, or an oblique external wound, being unable to escape during expiration; consequently, as the chest-walls descend, the lung is squeezed by the compressed air. This may be repeated at each respiration till no further collapse of the lung is possible. In the later stages it may be due to compression by blood or by inflammatory effusion.

The possible complications of wounds of the lung having been described, we are now in a position to consider the different varieties of these injuries.

Subcutaneous Wounds of the Lung from Fractured Ribs.—Slight injuries to the lung are extremely common in fractures of the ribs by direct violence, but as has already been pointed out, they are much less likely to occur in fractures by indirect violence, as in these the pointed ends of the fragments are directed outwards. These injuries rarely extend deeply into the lung. The usual symptoms are slight hæmoptysis, ceasing by the second day, followed by rusty sputa and limited dulness round the injury, and, possibly, at the base of the pleural cavity, from extravasated blood. There may be a little coarse crepitation from blood in the lung. Emphysema is of frequent occurrence, but pneumothorax is a rare complication; it seems that a little air readily finds its way across the pleural cavity, without any separation of the visceral from the parietal pleura, probably in consequence of the natural cohesion of two smooth moist surfaces. Occasionally the absence of air in the pleural cavity in these cases may be due to the presence of adhesions. The emphysema in these cases is rarely extensive. These slight wounds of the lung in a healthy subject scarcely add to the gravity of the case, and require no treatment beyond that of the fractured rib.

More severe wounds of the lung may occur from fractures of the ribs, accompanied by pneumothorax, extensive emphysema and hæmorrhage. These are occasionally followed by pleurisy with effusion, or even empyema. The majority of these severe injuries, however, do well if the patient is healthy and there is no open wound.

Penetrating Wounds of the Thorax with Wound of the Lung.—

A penetrating wound is recognized by the presence of an external opening, through which air is frequently drawn in and out during respiration, with the signs, already indicated, of wound of the lung. These cases are always serious, as owing to the admission of air from without there is great risk of the occurrence of septic pleurisy and pneumonia. Moreover, in a large proportion of cases the injury to the lung extends more deeply than any wound which can possibly be inflicted by a broken rib.

Wounds of the Lung by sharp penetrating instruments, as knives or swords, are specially liable to be complicated by profuse hæmorrhage, both into the pleura and into the air-tubes. When they penetrate the chest-wall obliquely, so as to leave a valved opening, they may give rise to emphysema and pneumothorax; in fact, it is in this class of cases that these conditions have most commonly been met with in an extreme degree. Septic pleurisy and empyema are common complications, but from the clean, incised character of the wound and the absence of foreign bodies carried into it there is a fair hope of preventing these complications and obtaining union of the external wound by the first intention if proper treatment be adopted.

Wounds of the Lung by blunt instruments, as in bullet or shell wounds or in machinery accidents, form by far the gravest class of these injuries. In consequence of the form and size of the external opening, emphysema is a somewhat rare complication, and when air is present in the pleura it is seldom at any degree of pressure. Hæmorrhage, to a greater or less extent, is always present, and in the majority of cases, as the external wound can scarcely heal by the first intention, septic pleurisy and empyema follow the injury. It is sometimes complicated by spreading inflammation of the lung, terminating in necrosis or gangrene. These cases are frequently complicated by the presence of foreign bodies, such as bullets or pieces of clothing.

The **Prognosis** in wounds of the lungs is necessarily extremely unfavourable if the injury be severe. The danger will depend greatly upon whether the wound be open or subcutaneous, upon the nature of the instrument inflicting it, and upon its extent. If the lung be wounded by the sharp end of a broken rib, recovery usually ensues. Punctured wounds of the chest, penetrating the lungs, are always very serious; but here the danger will depend partly on the depth of penetration, partly on the size of the instrument causing the wound. The nearer the wound penetrates to the root of the lungs, the greater is the danger of hæmorrhage from the larger vascular trunks. Gunshot wounds of the chest are far more dangerous than stabs, owing partly to the laceration attendant on a bullet wound, but chiefly to the fact that the external wound can rarely heal without suppuration and consequently, unless such complication be prevented by antiseptic treatment, septic pleurisy and empyema, and perhaps also pneumonia, are almost certain to occur. The danger of these wounds is also increased, in many cases, by the lodgment of the bullet or other foreign bodies.

In the Report of the American Civil War, a table is given of 1609 cases of penetrating wounds of the chest, collected from various sources, including the reports of Mouat on the New Zealand War, Chenu and Matthew on the Crimean War, Stromeyer on the Danish War, and others. Of these 1049 died, being an average mortality of 65·2 per cent. In the American Civil War 8715 cases were recorded, with 5260 deaths, or 62·6 per cent. The highest mortality recorded was in the Crimean War, in which 91·6 per cent. of these cases terminated fatally amongst the French troops, and 79·2 amongst the English. Longmore points out that the apparently great mortality in the Crimean returns was due largely to the proximity of the field-hospitals to the trenches, where the patients were wounded; if they had been wounded in the ordinary circumstances of a battle, many of them would never have reached a hospital. The great danger and principal cause of death in these injuries is unquestionably the hæmorrhage that ensues. This may prove immediately fatal if one of the larger pulmonary vessels be divided. As the bleeding is most abundant at and shortly after the receipt of the wound, Hennen states that, if the patient survive the third day, great hopes may be entertained of his recovery. After this period, the chief source of danger is the occurrence of septic inflammation in the pleura and sometimes also in the injured lung, the probability of the occurrence of which is greatly increased in gunshot injuries by the frequent lodgment of foreign bodies within the chest. The immediate cause of death at this stage is the accumulation of decomposing inflammatory effusion in the pleural cavity and the absorption of the products of putrefaction. This may prove fatal from the fourth to the eighth day. Emphysema is seldom a dangerous complication, though it may become so if very extensive and if it be allowed to increase unchecked.

If both lungs be wounded at the same time, the result is almost inevitably fatal, either by the abundant hæmorrhage suffocating or exhausting the patient, or else by induction of asphyxia in consequence of air being drawn into both the pleural sacs. This, however, does not necessarily result; and there is a sufficient number of cases of recoveries after stabs or bullet wounds traversing both sides of the chest on record to show that collapse of the lungs and consequent asphyxia do not necessarily result from this double

If there is no antiseptic lotion at hand the Surgeon should defer the examination till the patient has reached the hospital. Nothing is more certain to give rise to septic pleurisy than the introduction of a dirty finger.

In *Bullet wounds of the Lung* the treatment will chiefly depend upon the nature of the external wound. In a case in which one of the modern bullets has passed through the chest producing small almost clean-cut apertures, the Surgeon will probably best consult the safety of the patient by abstaining from all interference beyond thorough cleansing of the skin with an efficient antiseptic solution and the application of an antiseptic dressing. If the bullet remain in the chest, the aperture must be sufficiently enlarged to allow the introduction of the finger, purified by some antiseptic fluid. The Surgeon must not go too deeply or perseveringly in search of the foreign body, lest he excite more irritation than it would if left alone.

Large wounds must be left freely open, whilst medium-sized ones may need enlarging, so as to favour the escape of any foreign body which may have been left in, or of extravasated blood or inflammatory effusions. Careful antiseptic treatment of such cases is most important, and in the absence of the necessary means for carrying this out, the patient's chance of recovery will be increased by a free provision for drainage and the application of some dry absorbent dressing.

The **Constitutional Treatment** of wounds of the lung presents nothing peculiar. During the first few hours the chief danger is from loss of blood, and as the feeble state of the circulation during the state of shock that immediately follows the injury is favourable to the arrest of hæmorrhage, the patient should not be prematurely roused by the administration of stimulants. He must be kept lying on the injured side, and have ice to suck, or a little iced milk and soda-water, or barley-water, to drink, when these are obtainable. He must be forbidden to talk, and kept at perfect rest. If no complications ensue, he must be kept on moderate diet for a few days, after which he may take such food as he is inclined for.

Treatment of the Complications of Penetrating Wounds of the Lung.—Profuse hæmorrhage is a common complication in all wounds of the chest. It may occasionally come from a wounded intercostal or internal mammary artery, and must then be treated by the method described on p. 476. If the hæmorrhage come from the pulmonary tissue, the first indication is to diminish the quantity and force of the blood circulating through the lungs, and thus, by lessening the impulse of the heart and increasing the tendency of the blood to coagulate in the smaller vessels, to endeavour to arrest the hæmorrhage from these organs. If the hæmorrhage have been very abundant, the collapse and fainting consequent upon this may tend to induce a natural arrest of the bleeding, which thus often spontaneously ceases on the supervention of syncope. Should the hæmoptysis, however, continue or return from time to time, what should be done? Here a very considerable discrepancy of opinion exists amongst Surgeons: the question at issue being whether venesection should be adopted with the view of restraining the hæmorrhage, or whether the patient should be treated by rest, low diet, ice, digitalis, and similar remedies. Up to the close of the Crimean war, the most experienced Surgeons were unanimous in their opinion that the patient's safety lay in free and repeated venesection. John Bell, Hennen, and Guthrie, all concurred in urging the necessity of free venesection so as to keep down the action of the heart. According to

injury, which indeed has also been determined experimentally on animals by Cruveilhier. That perforation of both pleural cavities is not necessarily fatal is well shown by a case recorded by Bilton Pollard, in which a child falling from a height of more than thirty feet was impaled on the area railings. Both wounds were closed with sutures and recovery followed.

The **Treatment** of wounds of the chest, implicating the lungs, must have reference to the various sources of danger that have just been indicated and to the nature of the wound.

The **Local Treatment** in cases of *injury of the lung from a broken rib* without an external wound is very simple. The injured side of the chest should be strapped from spine to sternum so as to restrain its movements and leave the sound side free. There are two conditions in which it is especially inadvisable tightly to bandage or strap the whole chest. The first is when the fragments of the broken rib are sharp and angular, and, projecting inwards on the pleura and lung, produce pain, distress, and no slight danger of further injury to these structures if pressed down upon them; secondly, when the lung has become compressed by the effusion of air, serum, or blood into the pleural sac. In the latter cases, tight bandaging of the chest will cause great distress; for, the lung on the injured side being already rendered useless, or nearly so, by the compression, respiration is altogether carried on by the lung on the uninjured side. If the chest be uniformly or tightly compressed, the use of this lung also is interfered with to such an extent that a semi-asphyxial condition may ensue.

In a *penetrating wound of the chest by a sharp cutting instrument*, if it be a clean puncture, an attempt should be made to close it in such a way as to obtain union by the first intention. For this purpose some form of antiseptic treatment should always be adopted. The skin around the wound must be cleaned with some efficient antiseptic solution, such as carbolic acid lotion (1 in 20), and the wound itself may be wiped out by means of a sponge soaked in the same solution and held in a pair of forceps. If the wound be large the edges may then be brought together by sutures; if it be small and not gaping, these are not required. The surface must next be covered with an antiseptic dressing. In the absence of an antiseptic dressing the wound may be closed by lint and collodion, or a piece of lint may be soaked in the blood and allowed to dry upon it. If the wound be thus closed the patient must be carefully examined daily for effusion into the pleura, and the temperature must be watched. Should there be increasing dulness, with a high temperature, the fluid must be removed by means of the aspirator, and examined. Should it be curbed or purulent a free vent must at once be provided for it, either by opening up the original wound, or by making a new one at the most convenient spot.

Should the wound be large and deep, with blood and air issuing freely through it from the injured lung, it should not be completely closed, otherwise pneumothorax and emphysema, or hemothorax will certainly occur. It may be cleaned with an antiseptic solution, and partly closed by sutures, a large drainage-tube inserted, and an antiseptic dressing applied, or in the absence of antiseptics it may be covered with a piece of oiled lint. The patient should be laid on the wounded side, and the wall of the chest may be fixed by long broad strips of plaster applied to the injured side only, an aperture being left between the strips opposite the wound. Mouat states that excellent results have followed this plan of treatment in military practice.

If there is no antiseptic lotion at hand the Surgeon should defer the examination till the patient has reached the hospital. Nothing is more certain to give rise to septic pleurisy than the introduction of a dirty finger.

In *Bullet wounds of the Lung* the treatment will chiefly depend upon the nature of the external wound. In a case in which one of the modern bullets has passed through the chest producing small almost clean-cut apertures, the Surgeon will probably best consult the safety of the patient by abstaining from all interference beyond thorough cleansing of the skin with an efficient antiseptic solution and the application of an antiseptic dressing. If the bullet remain in the chest, the aperture must be sufficiently enlarged to allow the introduction of the finger, purified by some antiseptic fluid. The Surgeon must not go too deeply or perseveringly in search of the foreign body, lest he excite more irritation than it would if left alone.

Large wounds must be left freely open, whilst medium-sized ones may need enlarging, so as to favour the escape of any foreign body which may have been left in, or of extravasated blood or inflammatory effusions. Careful antiseptic treatment of such cases is most important, and in the absence of the necessary means for carrying this out, the patient's chance of recovery will be increased by a free provision for drainage and the application of some dry absorbent dressing.

The **Constitutional Treatment** of wounds of the lung presents nothing peculiar. During the first few hours the chief danger is from loss of blood, and as the feeble state of the circulation during the state of shock that immediately follows the injury is favourable to the arrest of hæmorrhage, the patient should not be prematurely roused by the administration of stimulants. He must be kept lying on the injured side, and have ice to suck, or a little iced milk and soda-water, or barley-water, to drink, when these are obtainable. He must be forbidden to talk, and kept at perfect rest. If no complications ensue, he must be kept on moderate diet for a few days, after which he may take such food as he is inclined for.

Treatment of the Complications of Penetrating Wounds of the Lung.—Profuse hæmorrhage is a common complication in all wounds of the chest. It may occasionally come from a wounded intercostal or internal mammary artery, and must then be treated by the method described on p. 476. If the hæmorrhage come from the pulmonary tissue, the first indication is to diminish the quantity and force of the blood circulating through the lungs, and thus, by lessening the impulse of the heart and increasing the tendency of the blood to coagulate in the smaller vessels, to endeavour to arrest the hæmorrhage from these organs. If the hæmorrhage have been very abundant, the collapse and fainting consequent upon this may tend to induce a natural arrest of the bleeding, which thus often spontaneously ceases on the supervention of syncope. Should the hæmoptysis, however, continue or return from time to time, what should be done? Here a very considerable discrepancy of opinion exists amongst Surgeons; the question at issue being whether venesection should be adopted with the view of restraining the hæmorrhage, or whether the patient should be treated by rest, low diet, ice, digitalis, and similar remedies. Up to the close of the Crimean war, the most experienced Surgeons were unanimous in their opinion that the patient's safety lay in free and repeated venesection. John Bell, Hennen, and Guthrie, all concurred in urging the necessity of free venesection so as to keep down the action of the heart. According to

these writers, whenever this rises and the cough or hæmoptysis recurs, recourse should be had to the lancet. In the Crimean campaign, Macleod states that "those cases did best in which early, active, and repeated bleedings were had recourse to." In the official Report of the Medical and Surgical History of the War in the Crimea, venesection is advocated with equal decision as a means of arresting hæmoptysis. The writer states: "When hæmoptysis to any considerable or dangerous extent is present, venesection for the rapid induction of syncope seems not only allowable, but seems to afford the only chance of safety, and may even require to be repeated." However paradoxical or even irrational it might at first sight appear to endeavour to restrain one hæmorrhage by establishing another, yet the practice seemed established as the result of experience; and its good effects could be explained by the sudden induction of syncope giving time for the sealing up of the pulmonary vessels by coagulation of blood within them. But although this was the practice up to a comparatively recent period, the views of military Surgeons on this point seem now to have undergone a complete change; and the experience derived from the great Civil War in America and from the Maori war in New Zealand, has led to the promulgation of different doctrines and the adoption of a different line of practice. In the American war, venesection appears to have been generally abandoned, while reliance was placed on rest, cold, and opium for the arrest of hæmorrhage; and this practice is said to have been generally satisfactory. In New Zealand, Mount states that bleeding was almost entirely discarded. Longmore says that, if the patient should survive, the loss of blood by venesection seems to interrupt the reparative measures adopted by nature.

If extravasation of blood into the pleura be going on, its further effusion must, if possible, be arrested by the same means. Should the hæmorrhage continue notwithstanding the employment of the means indicated, Guthrie advises that the wound should be closed, so that the blood which flows into the pleural sac may, by accumulating in this, compress the lung, and thus arrest the further escape of blood from the wounded vessels; the patient at the same time should be made to lie on the injured side, in order to increase the pressure exercised upon the wounded organ. When the bleeding has been checked in this way, the blood must be removed as early as possible from the pleural sac; for, if it be allowed to remain, it will in most cases decompose, the putrefactive ferment having found its way in before the wound was closed. Death then may take place from absorption of the products of putrefaction, or should the patient escape this, suppurative pleurisy inevitably follows. To prevent this, the pleura must be tapped with a large aspirator-needle on the fourth or fifth day, or earlier if the temperature be very high. Should it be found that the blood is free from putrefaction, the extravasation is best removed by repeated aspirations, care being taken not to remove too much at one time, lest by causing a forcible expansion of the lung the hæmorrhage may be started again. If the fluid withdrawn is decomposing, a free opening must be made either from the original wound, or at the most convenient spot, and a large drainage-tube inserted. The after-treatment will be the same as for septic empyema.

During the American war various drugs were made use of, with the intention of abiding the arrest of hæmorrhage, amongst them being tartarated antimony, lie and tannic acids, and acetate of lead; but their effects do not

seem to have been such as to justify any reliance being placed upon them. In the Crimean war the Russian Surgeons administered digitalis; but according to the present views of the action of that drug, its use could be productive only of harm.

Pleurisy and Empyema.—If the patient survive to the third day, the danger to be apprehended is no longer from hæmorrhage, but from inflammation and suppuration in the cavity of the pleura, consequent upon the decomposition of the discharges accumulated in that cavity. This is in some cases complicated by inflammation of the lung spreading from the track of the wound. Military Surgeons formerly recommended venesection as a means both of preventing and of reducing inflammation. Since, however, the part played by the decomposition of the discharges in the pleural cavity has become fully recognised, much more importance has been attached to draining and cleaning the pleural cavity than to any efforts by means of blood-letting or drugs to subdue the local inflammation and constitutional disturbance. Possibly, in civil practice, if a case were met with in which the inflammation was confined to the lung substance, and attended with much dyspnoea in a healthy young subject, some relief might be given by venesection; but such a condition is so rare that it may practically be excluded from our consideration. When the dyspnoea arises from pleuritic effusion, bleeding must necessarily be useless, and in fact could only be injurious by still further weakening the powers of the patient. The inflammation must be combated by removing its cause as far as possible.

In the first place every effort should be made to prevent the occurrence of decomposition, either of extravasated blood or of inflammatory exudation in the cavity of the pleura by the adoption of some efficient method of antiseptic treatment. Should these endeavours fail, and the pleura become distended with decomposing discharges, the freest possible drainage must be provided by enlarging the original wound, and if necessary, making a counter-opening at the most convenient spot. All counter-openings must be made on a probe passed from the original wound and made to project between two ribs, as the relations of the walls and contents of the cavity are often much altered in these cases, and unless a guide is obtained in this way, either the diaphragm or the lung might be accidentally wounded. Large drainage-tubes should be inserted at the wound and the counter-opening if one has been made. If any difficulty is experienced in doing this, a piece of rib may be cut away. If the discharges are offensive, the cavity of the pleura must be cautiously washed out with some antiseptic solution. König reports that he obtained very good results in the Franco-German war by using a strong solution of chloride of zinc.

It will always be necessary in these cases to support the patient's strength by abundant liquid nourishment and stimulants when they are obtainable. Pain and cough may often be relieved by opium.

If any extraneous body, such as a bullet, a piece of wadding or of clothing, have penetrated too deeply into the chest to be readily extracted through the external wound, it would not be safe to make incisions or exploratory researches, with a view to extracting it; for, though its presence would increase the patient's danger, yet attempts at extraction would not only add to this, but would in all probability be fatal. In many cases, bodies so lodged become surrounded by pus, are loosened, and eventually are spat up, or appear at the external wound. In other cases, they remain permanently fixed in the chest,

becoming enveloped in a cyst, and so remaining for years, without producing irritation. In this way, Hennen states, a bullet has been lodged in the chest for upwards of twenty years; and Vidal mentions the case of a man who lived for fifteen years with the broken end of a foil in his chest, which, after death, was found sticking in the vertebra, and stretching across to one of the ribs.

The *Treatment of Emphysema and Pneumothorax* consists of little in addition to what is called for by the wounded lung. In many cases, indeed, the air becomes absorbed in three or four days without the necessity for any local interference. If, however, the pneumothorax interfere with respiration by pressure on the opposite lung, the external wound, if any exist, must be freely opened, and punctures may be necessary to give exit to the air in the areolar tissue. If no wound exists the pleura must be tapped as for fluid, and, if necessary, the cannula must be left in. I doubt whether emphysema alone can ever prove fatal.

HERNIA OF THE LUNG, OR PNEUMOCELE.—This is an extremely rare condition. It consists in the protrusion of a portion of lung at some part of the thoracic wall. The hernia may occur through a perforating wound of the chest, beneath the cicatrix after the wound has healed, and in rare cases without any external wound. The protrusion of a portion of the lung through a wound of the chest is most likely to occur when the pleura is freely opened but the lung itself not injured. It has been seen more often in wounds of the front of the chest than in those behind, and especially in wounds situated over one border of the lung. Malgaigne has ascribed the occurrence of the hernia to air forcibly driven from the sound lung into that of the injured side, during a violent expiratory effort with closed glottis. Peyrot points out that if the lung itself be so much wounded that bronchial tubes are opened, the air thus driven into the lung will readily escape into the pleural cavity, and thus the necessary conditions for the production of a hernia are absent. If the wound be free the protruded lung may return on pressure or during inspiration. If left unreturned, it soon becomes livid and gangrenous; in these circumstances it may be removed by the knife or ligature.

As an instance of hernia of the lung beneath a cicatrix I may briefly relate a case which I saw in 1839 in Velpeau's wards at La Charité.

A man twenty-nine years of age, left-handed, received in a duel a sword-wound at the inner side of, and a little below the left nipple; he lost a considerable quantity of blood, but did not spit up any. The wound healed in about a fortnight, shortly after which he noticed the tumour, for which he was admitted three months and a half after the receipt of the injury. On examination, an indurated cicatrix about half an inch in length was found a little below, and to the inner side of, the left nipple. On expiring or coughing, a soft tumour of about the size of an egg appeared immediately underneath the cicatrix, which it raised up; it subsided under pressure, or when the patient ceased to expire or to cough; and its protrusion could be prevented by pressing the finger firmly on the part where it appeared, when a depression was felt in the intercostal muscles. If the fingers were slid obliquely over the tumour, it yielded a fine and distinct crepitation, exactly resembling that produced by compressing a healthy lung, and the spongy feel of the organ could be recognized. On applying the ear, a fine crackling and rubbing sound was distinctly perceived; the tumour was resonant on percussion. The portion of

protruded lung did not appear to re-enter the chest on inspiration, but was firmly fixed in its new situation. No treatment was adopted in the case, nor does any appear admissible in similar instances.

Hernia of the lung has been known to occur from fractured ribs without any wound, and even from violent straining during labour.

I have seen a case in a man who gained his livelihood by playing the cornet. In these cases it is probable that, the intercostal muscles and costal pleura having been divided or ruptured by the efforts of the patient and not having united afterwards, the lung has, during expiration, gradually insinuated itself into the aperture so formed until at last the hernial tumour has appeared. This protrusion may take place at any part of the thoracic parietes; thus Velpeau observed it in the supraclavicular region of a girl; but most commonly it occurs on one or other side of the chest. The tumour may attain a large size; I have heard Velpeau state that he had seen one half as large as the head. It does not appear to shorten life.

The only affection with which a hernia of the lung can be confounded is a circumscribed empyema which is making its way through the walls of the chest. Here, however, the dulness on percussion, and the absence of respiratory murmur and of crackling under the fingers, will readily enable the Surgeon to make the diagnosis.

WOUNDS OF THE HEART AND LARGE VESSELS.

WOUNDS OF THE PERICARDIUM.—The pericardium may be wounded with or without penetration of the chest, and with or without injury of the heart. Without wound of the chest-wall, it may be lacerated by a severe contusion; with penetration of the chest-wall, it may be wounded by a stab or by gunshot.

Laceration of the Pericardium may take place from a severe blow on the chest. I have seen the membrane split longitudinally for two or three inches, from contusion received in a fall.

The **Pericardium may be wounded** by a stab without the heart being injured. Thus I have seen a wound of the pericardium in a young man, inflicted by his sweetheart with a sharp-pointed pair of embroidery scissors.

The pericardium may be bruised or cut by an oblique gunshot wound without damage to the heart. This I have seen happen from a pistol-bullet penetrating the chest obliquely.

In injuries such as these, collapse to a greater or less extent is always met with. This is followed by inflammation; the ordinary auscultatory signs of pericarditis followed by effusion, such as friction, with extended dulness on percussion, become perceptible; and there are intense thoracic oppression, dyspnoea, and restlessness, with pallor and a small rapid pulse.

In some cases of wound of the pericardium, with a superficial injury to the heart, one of the *coronary vessels* may be divided, and blood effused into the sac. In these cases the interposition of the layer of blood causes the heart sounds to be weak and remote, the impulse of the apex to be indistinct or imperceptible, and the cardiac dulness to be widely diffused.

The *Prognosis* of cases of injury of the pericardium is necessarily very unfavourable. The heart may become choked by the intrapericardial extravasation of blood or the inflammatory effusion.

The *Treatment* of these cases of wound of the pericardium should be conducted as far as possible on antiseptic principles. In cases of a punctured wound, should the external opening close, and the pericardium become distended with effusion to such an extent as to embarrass the action of the heart and threaten to prove fatal, the fluid must be removed by means of the aspirator. (See Tapping the Pericardium, Vol. II.) The general treatment must be conducted on those ordinary medical principles that guide us in the management of pericarditis arising from other causes.

WOUNDS OF THE HEART.—The heart may receive a wound which does not penetrate through the walls; or one or more of its cavities may be opened by the agent that inflicts the injury. Most commonly the wound is inflicted by stab or gunshot, and then generally no foreign body is lodged in the cardiac cavities or substance. But in some instances bullets, pieces of stick, needles, iron pins, and other substances, have been lodged and encysted in the walls of the ventricles.

In the vast majority of cases, wounds of the heart are immediately fatal, but they are not necessarily or invariably so. Much will depend on whether or not they penetrate into the cavities, and on the extent of the injury that the heart has sustained.

Non-Penetrating Wounds may be fatal at once from direct shock to the heart; or the patient may survive a few hours or days and then die of pericarditis; or he may recover and live for years, as in a case reported by West of Birmingham, in which the man lived for four and a half years. After death, evidences of extensive and severe pericarditis were found, and there was a linear cicatrix half an inch long in the anterior part of the right ventricle.

Penetrating Wounds of the Heart are almost invariably at once fatal from loss of blood and shock to the organ and system. This is especially the case if the cavities be largely opened, or much of the heart substance destroyed. But there are many exceptions to this general law of fatality. Jannin has collected 84 cases in which people lived for considerable periods after having received a wound of the heart. Of these, in 35 cases the right ventricle was wounded, and the sufferers lived from four and a half hours to twenty-three days. In 19 cases the injury was to the left ventricle; and of these life was prolonged to periods varying from half an hour, in two cases, to six months in one instance. Both ventricles were wounded in five cases in patients who lived from one hour to nine and a half months; the right auricle in seven cases, the patients living from seven hours to twenty days; the left auricle in two cases, in which the patients lived respectively one and two days. In many cases, the patient has been known to walk or run some considerable distance after the receipt of the injury. Ollivier and Samson have collected 29 cases of penetrating wounds of the heart which did not prove fatal in the first forty-eight hours after the receipt of the injury. On analysing these, it would appear that the rapidity of death depends greatly on the direction of the wound and the part of the organ injured. When the wound is parallel to the axis of the heart, it is not so speedily fatal as when in a transverse direction, and wounds of the auricle are more immediately followed by death than those of the ventricle: the irregular contraction of the different planes of muscular fibre that enter into the formation of the wall of the ventricle tending to obstruct the free passage of the blood through the wound, and perhaps to close it entirely. The size

of the wound, however, will necessarily influence the result more materially than its direction. Not only may a person live a considerable time after having received a penetrating wound of the heart, but there are many cases on record in which life has been prolonged even though a foreign body was lodged in the cavities or substance of the organ. Thus Ferrus relates the case of a man who lived for twenty days with a skewer traversing the heart from side to side; and Roux that of a man who lived twenty-one days with a portion of a file, with which he had stabbed himself, in the wall of the left ventricle. Davis and Stewart found a piece of wood, three inches long, in the right ventricle of a boy, who lived five weeks after the accident; Carnochan relates a case in which the wounded man survived eleven days with a bullet deeply lodged in the substance of the apex of the heart; and Latour records the case of a soldier who lived for six years after being wounded by a musket-ball in the side, and in the right ventricle of whose heart the bullet was found lodged, lying against the septum.

The part of the heart that has been injured may be determined by attention to the situation of the wound and the direction it takes, for the situation of the different cavities of the heart in relation to the superficial structures is constant. Thus, a stab below the fifth rib, about one inch to the sternal side of the nipple, and two inches below it, would wound the apex of the heart; a stab through the second intercostal space close to the right side of the sternum would wound the most prominent part of the ascending aorta after passing through the lung. One through the third to the fifth intercostal spaces to the right of the sternum would wound the right auricle. The pulmonary artery would be reached by a thrust through the third rib on the left side at its junction with the sternum. The statistics collected by Fischer, Jamain, West, and others, show that the right ventricle is most commonly wounded.

There are instances on record in which a ball has entered the chest and caused a laceration of the heart substance without penetrating the pericardium, which escaped in consequence of its firmness and fibrous character. Again, as has already been stated, the pericardium alone may be injured: Fischer has collected 51 such cases.

The **Symptoms** of a wound of the heart, when immediately fatal, are as follows. The person struck springs up convulsively, or falls suddenly prostrate; sometimes with, sometimes without, a sudden sharp shriek. Death results from hæmorrhage, which will be profuse, the blood passing out beyond the pericardium, if the wound be large and that membrane be widely opened; or into the pericardium, preventing the action of the heart by compression, if the wound be small. In either case, death is hastened by collapse arising from shock to the heart itself, and to the system at large from the wound of so important an organ.

If the wound be small and death be not immediate, there are evidences of great shock in the intense depression of vital power, the pallid and anxious countenance, and the relaxation of the limbs. The action of the heart itself is tumultuous, weak, and irregular; the pulse is scarcely perceptible; the breathing is extremely embarrassed. If the patient survive a few days, these symptoms partially and intermittently subside, and the ordinary signs of pericarditis come on—friction, gradually disappearing more or less completely

as the pericardium becomes distended with fluid, when there will be increased dulness on percussion, with a weak impulse and elevation of the heart's apex. By auscultation the heart sounds will be found to be feeble and muffled, especially at the apex. To these symptoms may possibly be added evidences of endocardial inflammation. Of these consecutive inflammatory complications and of their consequences the patient will most probably die, though perhaps at a remote period and after prolonged suffering.

RUPTURE OF THE HEART FROM EXTERNAL VIOLENCE, without penetrating wound of the chest, is not of frequent occurrence. Gainger has, however, collected 22 published cases of this accident. On analysing these he finds that, in at least one half of the cases, the pericardium was intact; 12 of the ruptures were on the right, 10 on the left side. The right ventricle was ruptured in 8, and the left in 3 cases; whereas the left auricle was torn in 7, and the right only in 4 instances. Death is usually almost instantaneous, though there are instances on record in which the patient made some exertion after the rupture had taken place, and even lived for several hours. In a case of rupture of the right auricle recorded by Rust, the patient survived fourteen hours. In most of the recorded cases, the injury occasioning the rupture was directly applied to the region of the heart. But instances are not wanting in which this organ has been found ruptured through one or both ventricles or in one of the auricles, without any evidence of direct injury in the cardiac region—the patient having fallen upon his head or shoulders, or having merely been thrown forcibly to the ground with serious injury to the lower extremities. In some of these cases, there is reason to believe that the rupture was produced by the violence of the contractions of the heart, under the influence of great mental emotion or fear. The only case that has occurred in my practice was that of a man brought into the Hospital dead, having fallen from the top of a cart on to his right shoulder. On examination, the liver was found extensively torn, in fact smashed, and the pericardium was distended with blood—there being a triangular ragged aperture at the anterior part of the left auricular appendage, through which it had escaped.

WOUNDS OF THE AORTA AND VENA CAVA are usually as immediately fatal as those of the heart itself. In this respect, they resemble wounds of the auricles rather than those of the ventricles. Heil has, however, recorded a case in which the patient lived for a twelvemonth, after receiving a stab that penetrated the ascending aorta.

WOUND OF THE THORACIC DUCT is very rare. It has occurred during an attempt to ligature the first part of the left subclavian artery, in removal of tumours, and in stabs above the clavicle or in the chest. The chief symptom is a constant draining away of chyle. The injury has been almost invariably fatal. Bradley has collected and published the following six cases which well illustrate the characters of the injury:—

“Hoffmann's first case was that of a woman wounded through the left side with a knife. Following the wound there was a copious discharge of spontaneously coagulating fluid, which was observed to be milky during digestion, and clear while the patient was fasting. In his second case, the escape of chyle followed the opening of an abscess of the posterior mediastinum. Moore relates a case where the thoracic duct was wounded by a stab; the lymph escaped externally and also into the pleural cavity, interfering with the heart's action. Guifford's case is of a similar nature. Bonnet gives the history of a

Baron Heinden, who was wounded in battle by a bullet, which escaped beneath the left scapula. From this wound there gradually began to flow an excessive quantity of lymph." In Quinke's case, "the pleural cavity became so full of extravasated lymph that paracentesis had to be performed to prevent suffocation, from which, indeed, the patient eventually died." Krabbel subsequently recorded the case of a boy in whom the duct was completely torn across by a fracture of the ninth dorsal vertebra, from the passage of an empty coal-truck over the back. Death occurred on the fifth day, and the right pleural cavity was found to be distended with chyle. A doubtful case also occurred to Kirchner, in a girl aged 9, who, fourteen days before, had run violently against a "window parapet." A litre of chyle was withdrawn by aspiration from the right pleura, and the patient recovered.

Keen, of Philadelphia, has collected four cases, including one of his own, in which the thoracic duct was probably wounded during operations in the neck. In Cheever's case the patient died of shock thirty-six hours after the operation. In Boegehold's case the wound was plugged and the patient recovered. In Phelps's case the point from which the fluid escaped in large quantities was ligatured seven days after the operation, and the patient made an excellent recovery. In the case operated upon by Keen the wound in the duct was closed with fine silk, and recovery followed.

CHAPTER XXIX.

INJURIES OF THE ABDOMEN AND PELVIS.

INJURIES OF THE ABDOMEN AND ABDOMINAL VISCERA.

INJURIES of the abdomen may be divided into Contusions, with or without Rupture of Internal Organs; Non-penetrating Wounds; and Penetrating Wounds, either uncomplicated, or conjoined with Injury or Protrusion of some of the Organs contained in this cavity.

CONTUSIONS OF THE ABDOMEN derive their great importance from the frequency with which the various organs contained within the abdominal cavity are injured.

Contusions of the Abdominal Walls from blows or kicks usually terminate without serious inconvenience. In some cases, however, the muscles of the abdominal wall may be ruptured subcutaneously. A man was admitted under my care into the Hospital who had received a blow from the buffer of a railway carriage upon his abdomen. He complained of great pain at one spot; and, on examination after death, we found the rectus muscle torn across without injury either to the integuments or the peritoneum. If the patient live, an injury of this kind is apt to be followed by a ventral hernia. Occasionally the contusion is followed by abscess in the abdominal wall, which has a tendency to extend widely between the muscular planes. The abscesses should be opened early, lest they burst into the peritoneal cavity and occasion fatal inflammation.

Contusions of the Abdomen with Injury of some of the Viscera commonly result from blows and kicks, the passage of a cart-wheel over the abdomen, or a squeeze of the body between the buffers of two railway carriages. These "*buffer accidents*" are of common occurrence in hospital practice, the usual victims being railway porters, who, in trying to pass between carriages in motion, are caught and squeezed between the buffers. In these cases the most fearful internal injuries occur, without any external wound. A man was admitted under my care into University College Hospital, in whom the liver, stomach, spleen, and kidneys were crushed and torn; the heart was ecchymosed on its surface, and one of the lungs was lacerated, without any rupture of the skin or fracture of the ribs. The particular organ injured depends on the situation of the blow. The organ that is most frequently crushed in this way is the liver, owing to its large size and the unyielding nature and ready lacerability of its structure; the other solid organs, such as the spleen and kidneys, do not suffer so frequently. Among the hollow organs, the stomach most commonly suffers, and it is especially likely to do so if struck while distended by food. Any portion of the intestinal canal may be lacerated. I have seen the duodenum, the ileum,

the jejunum, and the large intestine ruptured in different cases; the mesentery likewise may be lacerated, and the spermatic cord torn across.

The **Symptoms** of a severe contusion of the abdomen necessarily vary according to the nature of the accident and the extent of the damage to the abdominal viscera. The injury is usually followed by more or less profound shock, which may of itself prove fatal, though there be but little apparent internal mischief; thus, I have seen a man die collapsed eight hours after a buffer accident, in whom no injury was found except a small rupture of the mesentery, attended with but very slight extravasation of blood.

The severity of the shock, amounting often to prolonged and complete collapse, is one of the most remarkable phenomena attending these injuries. It is difficult to account for it, except on the supposition that it is due to wound or concussion of the sympathetic nerves and the large abdominal ganglia. To whatever cause it may be referred, it is certain that it is greater than that which follows a corresponding injury, unattended with loss of blood, of any other part of the body except the central portions of the cerebro-spinal nervous system. So far as my experience goes, I would say that the shock is most severe in injuries of and about the stomach, probably from damage to the solar plexus. It has been pointed out that the persistence, rather than the severity, of the shock, is an indication of severe internal injury.

In many cases of abdominal contusion, the patient presents symptoms characteristic of internal hæmorrhage, and in certain instances, the presence of an extensive effusion of blood is revealed by dulness in the flanks, shifting with change of posture. The most usual source of severe abdominal hæmorrhage is a ruptured liver or spleen.

Vomiting is a very variable symptom after abdominal injuries, and is of little value as a means of diagnosis. It frequently occurs in cases followed by recovery, and on the other hand it may be absent throughout in cases of rupture of the stomach or intestines. At a later stage, repeated bilious vomiting may be a symptom of peritonitis. Bloody vomiting may be, as we shall see, a symptom of rupture of the stomach.

A careful examination of the abdomen should be made, and the presence of bruising or abrasion of the skin may be of value in forming a conclusion as to the probable nature of the injury. Thus, if in a case presenting the general symptoms of internal hæmorrhage there be marked bruising in the right hypochondrium, the diagnosis of rupture of the liver is justified. The possible presence of dulness in the flanks as the result of intraperitoneal hæmorrhage has already been mentioned. The presence of free gas in the peritoneal cavity may be shown by general tympanites and especially by a resonant note over the liver. This symptom can only be due to rupture of some part of the digestive tract. Careful palpation of the abdomen may, if the patient be not too deeply collapsed, elicit marked tenderness definitely localised to one spot: this may be of value in determining the probable seat of an internal injury. In every case of severe abdominal contusion it is the duty of the Surgeon to pass a catheter; he may thus detect evidences of rupture of the bladder (p. 893), whilst the presence of blood in the urine may be the result of bruising or laceration of the kidney.

It has already been stated that intense shock may follow an abdominal contusion unattended with any serious lesion of the viscera. Although intense, the shock is in such cases usually of short duration, and severe internal injury

may be suspected if it be persistent. It has further been pointed out that the suspicion is increased if persistent shock be associated with localised abdominal pain and tenderness.

The patient who has survived the more immediate effects of the accident is still liable to the occurrence of peritonitis, which is not necessarily the result of rupture of one of the viscera.

Having thus briefly considered the chief points to be observed in a case of severe contusion of the abdomen, it remains to describe in greater detail the symptoms which result from injury of the principal abdominal viscera.

If the **Liver** has been ruptured, pain over the region of that organ, dulness on percussion from extravasated blood, and great collapse, followed, if the patient live, by diffuse peritonitis, bilious vomiting, white stools, and jaundice, will, with sufficient precision, indicate the true nature of the injury. Bernard has further shown that contusions of the liver may be followed by the appearance of sugar in the urine.

Rupture of the liver is by no means always speedily or even necessarily fatal. It may be, and usually is so, from extravasation of blood or of bile; but if neither of these be largely poured out, the patient may live for some considerable time, though he may eventually succumb to peritonitis. A man was once admitted under my care into University College Hospital, who had been crushed between the buffers of two railway carriages. He was collapsed and apparently moribund, but rallied in a few hours. Two days after the accident, great pain and tenderness in the right hypochondrium were complained of, and dulness on percussion was found to extend as low as the umbilicus. He became jaundiced, and there were symptoms of peritonitis; these were followed by great swelling of the abdomen, which became tympanitic; the peritonitis continued, and symptoms of intestinal obstruction came on, the dulness increasing, with fluctuation in the flanks. He died on the sixteenth day after the accident, and on examination no less than 240 ounces of bilious fluid, mixed with flakes of lymph, were found in the abdominal cavity; the obstruction of the bowels being dependent on the pressure of this effusion, and on the matting together of the intestines by lymph. There was a large rent in the thick border of the liver, which was beginning to cicatrize.

The following is an example in which recovery took place. A man, about forty years of age, fell from a scaffold to the ground. In falling, he struck violently against a beam, injuring his abdomen on the right side. He was brought to the Hospital in a state of collapse, from which he slowly rallied. There was no injury but that of the abdomen, of which he complained much, more particularly over the region of the liver, which was very tender. Peritonitis speedily set in, with great tympanitic distension of the belly, vomiting of bilious matter, and the passage of colourless stools. These symptoms continued many days, and the man became jaundiced. As the tympanites subsided, it was found that there was dulness on percussion in both flanks, and that the fluid, which was evidently extravasated into the peritoneal cavity, rose to a level with the umbilicus when he lay on his left side, which he did habitually. He was treated with opium, and put on a very mild unstimulating diet. He gradually but slowly recovered, the vomiting becoming less frequent, and eventually ceasing, and the fluid in the abdomen being slowly absorbed, bile at the same time appearing in the motions; but the tenderness over the

region of the liver continued up to the time at which he left the Hospital, nearly two months after the accident. In this case the long and severe collapse, the seat of pain and injury, the peritonitis, the bilious vomitings, and the white stools, all pointed to serious injury of the liver; and rapid intra-abdominal extravasation could be accounted for only by rupture of that organ.

If the **Spleen** has been lacerated, there will be severe shock, accompanied by signs of internal hæmorrhage; coldness and pallor of the surface, a small and feeble pulse, anxiety of countenance, and great depression of the vital powers, with pain at the seat of injury, and dulness on percussion from extravasated blood. These symptoms usually terminate rapidly in death. Rupture of the spleen is specially liable to occur from slight blows when that organ is enlarged as the result of exposure to a malarious climate.

If the **Kidneys** are injured, there will often be a frequent desire to pass urine, and that fluid will be tinged with blood, often to a considerable extent. If the ureter become plugged by a clot there may be severe renal colic, the pain shooting down to the testicle and thigh. Sometimes the bladder becomes distended with coagulated blood. After the discharge of blood ceases, the urine will become albuminous, and may continue so for a great length of time. On examining such albuminous urine under the microscope, it will generally be found to contain a few blood-corpuscles, and possibly some tube-casts, which at first, perhaps, contain blood-corpuscles, and later on become granular. Pus and mucus, with epithelium-cells from the pelvis of the kidney, and occasionally renal epithelium, may be met with later on, showing the existence of inflammation in the kidney. It is an important practical fact, so far as my experience goes, that albumen never appears in the urine as the result of renal injury, unless it has been preceded by blood. The absence of blood from the urine must not, however, be taken as an indication that the kidney is not injured: it may be so disorganized as to be totally incapable of secreting, or the ureter being torn across no bloody urine finds its way into the bladder. A man was admitted into the Hospital under my care for a buffer injury of the back; he passed urine untinged with blood, but after death his right kidney was found completely smashed by the blow, and there was an extensive extravasation of blood in the fat around it; here it was evident that the disorganisation was so sudden and complete that no urine could find its way into the bladder. In another case, in consequence of a fall from a window, an elderly man died in the course of an hour, having struck his back and sustained several fractures of the limbs. The left kidney was ruptured in a starred manner, with extensive extravasation of blood into the tissues around it, but there was not a tinge of blood in the urine which was retained in the bladder.

Rupture of the kidney is by no means necessarily fatal. Patients have lived after exhibiting all the signs of it—the passing of bloody urine, and the presence of circumscribed peritonitis; and, when death has occurred at a later period, cicatrices have been detected in the organ. A patient was admitted under my care into University College Hospital for a severe blow upon the back from the buffer of a railway carriage, followed by hæmaturia and other symptoms of renal injury; on his death from pneumonia nine weeks after the accident, an extravasation of blood, with the marks of recent cicatrization, was found in the left kidney.

If the **Ureter** or **Pelvis of the Kidney** is ruptured the urine may accumulate in the loose tissue around the kidney. A large fluctuating tumour is thus gradually formed in the injured side of the abdomen, bulging in the loin and filling the interval between the iliac fossa and the ribs. The absence of acute inflammation in such cases is worthy of note, the fluid gradually becoming encysted by consolidation of the surrounding tissues. The presence of blood in the urine may or may not be detected after the accident. In one recorded case of this nature as much as six pints of urine were removed by tapping at one sitting. On examination after death, which occurred in the tenth week from the accident, a large cyst was found behind the peritoneum, communicating with the pelvis of the kidney. Two cases of this kind have occurred in University College Hospital. In the one the patient, a child aged 3 years, under the care of Barker, was run over by a cab. The right side was bruised, and a few small clots were passed in the urine. About three weeks later a large fluctuating tumour was found reaching from the iliac fossa to the ribs. Aspiration showed that it contained urine. As repeated aspiration failed to give any relief, a drainage tube was inserted, with the result of establishing a fistula. Finally, as the only means of cure, the kidney was removed. The child recovered from the operation, but died subsequently of general tuberculosis. The kidney and pelvis were found to be uninjured. The second case was under the care of Godlee, and similar treatment was successfully adopted.

Another possible result of rupture of the ureter is the rapid development of hydronephrosis. In a case of this kind under the care of Pickering Pick at the Victoria Hospital for Children, the boy had fallen on the edge of a kerbstone. The accident was followed by blood in the urine and the rapid development of a tense fluid swelling in the left loin. Urine was several times withdrawn by aspiration, and for the cure of the fistula which resulted from drainage, the dilated kidney was finally excised. It is interesting to note that in two cases apparently of this nature recorded by Goodhart, spontaneous cure gradually took place after an interval of many months.

When the **Stomach** is ruptured the nature of the accident is usually revealed by bloody vomiting, with pain in the region of the stomach, and the most profound shock. These signs, however, do not occur in all cases. A man was admitted to the Hospital under my care, whose abdomen had been squeezed between a cart-wheel and a lamp-post: during the five hours that he lived he vomited several times, bringing up a meal which he had taken immediately before the accident. In the vomited matters there was no blood to be seen; but after death it was found that not only the liver and spleen were ruptured, but the stomach was torn almost across near the pylorus.

Rupture of the **Intestine** is much more common than that of the stomach. It may occur at any part, but is most commonly met with in the duodenum or at the junction of the duodenum and jejunum. The frequency with which the duodenum is ruptured is due partly to its position, and partly to its fixity. The third part of the duodenum crosses the spine in front of the second lumbar vertebra, or about one inch above the umbilicus, and thus receives no protection from the costal cartilages. In this part of its course it is uncovered by peritoneum, and is consequently fixed so firmly that it receives the full force of any violent pressure, being unable to slip away from beneath it, as do those parts of the intestine which are completely covered by peritoneum,

and attached to a loose mesentery. When the force is applied in an oblique direction from right to left, rupture occasionally takes place at the junction of the movable jejunum with the fixed duodenum. Rupture of the duodenum may therefore occur with or without injury to the peritoneum. Rupture of the gut into the peritoneal cavity is indicated by intense pain in the belly with severe shock. Free gas in the peritoneal cavity may sometimes be recognized by tympanitic resonance in front of the liver. Peritonitis speedily sets in, with vomiting, at first bilious, but soon becoming dark-coloured or almost black. The abdomen becomes tympanitic and tensely distended, with gradually increasing dullness in each flank. The belly is acutely tender, and the patient lies on his back with his knees drawn up. These injuries are extremely fatal: in fact if the aperture in the gut be of sufficient size to allow of the escape of its contents into the peritoneal cavity, death almost inevitably results. Rupture of the third part of the duodenum behind the peritoneum is accompanied by much less clearly marked symptoms: there are pain and tenderness, and possibly vomiting of blood. If the patient survive sufficiently long he may pass a motion blackened by altered blood. Death takes place in those cases usually from diffuse suppuration spreading in the loose subperitoneal tissue downwards in front of the kidneys or even to the iliac fossæ, in consequence of which peritonitis with effusion is often set up.

An occasional symptom of rupture of the intestine is **Emphysema of the Abdominal Wall**, and subsequently of the trunk generally, from the escape of gas from the wounded intestine into the subperitoneal areolar tissue, and thence into the more superficial planes. When this takes place, the same doughy, puffy, inelastic, crepitating swelling of the subcutaneous areolar tissue, that is met with in thoracic emphysema, is observed. It usually commences in one or the other flank, and may then creep up towards the axilla, or into the anterior abdominal wall.

As a diagnostic sign, this form of emphysema is valuable in those cases in which the intestines have been injured, either without any wound of the abdominal parietes, or, if there be wound, without protrusion of the injured portion of gut. In two of the cases in which I have observed it, this condition was the only positive sign of intestinal injury. In one case, the third part of the duodenum had been ruptured where uncovered by peritoneum, by a buffer accident; and, in the other the rectum and meso-rectum had been traversed by a pistol-ball. In both these cases the emphysema was extensive, the gas having passed directly into the subperitoneal areolar tissue. In other cases it may in the first instance pass into the cavity of the abdomen, and render that tympanitic, and then, as in thoracic emphysema after pneumothorax, escape into the areolar tissue at the edges of the wound. In a case under my observation, it occurred after tapping of the bladder through the rectum. The gas escaped, after the removal of the cannula on the sixth day, through the small aperture in the walls of the gut into the subperitoneal areolar tissue of the pelvis, and thence, through the sciatic notches, down the posterior and outer parts of the thighs and the flanks.

The diagnosis of abdominal emphysema requires to be made from thoracic emphysema, and from putrefactive infiltration of air into the areolar tissue. In the first case, this may readily be effected by the absence of any signs of thoracic injury, and by the situation of the emphysema in the posterior or lateral abdominal wall, or around the lips of a wound. From putrefactive

INJURIES OF THE ABDOMEN AND PELVIS.

Abdominal emphysema is distinguished by the absence of the signs of diffuse inflammation of the areolar tissue.

There can be no doubt that more or less extensive bruising of the abdominal wall is a usual accompaniment of many cases of abdominal contusion which end in recovery. It is necessary, however, that the damage to the wall of the bowels should not be so great as to require any surgical interference. As the result of the separation of the slough the intestinal contents may escape into the peritoneal cavity, with the production of symptoms similar to those which occur when the gut is ruptured at the site of the injury. If, however, the affected portion of bowel becomes encased by adhesions the extravasation and consequent suppuration may be delayed. Under these circumstances the abscess, if left untreated, may slowly point in the abdominal wall, and after it has burst a faecal fistula may result. Macewen has recorded the case of a boy in whom fatal perforation of the bowel occurred forty-seven days after he had been run over by a horse. It thus behoves the Surgeon to be very careful in his treatment and guarded in his prognosis of every case of abdominal injury, and not to assert too hastily that the patient is out of danger.

In considering the question of the **Treatment** of a case of severe abdominal contusion the Surgeon has to choose between the adoption of expectant methods and the performance of an exploratory laparotomy. Every case must be judged upon its own merits, and the universal adoption of either line of treatment in all cases can only lead to disastrous results. The Surgeon who persistently avoids operative interference will be rewarded by finding conditions *post mortem* which a timely operation might have remedied; while on the other hand it is certain that the last chance of life will be taken from many patients, if the shock of an abdominal section be added to that of the injury itself. The presence of severe shock is suggestive of serious damage to one or more of the viscera, but reference has already been made to cases of death from this cause in which no gross visceral lesion has been found. Moreover, it is just in these cases that the dangerous condition of the patient, with cold extremities and flickering pulse, forbids operation, and it may be stated broadly that expectant treatment should be adopted if the only evidence of visceral lesion is the severity of the shock. The same rule must be followed even though there be vomiting and localized or general abdominal pain.

What then are the circumstances under which immediate laparotomy is indicated? First, if the general symptoms of internal hæmorrhage be present, with, it may be, the signs of an extensive effusion of blood into the peritoneal cavity, the Surgeon should open the abdomen, in the hope of arresting the bleeding from a ruptured liver or spleen, and for the removal of such blood as has already been effused. Secondly, if the occurrence of repeated bloody vomiting, with feeble pulse and the other signs of profound shock suggest rupture of the stomach. Thirdly, if the presence of free gas in the peritoneum, with general tympanites obscuring the hepatic dulness, indicates rupture of the bowel. Such a condition is necessarily fatal unless the opening in the bowel be closed, and the peritoneal cavity efficiently cleaned. Lastly, the signs of rupture of the urinary bladder are an indication for immediate laparotomy (p. 894). In certain cases of abdominal contusion operation may subsequently be required although there may have been no indication for its performance at the time of the injury. Thus it may at

times be thought advisable to make an exploratory incision if the shock persist and the seat of the supposed internal injury be suggested by local pain and tenderness. An operation should certainly be performed if the injury be followed by symptoms of peritonitis.

Ruptures of the stomach and intestine must be treated on the same lines as those laid down for the treatment of perforating wounds (p. 881) ; whilst a segment of hopelessly bruised intestine may be treated by resection. Croft has collected 14 cases in which laparotomy was performed for rupture of the intestine ; of these 13 ended fatally. In the successful case, under his own care, the operation was performed 15½ hours after the accident ; there was a small rupture near the end of the jejunum, with faecal extravasation and commencing peritonitis. The damaged piece of bowel was excised and the ends adjusted with Lambert's sutures.

In a second case under the same Surgeon a rupture of the ileum was treated by the formation of an artificial anus ; death occurred four weeks later after a secondary operation for the cure of the artificial anus. Rupture of the liver has been successfully treated by suturing the rent in the organ, or, if this be impossible, by temporarily plugging the wound with strips of antiseptic gauze. The hæmorrhage from a ruptured spleen is so profuse, as usually to be rapidly fatal ; if practicable the ruptured organ should be excised.

In the statistics compiled by MacCormac, Croft, and Morton of Philadelphia, are 20 cases in which laparotomy was performed for supposed rupture or contusion of the abdominal viscera without external wound. Of these only two recovered : one a case of rupture of the intestine under the care of Croft and already referred to ; the other a case of extensive intraperitoneal hæmorrhage in which a branch of the pancreatico-duodenal artery was ligatured by McBurney. In 12 of the fatal cases the intestine was ruptured, and in 2 contused ; in 2 cases the spleen was ruptured, in one of which the organ was excised ; in one case there was rupture of the liver, and in one of the gall-bladder. The operation has, therefore, not as yet been attended with much success ; but Croft's case, and the experience derived from stabs and gunshot wounds treated in the same way shows that in the case of a rupture of the small intestine it does give a chance of life. In ruptures of the solid viscera it is doubtful if much success is likely to attend operative interference. The great mortality of these injuries, if untreated, must however be borne in mind ; thus Chavasse, quoted by MacCormac, estimates the mortality of rupture of the intestine without external wound at 96 per cent., whilst Edler gives the mortality of rupture of the liver as 85·8 per cent., and of the spleen, as 86·7 per cent.

The great difficulty in all these cases lies in making the diagnosis sufficiently early to be of any use. If it be delayed until septic peritonitis has set in, there is little hope for the patient, but even here laparotomy and drainage give the only conceivable chance of life.

In cases in which there are no indications for operation, the Surgeon must endeavour to induce reaction from shock by the means described in Chapter VIII. Opium may be administered freely and nourishment should be given entirely by the rectum. By these means the intestines are kept as completely at rest as possible, and recovery follows in some cases which at first seem hopeless. In cases of internal hæmorrhage, the intravenous injection of salt solution may be of service (p. 412).

In laceration or rupture of the kidney, operative interference is justified by three conditions: First, profuse and prolonged hæmorrhage, filling the bladder with clots, and threatening to prove fatal; secondly, if the symptoms indicate suppuration round the injured kidney; and, thirdly, if a large fluctuating tumour forms which on aspiration is found to be a collection of urine. (See Rupture of the Ureter.) In these cases the kidney may be exposed by a lumbar incision, and, if necessary, removed. (See Surgical Operations on the Kidney, Vol. II.)

WOUNDS OF THE DIAPHRAGM may be occasioned by stabs or by gunshot injury; in rare cases by the fragment of a broken rib, without external wound. The lesion, though not in itself mortal, is usually complicated with so much visceral injury as to be followed by death. If the patient survive, the aperture may be closed by a cicatrix, to which the lung will probably adhere; and thus the separation between the cavities of the chest and abdomen will be maintained. Should this not happen, and the injury be on the left side, a hernial protrusion of some of the abdominal viscera may take place into the pleural cavity. (See Diaphragmatic Hernia.)

WOUNDS OF THE ABDOMEN.—**Wounds of the Abdominal Wall that do not penetrate the Peritoneal Cavity**, if uncomplicated with internal injury, usually do well, and require merely to be treated on ordinary principles. If they be incised, and so extensive as to require sutures, the stitches should be introduced deeply through the muscular and tendinous structures, and the parts injured must also be relaxed by careful attention to position. When they are the result of gunshot injury, they often suppurate extensively, and are slow in healing. The epigastric artery is occasionally divided, and this may give rise to free extravasation of blood into the sheath of the rectus; the wound must then be enlarged, if necessary, the extravasated blood cleaned out, and the artery secured.

Wounds that penetrate the Cavity of the Abdomen are of especial interest, on account of the frequency with which they are complicated with peritonitis, and with injury of the viscera. They may, for practical purposes, be divided into 1, those that are unaccompanied by protrusion of any of the viscera; and 2, those that are complicated by protrusion of one or more of the contents of the abdomen.

1. **Penetrating Wounds of the Abdomen, without Visceral Protrusion**, are often somewhat difficult to distinguish from simple wounds of the abdominal wall, though the escape of a small quantity of reddish serum may reveal the nature of the accident. The distinction can however in many cases be made only by carefully enlarging the superficial wound. Penetrating wounds of this nature are usually complicated with injury of the viscera, but it is a remarkable fact that the cavity of the abdomen may be perforated from front to back by bullet wounds or sword thrusts, without any signs of visceral injury. Senn points out that in gunshot wounds the intestines are more likely to escape if the track of the bullet be antero-posterior than if it traverse the abdomen obliquely or from side to side.

Any of the abdominal viscera may suffer from a penetrating wound, whilst fatal hæmorrhage may result from division of one of the large blood-vessels. Wound of the intestine is a most serious complication, and is very likely to be followed by **extravasation of the intestinal contents** into the peritoneum. This extravasation is unquestionably one of the greatest dangers that can

occur in wounds of the abdomen, and gives rise to the most intense peritonitis. It is not, however, an invariable sequence of penetrating wounds of the intestine, especially if the wound be made by a sharp instrument: and even in bullet wounds of the gut no fecal extravasation may take place. This was well illustrated in a case in University College Hospital of a man who was shot through the abdomen. The intestines, which contained much feculent matter, were traversed by the bullet in four places. He lived twenty-four hours, and yet no feculent extravasation took place. In another case to which I was called, that of a young gentleman who had been accidentally shot through the abdomen with the ramrod of a horse-pistol, the descending colon was cut completely across, and the small intestines perforated in two places: and yet no extravasation took place, though he survived the accident two days. Otis, however, points out in the Report of the American War, that these cases are entirely exceptional, and that in the vast majority of gun-shot wounds of the intestine, fecal extravasation does take place, and gives rise to fatal peritonitis. That certain cases escape this danger may be due to several causes. In the first place, if the wound in the gut be under a certain size, there is a natural tendency to its occlusion by eversion of the mucous membrane. In other cases again, as in the duodenum or colon, the gut may be wounded at a part that is not covered by peritoneum. Besides this, it must be borne in mind that, though in ordinary language we speak of the "cavity" of the abdomen, there is in reality no such thing: there being no empty space within the peritoneal sac, but the whole of the visceral contents of the abdomen being so closely and equably brought into contact by the pressure of the abdominal muscles and of the diaphragm, that it requires some force for the intestinal contents to overcome this uniform support, and to insinuate themselves between the coils of contiguous portions of intestine. The influence exercised by the continuous pressure of the abdominal walls upon the intestinal contents is well shown by the greater facility with which these escape from a portion of wounded intestine that has been protruded than from one that is still lying within the abdomen. In the former case, feces will escape from a much smaller aperture than in the latter. The close and uniform contact of the coils of intestine with each other also favours the adhesion of the wounded coil to the neighbouring parts, and thus tends either completely to prevent or to limit fecal extravasation. In some cases also it is probable that the shock of the injury arrests for the time the peristaltic movements of the gut, and in these circumstances adhesions sufficiently firm to prevent fecal extravasation may form within twenty-four hours. Thus, in a case under my care, the patient, a young man, aged 22, cut his throat, and stabbed himself twice in the abdomen with a dinner-knife. One of the wounds divided more than a third of the circumference of the jejunum. The patient survived thirty-six hours, and at the *post-mortem* examination the wounded coil was found to contain blood and liquid contents, but it was adherent by firm inflammatory exudation to the neighbouring coils of intestine, and no extravasation had taken place. The patient more frequently escapes without extravasation when the great gut is wounded than when the small intestine is perforated.

When the contents of the intestine escape into the peritoneum diffuse peritonitis almost invariably results, the feces becoming mixed with the abundant inflammatory effusion. In rare cases, however, extravasations, whether of feces or blood, if in small amount, may show but little tendency to diffuse

themselves, and may become localized in the neighbourhood of the part from which they were originally poured out; owing, in the first instance, to the surrounding pressure, and, at a later period, to the formation of adhesions between the folds of intestine and the neighbouring viscera.

In rare cases, the existence of a wound of the intestine is proved by the escape of the intestinal contents through the wound in the abdominal wall. In a certain number of cases there is emphysema of the abdominal wall, and very rarely hæmorrhage from the rectum. The evidences of free gas in the peritoneum may sometimes be present. All these symptoms of wound of the intestine are, however, absent in the majority of cases: their presence is of the greatest value in determining the existence of a wound of the bowel, but on the other hand the Surgeon is not justified in concluding that no such injury exists because the above-mentioned symptoms are absent.

2. Penetrating Wounds of the Abdomen with Visceral Protrusion are much less common than those above described. Intestine, mesentery, or omentum may protrude through the opening in the abdominal wall, and the bowel may or may not be wounded. The protruded mass is often large in comparison with the aperture from which it escapes, the sides of which constrict it tightly, so as to form a distinct neck to the protrusion. If left unreduced, the mass speedily loses its polish and bright colour, becoming dull and livid from congestion; it then swells, and soon becomes gangrenous from the pressure exercised upon it by the sides of the aperture.

The existence of a wound of the protruded bowel will readily be ascertained by the escape of gas, or of the fluid contents of the gut. The characters of the wound vary, as Travers pointed out, according to its size. If it be a mere puncture, or even an incision two or three lines in length, eversion or prolapse of the mucous membrane will take place, so as to close it sufficiently to prevent the escape of the contents. If the aperture be above four lines in length, the plugging of it by everted mucous membrane cannot occur, and then the contents of the bowel escape; but, even in these circumstances, there will be a tendency to the protrusion of the membrane, which forms a kind of lip over the edge of the cut.

Although the protruded portion of intestine be uninjured, it must be remembered that a wound of some neighbouring coil, which has not escaped from the abdomen, may yet be present.

Prognosis of Penetrating Wounds of the Abdomen.—Penetrating wounds of the abdomen are amongst the most fatal of all injuries. In the reports of the American Civil War, thirteen cases of punctured or incised wounds without injury to viscera are recorded, with nine recoveries, and nineteen similar injuries from gunshot, with twelve recoveries. Of fourteen recorded cases of punctured or incised wounds with visceral lesion only two recovered. The recorded cases of gunshot wound with visceral injuries amounted to 3,771, and of these only 421 recovered, and in 242 the result was unknown. In the great majority of these cases the exact visceral injury was not recorded. In seventy-nine the stomach was wounded, and of these nineteen recovered. In 653 the intestines were wounded, and of these 118 recovered; but the exact part of the gut is not specified in a large proportion of these cases. Otis, however, states that he has been unable to find a single incontestable case of bullet wound of the small intestine in which recovery took place. On the other hand, there are good records of at least fifty-nine cases

of wound of the great intestine, which terminated favourably, usually with a temporary establishment of a fæcal fistula. The liver was wounded in 173 cases, of which sixty-two recovered. Injuries of the spleen were more fatal, only two recovering out of twenty-nine cases. In seventy-eight cases the kidney was wounded, and of these twenty-six recovered. Of the 2,599 cases in which the lesion was not specified, only 186 are reported as having recovered. It is evident, therefore, that the records of the cases in which the exact injury is specified give much too high a proportion of recoveries, the mere fact of the patient's surviving having led to a more detailed account of the injury being preserved.

Treatment.—In many cases there is doubt as to whether or not the wound has actually penetrated the peritoneal cavity. Under these circumstances it is the duty of the Surgeon carefully to enlarge the wound and follow the track to its deepest part, with the object of ascertaining the presence or absence of penetration. By this means much more certain information is obtained than by the mere use of a probe, and with less risk of converting a non-penetrating wound into a penetrating one. Having in this way determined that the wound does really enter the abdominal cavity, the Surgeon should proceed to determine whether or not visceral lesion exists. If wounded bowel is protruding from the wound, the nature of the injury is obvious, but if no such protrusion exists, the presence of a wound of the stomach or intestine cannot as a rule be recognized with certainty by the symptoms. It has already been pointed out that the nature of the injury is but rarely evidenced by the escape of intestinal contents from the wound or the existence of the other symptoms mentioned above (p. 878). In the unusual cases in which the wound in the abdominal wall is sufficiently extensive to allow a thorough examination of the contents of the abdomen, this should be done. In simple stabs and in gunshot wounds this is impossible, and the only way of clearing up the uncertainty is to enlarge the wound, or to open the abdomen in the middle line, and to examine the abdominal viscera. This treatment may seem severe, but experience has taught us that an exploratory incision into the abdomen, if undertaken with proper precautions, is practically free from danger; and, on the other hand, if we wait till the injury to the intestine becomes evident by the commencement of septic peritonitis, the case is altogether hopeless. The advantages of the median incision over enlargement of the wound are very great. It enables the whole length of the intestines to be systematically examined, commencing from the cæcum, which is usually easily recognizable, and working upwards to the duodenum. It also greatly facilitates the necessary cleaning of the abdominal cavity. In performing the operation all the details described in Chap. LXI., Vol. II., must be strictly attended to. The method of treating the intestine is described on pp. 884 *et seq.*

Gross many years ago expressed the opinion that in such cases "the duty of the Surgeon is to enlarge the abdominal orifice, to seek for the wounded tube, and to sew up the cut." He did not, however, anticipate much benefit from this treatment in gunshot wounds, owing to the multiplicity of the openings in the gut met with in such cases.

Reference must here be made to a method introduced by Senn, of Chicago, for the detection of wounds of the stomach and intestines. He has shown that hydrogen gas injected into the rectum can be made to pass along the whole length of the intestinal tract as far as the stomach, from which it can

be withdrawn by an œsophageal tube. If, however, the intestine be wounded, the gas fails to reach the stomach, but passes into the peritoneal cavity, and escapes from the external wound if such be present. In one hundred cases of experimental gunshot wounds of the abdomen of dogs, the method did not fail. In six cases of gunshot wound, Senn employed the method clinically: in two cases which recovered with expectant treatment, the absence of intestinal wound was proved by the hydrogen test. In one case in which eleven wounds of the intestine were successfully sutured, one of them would have escaped notice had not hydrogen been injected after the other wounds had been closed. The method has not proved so certain in the hands of some other Surgeons who have employed it, but it certainly seems worthy of further trial.

Morton of Philadelphia has collected 79 cases in which laparotomy was performed for stab wounds of the abdomen; of these 48 recovered and 31 died. This series includes 13 wounds of the stomach, with 8 recoveries; 27 wounds of intestine, with 14 recoveries; 7 wounds of the mesentery or omentum with 5 recoveries. In one case the spleen was excised with a fatal result. Of 6 cases of wounded liver 2 recovered, the wound being sutured in one and packed with gauze in the other. In one case an intraperitoneal wound of the bladder was successfully sutured. In 4 other cases ending fatally there was peritonitis at the time of the operation in 3, and injury to the colon in one. Of 19 cases in which no visceral injury was found 16 recovered. In one case ending in recovery the nature of the injury is not stated.

Of 110 cases of gunshot wounds of the abdomen treated by laparotomy 36 recovered and 74 died. In these the intestine only was wounded in 63, and 21 recovered; in 5 the stomach, and 1 recovered; in 6 the stomach and intestines with one recovery. Wounds of the liver were present in 15 instances, with six recoveries, in one of which the right kidney was excised. Four times the abdomen was laid open and no visceral wounds were discovered: all of these recovered. In most of the remaining cases the injuries were complicated, and in 4 there was peritonitis at the time of operation.

Miles of New Orleans has recorded a case of gunshot wound of the abdomen in which sixteen perforations of the small intestine and three wounds of the mesentery were sutured, the patient making a speedy recovery.

The results of operative interference in penetrating wounds of the abdomen must on the whole be looked upon as hopeful. The mortality after gunshot wounds so treated is as high as 67 per cent.; but in the large majority of the cases the injuries would have been almost necessarily fatal. It is important also to observe that of 23 cases in which no internal injuries were found only 3 died.

Although therefore it may be laid down as a general rule that penetrating wounds of the abdomen should be treated by an exploratory laparotomy, circumstances may arise in which this treatment is impracticable. Without all the means necessary for efficient antiseptic precautions it should not be undertaken in doubtful cases. The wound should be closed with sutures, preferably of silver wire, and a dry absorbent dressing applied. The patient should have a full dose of opium; about two grains of the solid opium or a hypodermic injection of the third of a grain of morphia may be given, after which the effect must be kept up by doses of half that amount, repeated every four or six hours. This serves the important purpose of arresting the peristaltic

movement of the intestine and thus preventing extravasation from any wound of the bowel which may be present.

Travers showed experimentally—and his investigations have been confirmed by subsequent observations on the human subject—that wounds of the intestines are closed by lymph that is thrown out, not only from the contiguous peritoneal surfaces of the part actually injured, but from that of neighbouring coils; so that the aperture in the gut becomes permanently glued and attached to the structures in its vicinity. In order that this process should take place, it is necessary that the movements of the bowels should be arrested until the adhesions have become firm enough to prevent extravasation of fæces. The patient must be kept perfectly quiet in bed, and no nourishment given but iced milk, or milk and soda-water, and some cold beef-tea or essence of meat, during the first three days. The bowels should not be opened by aperient medicine, lest abdominal irritation be set up, but oleaginous enemata may be administered at the end of a week or ten days.

If the symptoms of extravasation of feculent matter into the abdomen present themselves, an attempt must be made to facilitate its escape externally. The dressing must be removed, and, should the lips of the wound have already become adherent to one another, they should be carefully separated. Should an immediate escape of feculent matter take place, a drainage-tube should be inserted to ensure a ready exit for the discharges.

In those cases in which the wound is situated in the loin the gut may be wounded without implication of the peritoneum, as in lumbar colotomy. In these recovery commonly takes place with the formation of a faecal fistula. In the early stages it may be necessary to enlarge the opening to prevent burrowing of matter in the loose tissue around the gut.

When a portion of intestine or of omentum has protruded, it should be carefully cleaned with an antiseptic lotion and replaced as speedily as possible, before strangulation has occurred, which may occasion gangrene.

If the protruding bowel be wounded it must be treated in the manner presently to be described.

Experience has shown that carbolic acid lotion (1 in 40), or perchloride of mercury (1 in 2000), or dilute tincture of iodine (5ij to Oj) exerts no injurious influence on the bowel. In replacing the protruded gut, the abdominal muscles should be relaxed by bending the thighs upon the abdomen and raising the shoulders, when the Surgeon may gradually push back the protrusion by steady pressure upon it; he must not, however, employ any force, nor any rough handling of the exposed parts; but if their return cannot readily be effected, owing to the constriction of the neck of the protrusion, the aperture through which they have escaped must be enlarged in a direction upwards, by means of a probe-pointed bistoury, or a hernia-knife guided by a flat director. In replacing the protruded parts, whether by the aid of incision or not, care must be taken that they are fairly put back into the cavity of the abdomen, and not pushed up into the sheath of the rectus, or into the subserous areolar tissue lying before the peritoneum: an accident that would be fatal by allowing the constriction of the neck of the protrusion to continue unrelieved. The protruded gut or omentum should be allowed to remain in the immediate neighbourhood of the wound, to which it will contract adhesions; and through which its contents may escape, in the event of any sloughing taking place. After the gut has been returned, the external wound must be closed by sutures.

If the protrusion be inflamed, it must equally be replaced without delay : but should the intestine have become gangrenous from continued constriction and exposure, the Surgeon will have the choice between two lines of treatment :—excision of the gangrenous portion of intestine, or the formation of an artificial anus to be cured subsequently by a secondary operation.

If any difficulty be found in returning a mass of protruded omentum it may be ligatured in one or more pieces with carbolized catgut or silk, and cut off, after which the stump can easily be passed into the abdominal cavity. If the protruded omentum be gangrenous, it must be excised on a level with the peritoneum, to the aperture in which that portion lying within the abdomen will have contracted adhesions.

Treatment of Wounded Bowel.—In most cases of wound of the stomach or intestine by stabs of the abdomen it will be found possible to close the wound with sutures. In some cases of gunshot wound, however, and sometimes when the intestine is ruptured by a contusion of the abdomen, the nature of the injury renders this simple treatment impossible. Under these circumstances excision of the damaged segment of bowel and suture of the two ends have been successfully practised.

For the successful suture of a wound of the bowel it is essential that the

Fig. 322.—Application of Lambert's Suture to Wounded Bowel.

Fig. 323.—Lambert's Suture, a, serous; b, muscular; and c, mucous coat.

serous surfaces be brought well into contact. It is almost needless to observe that no union can possibly take place between two mucous surfaces, or between a serous and a mucous surface. Leakage after suture is most apt to occur from the extremities of the wound, and whatever form of suture be employed, it must be commenced and finished well beyond the ends of the opening.

Carbolized or chronic catgut and very fine carbolized silk are the materials usually employed, and it is very possible that these may be absorbed without ulcerating into the gut if they are applied so as not to include the mucous membrane. Very fine silk is generally preferred as being more manageable, and tying more accurately. The sutures should be introduced by means of fine round sewing needles. The ordinary flat surgical needle cuts the gut to such an extent that the sutures may fail to hold.

With the view of stitching together the serous surfaces, much ingenuity has been displayed, and many devices have been practised. The mode of

application most frequently adopted in the present day is that recommended by Lembert. The needle is introduced about a quarter of an inch or a little more from the wound, and made to penetrate as far as the submucous tissue; it is then brought out again about one-sixth of an inch from the edge of the cut on the same side; on the opposite side, it is made to enter one-sixth of an inch from the edge of the cut and brought out at a quarter of an inch from it (Figs. 322, 323). The stitches must not be more than a line apart, and the whole number required must be introduced before any are tightened. One or more stitches at each end must be inserted beyond the limits of the wound, otherwise leakage is inevitable. When the sutures are tightened the mucous membrane is inverted, and the serous surfaces are brought into accurate contact. This suture is easily applied in the stomach or large intestine, but from the thinness of the coats of the small intestine it is not quite so easy of application in that part. If there is any difficulty the suture may be applied in the same way, but may be made to penetrate the whole thickness of the gut on each side, as recommended by Jobert (Fig. 324).

Fig. 324 - Jobert's Suture for partial division of the gut.

Fig. 325 - Application of Gely's Suture to Wounded Bowel.

The great objection to this is, that the stitches are apt to become irritating by absorbing the contents of the intestine. When the lips of the wound have been brought into apposition, the ends of the sutures should be cut short close to the knots.

Gely's method of suture is sufficiently explained by the accompanying figure (Fig. 325). It undoubtedly brings the serous surfaces into good apposition, but is not so easy of application as Lembert's method. All continuous sutures have the great disadvantage that if one stitch happen to cut the whole becomes loose.

Various methods of suture have been devised for the union of intestine which has been completely divided, or for use in those cases in which resection of a portion of damaged bowel is necessary. The same methods are available after the removal of portions of intestine for gangrene in strangulated hernia, for adhesion to abdominal tumours, for malignant growths of the gut, &c.

The damaged loop of intestine must be carefully withdrawn from the abdomen, and the incision in the abdominal wall closed with carbolized sponges. The bowel is next clamped above and below the part to be excised.

This can be quite efficiently done by the fingers of an assistant, but numerous clamps have been devised, of which one of the best is that recommended by Makins. A simple method consists in surrounding the gut with a piece of small drainage-tube passed through the mesentery and knotted or held in catch-forceps. The segment of bowel is now removed, care being taken that the incisions are made well beyond the diseased or injured portion. If the part requiring removal is small no mesentery need be excised; if large, a triangular piece of the mesentery should be cut away, and the edges sutured. Whatever method be employed for uniting the intestine, great care must be taken in inserting the sutures at the mesenteric border, where a narrow strip of the muscular coat is exposed between the layers of the serous membrane.

The principal methods of uniting the intestine will now be shortly described.

1. *Czerny-Lembert Method.*—This consists of a double row of interrupted

Fig. 326.—Czerny-Lembert Suture for Divided Intestine. First Stage: Application of Sutures to the Mucous Membrane.

Fig. 327.—Czerny-Lembert Suture for Divided Intestine. Second Stage: Application of Sutures to the Serous and Muscular Coats.

sutures. The first row approximates the edges of the mucous membrane, and the knots are as far as possible tied inside the bowel. The second row includes the serous and muscular coats, and is passed after the manner of Lembert's

Fig. 328.—Maunsell's Method of Intestinal Suture. First Stage.

suture above described (Figs. 326, 327). MacCormac looks upon the inner row of sutures as unnecessary, and advises the use of a single row of Lembert's sutures only.

2. *Maunsell's Method*.—The ends of the bowel are first brought together by two temporary sutures, one introduced at the mesenteric border and the other opposite this. A longitudinal incision about an inch and a half long is made in the lower segment of the gut opposite the mesenteric border; the incision begins one inch from the line of division (Fig. 328). The ends of the temporary sutures are drawn out through this incision, and by gentle traction

Fig. 328.—Maunsell's Method. Second Stage: Introduction of Sutures.

the divided ends of the gut are invaginated through it, the peritoneal surfaces being in contact all round. Sutures are now easily passed through all the coats of the two portions of intestine (Fig. 329). The temporary stitches are now removed, the gut drawn back, and the incision in the lower part closed with

Fig. 329.—Maunsell's Method. Third Stage: Closing Incision with Lembert's Sutures.

interrupted Lembert's sutures (Fig. 330). Maunsell recommends stout horse-hair as the best material for the sutures.

3. *Paul's Method*.—A decalcified bone tube, having a needle and strong silk thread attached, is sewn with fine catgut into the upper end of the intestine. The traction thread is passed through the wall of the lower segment about three inches down (Fig. 331). The cut ends of the intestine are now sewn together with fine catgut, and the edges of the divided mesentery adjusted. By firm traction on the thread a short invagination is produced, and retained in position by three or four Lembert sutures (Fig. 332). The traction thread is then cut off short, and its ends dropped into the bowel. The principle of union of divided intestine by the formation of an invagination

was first recommended by Jobert in 1822. His method is illustrated in the accompanying diagrams (Fig. 333, 334). Senn has recommended a very similar method; instead of the bone tube an india-rubber ring is stitched with catgut into the proximal end of the bowel, before the invagination is made.

Fig. 331. — Paul's Method of Intestinal Suture. The bone tube is secured in position by a fine suture, and the silk threads attached to it are passed along the distal end of the bowel.

Fig. 332. — Paul's Method. Diagram showing production of invagination.

All the above methods of intestinal suture have been successfully employed, but at the present time it is impossible to decide which is likely to be found the most generally useful. The first two methods have the advantage of requiring no special apparatus. The Czerny-Lembert suture or some modification of it is easy to apply and has given excellent results. Objection has been raised to Maunsell's method that the sutures pass through all the coats of the bowel. The risk of leakage along the sutures is small if horsehair be used as recommended by Maunsell, whilst

Fig. 333. — Jobert's Suture for complete Transverse Division of the Intestine.

Fig. 334. — The Suture Tightened. The figure shows a Lembert's Suture introduced to give additional security.

it may be advisable to insert a few additional points of Lembert suture as suggested by Stanley Boyd, who has successfully employed the method. Senn's method of so-called "lateral anastomosis" by the use of decalcified bone plates does not appear to present any special advantages in the suture of two segments of intestine of the same calibre (see Chap. LXIV.). In any case of intestinal suture additional security may be attained by adjusting an omental graft over the line of the sutures, as suggested by Senn.

The sutured intestine is carefully cleansed and replaced in the abdomen,

and great care must be taken in thoroughly purifying the peritoneal cavity. This is best done by repeated sponging, aided perhaps by flushing with water sterilized by boiling or with boric acid lotion.

Finally, the wound in the abdominal wall is closed with silk sutures passed through its whole thickness.

In the after-treatment, care must be taken, by attention to the position of the patient, and by the free administration of opium, to keep the bowel as quiet as possible: the urine should be drawn off twice in the twenty-four hours, and no purgative whatever administered, lest, by the excitation of peristaltic action, adhesion be disturbed, and extravasation take place. After the lapse of eight or ten days an enema may be thrown up, and repeated from time to time. No food should be allowed for the first three days, during which time ice and barley-water should be freely taken: after this, beef-tea, and light food that leaves no solid residue, may be given. It is of great importance that no solid food should be administered for at least two or three weeks after the occurrence of the injury. In a case of knife-wound of the intestine which was under my care, the patient, who was progressing very favourably, and eventually recovered, nearly lost her life by eating the pulp of an orange on the tenth day.

In the treatment of extensively wounded intestine, the only alternative open to the Surgeon is to fix the edges of the opening in the gut to the margins of the external wound in the skin, in the hope of an artificial anus being formed, which may possibly afterwards be closed, either by the contraction of the wound or by operation at a later period. This method should, however, never be adopted when resection and suture are possible, as should the patient escape the danger of peritonitis, the operation for the subsequent cure of the artificial anus is necessarily a serious one.

WOUNDS OF THE KIDNEY.—These may be caused by stabs or bullet-wounds in the lumbar region. The symptoms characteristic of this injury are the same as in rupture (p. 873), with the addition of the open wound, from which urine may escape. The experience of operations for the removal of stones from the kidney has taught us that a simple wound of that organ is not accompanied by any very serious danger if proper drainage be provided. In deep stabs in the loin, implicating the kidney, the best practice would be to enlarge the wound so as to expose the gland. If it be so injured that it is not likely to heal, or if there be hæmorrhage which threatens life, the kidney may be removed (see Nephrectomy). If it is but slightly wounded, a drainage-tube may be inserted, and the wound treated as after nephrotomy (see Nephrotomy). Gunshot wounds of the kidney are usually complicated by injuries of other viscera and wounds of the peritoneum, and in these but little can be done. Enlarging the wound if it be in the loin, and providing good drainage, would give the patient the best chance of life.

CYSTS IN THE ABDOMEN AFTER INJURY.—Large collections of fluid are occasionally met with in the abdomen as a remote consequence of injury, not connected with the kidney. These seem to be, in some cases at least, formed by imperfectly absorbed extravasations of blood enclosed in a space formed by adhesions amongst the surrounding viscera. In one case under Marshall in University College Hospital the injury had been in the region of the spleen, and some months after more than a pint of darkly-stained fluid was removed from a cyst filling the left side of the abdomen. The cavity was drained, and the patient, a girl aged about 12, recovered.

Cysts in connection with the pancreas which occasionally follow abdominal injury are described in Chap. LXIV., Vol. II.

TRAUMATIC PERITONITIS is the great danger to be apprehended in all serious injuries of the abdomen. It occurs in two forms, the localized and diffuse. **Localized Peritonitis** may follow a severe contusion, without recognizable injury to any viscus. It occurs also in cases of wound or rupture of the intestine, in which there is no extravasation of the contents of the gut, and in slight lacerations of the liver, spleen, or kidneys. Localized peritonitis is accompanied by the pathological phenomena common to all inflammation; the vessels become engorged and exudation takes place, composed of blood-plasma, more or less pure, and migrating white corpuscles. The exudation coagulates, the fibrin and the corpuscles forming the "lymph" which glues the contiguous surfaces of the peritoneum to each other, and the serum draining away into the cavity of the abdomen, from which it is rapidly absorbed. In these cases, in which there is no persistent source of irritation, the inflammation speedily subsides, the exudation becomes penetrated by new vessels, and finally firm bands of fibrous tissue are formed, uniting the coils of intestine or the injured viscera to each other or to the abdominal wall. In other cases again, firm adhesions may form at the circumference of the inflamed area, and the process may reach the stage of suppuration opposite the wound of the gut in consequence of a very slight escape of its contents, or the same may occur opposite a wound or laceration of one of the solid viscera. There is thus formed a collection of pus bounded by the neighbouring viscera or coils of intestine, and shut off by firm adhesions from the general cavity of the abdomen. Such a collection of pus may finally burst through the surrounding adhesions, and thus set up diffuse peritonitis, or it may make its way into one of the hollow viscera or to the skin, and be safely discharged.

The **Symptoms of Localized Peritonitis** are intense pain and tenderness over the affected spot; often aggravated by movement or respiration. There is some elevation of temperature, and there may be vomiting. Should a localized collection of pus form, the tenderness and pain will remain, there will be a definite swelling and hardness to be felt at the affected part. The febrile disturbance remains unrelieved, and there may be one or more rigors. Should the pus burst through the surrounding adhesions and find its way into the general cavity of the peritoneum there will be intense sudden aggravation of the pain, followed by the symptoms of diffuse peritonitis.

Diffuse Peritonitis occurs first, as the result of extravasation of the contents of the gut, either in penetrating wounds from without or from within the gut, or from ruptures from external violence; and secondly, from decomposition of extravasated blood or inflammatory exudation in the cavity of the peritoneum. The putrefactive ferment may find its way into the cavity of the peritoneum from without by means of an external wound, or from within, from the intestine, either by rupture or perforation of its coats, or in consequence of sloughing of the wall of the gut from the violence to which it has been exposed. The experience of the operation of ovariotomy shows us that the peritoneal cavity may be opened and freely exposed to the air without any great risk of the occurrence of septic peritonitis provided that it be thoroughly cleaned and no decomposable matter be left within it. The subject has further been experimentally investigated in animals by Wegner, and the results obtained by him tend to show, that if only a portion of the per-

toneum be exposed to irritation, the liquid exudation is rapidly absorbed by the healthy part of the membrane, so that the cavity is kept dry and free from putrescible matter. In rabbits it was found that a considerable quantity of simple water, or even of fluids containing septic bacteria, could be injected into the peritoneal cavity without evil results following, the fluids being rapidly absorbed and carried into the blood-stream. If, however, the quantity injected was greater than could be thus rapidly disposed of, septic peritonitis invariably followed. It seems probable, therefore, that the occurrence of septic peritonitis after wounds opening the cavity of the abdomen, whether in surgical operations or in accidents, depends to a great extent upon the amount of putrescible matter in the cavity. If from a wound of some considerable vessel a large quantity of blood is extravasated, or if in consequence of local irritation, as from a wound or rupture of the gut with or without slight faecal extravasation, the amount of inflammatory effusion is greater than the uninjured part of the peritoneum can rapidly absorb, the putrefactive ferment finds material upon which it can act, and decomposition and septic peritonitis follow. With a clean peritoneal cavity and little exudation the patient escapes. In injuries of the liver, peritonitis may result from the escape of bile into the cavity of the abdomen without decomposition taking place.

In a case of diffuse peritonitis the *post-mortem* examination shows excess of fluid which, in the earlier stages, is found chiefly in the most dependent parts, the cavity of the pelvis and the flanks. The intestines are reddened, and the coils are distended. In the earliest stage the peritoneal surface has lost its natural gloss to some extent, and feels greasy. When the inflammation is further advanced, lymph is found on the gut, and especially in the angles between two contiguous coils. If two coils be separated, they will be found paler in colour from mutual pressure at the points which have been in contact, and marked by a darker red line where they separate. The intestines are very slightly adherent to each other. In the most dependent parts of the cavity is a large quantity of turbid serum, mixed with shreds of coagulated exudation, or the fluid may assume the form of thin pus. It is usually very offensive, and is excessively dangerous if inoculated, giving rise to the worst forms of dissecting-wound. Gas from the intestines is also frequently met with in the abdominal cavity.

The **Symptoms of Diffuse Peritonitis** are pain and tenderness, at first most marked in the neighbourhood of the injury, but gradually extending to the whole abdomen, and aggravated by occasional stabbing pains. This is followed by tympanitic distension of the abdomen, from paralysis of the muscular coat of the gut, and also in some cases partly from the escape of flatus into the peritoneal cavity. The patient suffers great distress; he lies on his back with his knees drawn up to relax the abdominal muscles, and the slightest pressure causes intense agony. Occasionally, respiration is seriously interfered with by the distension of the abdomen. Vomiting is an early symptom; the contents of the stomach are brought up without straining, seeming to pump out almost without effort. As the effusion increases, there will be dulness in the flanks, shifting its position as the patient is moved, and tympanitic resonance in front. As the case advances, the vomited matter becomes dark from admixture of blood from the congested mucous membrane. Hiccup may be a troublesome symptom. The pulse is at first small, quick,

and hard, often assuming a wiry, incompressible character. The temperature is at first high, reaching often 103 or 104 Fahr.; but in septic cases it usually falls rapidly before death, and may even become subnormal. There is great anxiety of countenance, and before death the extremities become cold, and the patient dies with the signs of collapse. This diffuse traumatic peritonitis will set in and run its course with great rapidity. In a case in University College Hospital already alluded to, of bullet-wound in the abdomen, the patient lived twenty-four hours. Two or three pints of serous effusion with much puriform fluid were found; and great reddening of the whole of the visceral, and much of the parietal, peritoneum had ensued. In another case of rupture of the ileum, the consecutive peritonitis proved fatal in about thirty hours after the accident. This extreme rapidity in its course and fatal termination is due to the rapid absorption of the unhealthy inflammatory products, in septic cases aggravated by the presence of the products of putrefaction; in fact many of these cases form the most marked instances of this form of blood-poisoning. The rapidity of the fatal termination is due to the great extent of the absorbing surface, and the large dose of the poison that is thus taken up in a very short time.

Treatment of Traumatic Peritonitis.—In the treatment of this complication, we must be guided by the character of the inflammation. If the peritonitis be localized, leeches may be applied over the tender part of the abdomen, followed by hot fomentations, and opium must be administered in moderate doses. Operative interference should be avoided, unless there be evidence that suppuration has occurred, in which case the abscess should be opened and drained. Great care must be taken not to break down the adhesions by which the abscess is surrounded, lest general peritonitis be the result.

The occurrence of diffuse peritonitis after an abdominal injury is usually an indication for immediate laparotomy, and the same treatment should be followed, even though the peritonitis has occurred after an operation for wound of the intestine or stomach. The chances of recovery under these circumstances are remote, but success has followed the closure of a wound of the bowel even when peritonitis was already present. The peritoneal cavity should be carefully flushed, and free drainage provided for by a tube passed down into the pelvis.

Allopathics should be strictly avoided, and opium given in doses sufficient to allay pain. In these cases nourishment must be given in a fluid form only, and the administration of stimulants will often be required.

INJURIES OF THE PELVIC VISCERA

BLADDER.—**Rupture of the Bladder**, from blows upon the abdomen, is not a very unfrequent occurrence. It can scarcely happen when the organ is empty, as it then lies under cover of the pubes. But when the bladder is distended, and thinned proportionately to its distension, it may very readily be ruptured, even by slight degrees of external violence, as by one man falling over another in a drunken scuffle, or by a person running against a post, or falling out of bed.

When the bladder is ruptured by a blow on the abdominal wall, the rent takes place almost invariably through that portion of it which is covered by peritoneum, which is the least supported as well as the thinnest part of its

viscus. Hence there is extravasation of urine and blood into the abdominal cavity. When **the bladder is wounded** by gunshot or other injury, such as by falling on a spike, which penetrates the perinæum or rectum, or by a splinter of a fractured pelvis, those anterior and inferior parts of the organ which lie outside the peritoneum may be perforated, and thus intraperitoneal extravasation may not occur. In any case the shock following rupture of the bladder is usually great; but the secondary consequences will of course depend on the situation of the rupture or wound. If the laceration have occurred in those portions of the viscus that are invested by peritoneum, the urine will at once escape into the pelvic and abdominal cavities, and speedily occasion death by causing intense inflammation. If, on the other hand, that portion of the organ has been ruptured which is uncovered by the peritoneum, the urine may infiltrate the areolar tissue between this membrane and the abdominal wall, and, diffusing widely, produce destructive sloughing of the tissues. In these cases life may be prolonged for some days, when the patient commonly sinks from absorption of septic matter from the gangrenous tissues.

The danger of a wound of the bladder is due to the effusion of continually increasing quantities of urine. It is in exact proportion to the difficulty that the extravasated urine has in finding an exit. Hence an open wound of the bladder is by no means so dangerous as a subcutaneous rupture. Many patients have recovered whose bladders have been perforated and traversed by bullets, for the urine finds a free exit through the apertures, and consequently does not tend to extravasate. Guthrie relates several cases of this kind; and Thomson saw fourteen cases after the battle of Waterloo, in a fair way of recovery. In the American War, out of one hundred and eighty-three reported cases of gunshot wound of the bladder, eighty-seven patients survived, "though a large majority suffered from grave disabilities, and many from distressing infirmities, which resulted fatally in a few cases after years of suffering." Thus, although we may look upon this accident as of the gravest character, yet it is by no means necessarily fatal. Probably in most of those who recovered, the wound did not implicate the peritoneum.

Symptoms.—The situation of the injury in the hypogastric region, the supervention of collapse followed by intense burning pain in the abdomen and pelvis, with inability to pass urine, or, if any have escaped from the urethra its being tinged with blood, are usually sufficient to point to the nature of the accident. If, in addition, it be found on introducing a catheter that the bladder is contracted and empty, or that but a small quantity of bloody urine escapes, not in a uniform stream, but rising and falling with the movements of the abdominal muscles, the Surgeon may be sure that this organ has been ruptured. In the case of gunshot injury, the escape of urine which generally takes place through the track of the bullet will afford incontestable evidence of the mischief that has been produced.

When the bladder is ruptured through that portion which is covered by peritoneum, the urine escapes into the abdominal or pelvic cavity; there, however, it does not at first diffuse very widely—remaining, under the influence of gravity, chiefly in the pelvic cavity, with the small intestines floating above it. This localized extravasation may be emptied by the catheter through the rent in the bladder, hence the escape of urine is not incompatible with rupture of the bladder. This important practical point is well illustrated by the following case. A man was admitted into the Hospital under my care,

who had suffered rupture of the upper and posterior wall of the bladder by falling down stairs; when admitted he was profoundly collapsed and semi-unconscious. The abdomen was swollen, tender, tympanitic in front, dull in the flanks. On passing a catheter the bladder was found to be empty and contracted: but with a little gentle manipulation the point of the instrument could be passed through the laceration in the posterior wall of the bladder, and a large quantity of clear urine was drawn off. For two days the patient seemed to be doing well. The catheter was taken out to be cleaned, could not be introduced afterwards, little urine escaped, and the patient died of peritonitis. In another case under my care, the patient lived ten days, the bladder being kept drained.

Keen suggests injection of filtered air or hydrogen: if no rupture exists a tense tympanitic tumour will rise above the pubes; whilst if the bladder is ruptured the air will escape into the peritoneal cavity. As an additional means of diagnosis in a case where rupture of the bladder is suspected, it has been recommended to inject it with boric acid lotion; if the bladder be intact it will be felt to become gradually distended and the total quantity of fluid injected will return through the catheter.

When the rupture does not implicate the peritoneum the most important point in the **Treatment** consists in drainage of the organ, in order to prevent extravasation of urine. This is best effected by means of a full-sized catheter, tied in and connected to a long india-rubber tube passing into a basin of carbolic acid lotion. Should this not be efficient, free drainage must be ensured by suprapubic or perineal cystotomy.

When the peritoneum is implicated, drainage by a catheter or cystotomy is much less hopeful, and although cases have recovered when treated in this way, the results have not been sufficiently satisfactory to justify us in relying upon them. Abdominal section and suture of the rent in the bladder hold out a far better prospect of success.

Kerr of Washington has collected 29 cases in which this operation has been performed up to the middle of 1893. In 23 of these the wound in the bladder was closed by sutures; of these 9 recovered. Of the four successful cases in this country, two were treated by MacCormac, one by Holmes and one by Walsham. In two earlier cases under Heath and Willett the sutures gave way and death occurred from peritonitis. In 6 cases no sutures were introduced. Of these 3 recovered, but in one it was not certain that the peritoneum was wounded; in one of these cases a large drainage tube was inserted into the peritoneum, and in one a stellate rent in the bladder was packed with iodoform gauze and a drain placed on either side of it. Of the 3 fatal cases two were treated by drainage and in one the rupture was not detected at the operation. The *post-mortem* examination showed a puncture not implicating the serous coat, made by a fragment of a fractured pelvis. Thus of the 29 cases in which laparotomy was performed 12 recovered—a much higher rate of success than has been obtained by any other means. The best operation is undoubtedly complete suture. The stitches should include the serous and muscular coats only, and must extend beyond the wound at each end to prevent leakage. The perfection of the suturing may be tested by moderately distending the bladder with boric acid solution. If the cavity of the pelvis can be thoroughly cleaned, and the rent is perfectly closed, no drainage of the abdominal cavity is necessary. If, however, there is much peri-

tonitis, a drainage tube should be inserted. The bladder must not be allowed to become distended after the operation, but it is not advisable to tie in a catheter on account of the risk of cystitis.

Foreign Bodies, such as pieces of catheters, tobacco-pipes, pencils, &c., are occasionally met with in the male urinary organs, having been introduced through the urethra. In some cases they are soon spontaneously expelled. If left in the bladder they become encrusted with phosphates and thus often become the nuclei of large and irregularly-shaped calculi; hence it is absolutely necessary to remove them speedily. This may occasionally be done by fortunately seizing the foreign body with a small lithotrite or urethral forceps at one end, and withdrawing it in the direction of its long axis. But if this procedure be unsuccessful, it must be cut out. This is most safely done by suprapubic cystotomy.

Bullets, pieces of clothing, &c., are occasionally lodged in the bladder, in gunshot wounds of that organ. These speedily become encrusted with phosphatic deposits, and, giving rise to the symptoms of stone in the bladder, require to be removed by cystotomy, an operation that has proved very successful in these cases, evidently in consequence of the healthy condition of the urinary organs. Dixon has collected from various works the details of 15 cases, in which balls, that had either primarily entered the bladder, or had found their way into this organ by abscess or ulceration after having been lodged in the neighbourhood, were extracted by operation. In 10 of these the result was successful; in the remaining 5 no record is made of the termination. In the Surgical History of the American War, 21 cases are recorded in which lithotomy was performed for the extraction of foreign bodies, or traumatic calculi. Of these three died, the result in one case is unknown, and the rest recovered. In 13 cases the missile itself was removed from the bladder; in 3, a splinter of bone formed the nucleus; in one the stone had formed round a piece of cloth, and in another on a curl of hair from the pubes; in the remaining cases soft organic matter of doubtful nature formed the nucleus.

Arrow-heads have also been met with in the bladder. There is, in the Army Medical Museum at Washington, a remarkable specimen of an Indian arrow-head which formed the nucleus of a large phosphatic calculus.

In the female also, various foreign bodies are occasionally passed up the urethra, and slipping from the fingers, are lost in the bladder. Hair-pins, bongies, pencils, penholders, and a vast variety of similar objects have here been met with. As a rule they may easily be extracted through the urethra, which should be expanded by a proper dilator.

WOUNDS OF THE ORGANS OF GENERATION in the male may be accidental, occasioned by sharp instruments or gunshot, or may be self-inflicted. When involving only the integuments, they present nothing peculiar and do not differ from similar wounds in other situations, except in the great reparative power that the scrotal and penile coverings possess. Even when the whole of the skin of the part has been torn away, the organ is speedily re-covered. In one curious case under my care, in which a jealous wife had unsuccessfully attempted to cut off her husband's penis with a carving-knife, the organ, which had had the whole of its integuments torn off from the root forwards, quickly became covered with a new integument, which speedily assumed the supple character natural to the skin of these parts.

When the penis is more deeply wounded, there are two special sources of danger, viz., hæmorrhage and wound of the urethra. The hæmorrhage is usually very profuse. If it proceed from a distinct arterial trunk, such as the dorsal artery or that of a corpus cavernosum, the vessel must be ligatured. If it occur from general oozing from the vascular tissues of the penis, it may be arrested by cold, pressure, or astringents. Pressure is best applied by passing a large catheter into the bladder, and then compressing the organ against this by means of a narrow bandage or circular strip of plaster.

Injury of the genital organs by self-mutilation is occasionally met with in cases of sexual mania or melancholia. In some cases the patient has cut off one testis; in others, the penis; in others, again, the whole of the external sexual organs. Injuries such as these present no very special characters, and require to be treated on ordinary principles, the great point being to restrain the hæmorrhage and to prevent contraction of the urethral orifice.

URETHRA.—**Wounds of the Urethra** by gunshot injury, or sharp instruments, is a troublesome accident, on account of the liability to the infiltration of urine and ultimately to fistula. It may be recognized by the escape of blood from the meatus, and of urine from the wound. The *Treatment* consists in the introduction of a catheter, which should be tied in; and if the edges of the wound be clean cut, they may be brought together by interrupted sutures. The catheter should not be kept in longer than is necessary. After the first week, the patient can in many cases be taught to pass a soft instrument for himself whenever he desires to pass water.

Laceration of the Urethra is immediately attended with most serious symptoms, and remotely followed by most disastrous consequences. It very frequently occurs in men employed in building, from slipping or walking across an unfinished floor, in such a way as to fall heavily astride upon one of the joists. I have seen it in a farrier, kicked in the perineum whilst shoeing a horse; and it is not uncommonly met with as a consequence of injury by a fragment of bone in fracture of the rami of the pubes and ischium.

In all forms of the accident it is almost invariably the membranous part of the urethra that suffers. In a violent blow on the perineum the urethra is forcibly driven upwards, and crushed against the pubic arch. When the laceration occurs from a fragment of bone in a fracture, it is usually in those cases in which the pelvis is forcibly compressed, and gives way both behind and in front (Fig. 206). The outer fragment is driven across the middle line in the perineum, and thus tears the urethra. In both these accidents the inferior layer of the triangular ligament is torn; it is impossible that the membranous part of the urethra could be lacerated by a blow in the perineum while it remained intact; and in the fracture it is torn at its attachment to the pubic arch; consequently if urine escapes from the urethra it readily finds its way into the loose areolar tissue beneath the deep layer of the superficial fascia.

In these injuries the integuments are usually un torn, but deeply ecchymosed. The extravasation of blood is often considerable, extending into the scrotum, which rapidly swells up and becomes black. It may, indeed, be very serious, arising in some cases from the lacerated structures and the torn superficial or transverse arteries of the perineum; in other instances from the corpus spongiosum, the bulb, or the artery of the bulb. In all cases of lacerated urethra, blood will drip from the orifice; and, if the bulb and its arteries have

been torn, the hæmorrhage from these may be very great, a pint or more of blood being thus rapidly lost, in addition to great accumulations in the perinæum and scrotum, distending these parts with coagula.

In consequence of the interruption in the continuity of the canal and the compression or plugging of the torn part by coagula of extravasated blood, the urine cannot be voided and the bladder gradually fills. If the patient attempt to empty it, only a few drops will issue from the urethral orifice; but he will be seized with severe burning, smarting pain in the perinæum, and the ultimate evils of the injury will be greatly aggravated, for, wherever the urine penetrates, sloughing of areolar tissue will rapidly ensue. There is this great difference between extravasation of urine from ruptured bladder and from lacerated urethra: in the former case the urine escapes involuntarily from the injured organ; in the latter, no urine will escape from the torn urethra, unless by a voluntary expulsive effort on the part of the patient. The sufferings of the patient are speedily increased by retention of urine and the distress occasioned by distension of the bladder; and the necessity for relief thus becomes urgent, lest by an involuntary spasmodic effort the urine be pumped widely into the already broken-down areolar tissue of the perinæum.

The pathology and symptoms of extravasation of urine are fully described in the Chapter on Stricture of the Urethra. (See Vol. II.)

The ultimate results of a lacerated urethra are no less serious than the immediate effects. If the floor only of the urethra have been lacerated, leaving the upper part of the wall of the canal intact, the continuity of the urethra will not be lost, but a permanent traumatic stricture of the worst kind will ensue. If the urethra have been completely torn across, or slough as a result of the injury, obliteration of a portion of the canal may take place, and an incurable urinary fistula will be left in the perinæum.

The *Treatment* consists in the early introduction of a catheter into the bladder. If this can be done before the patient has made an attempt to pass his urine, much of the immediate danger of the case may be averted, by the prevention of urinary infiltration. The catheter, which should be an elastic one, must not be too small; as a rule, No. 8, English scale, will be found the most convenient size. A catheter *coudé* will often pass most readily, as the point is kept towards the roof of the canal which usually is uninjured. If this do not enter readily, an English gum-elastic catheter on a stylet bent to a proper form, various angles and curves being tried one after another, will often be successfully passed. No force must on any account be used: there is no resisting stricture to overcome: the passage is free enough if the right way in be found. When a catheter has been passed it must be left in for a week, or longer if it causes no irritation. It should not be plugged, but should have an india-rubber tube attached, so that the urine may readily escape. If any hardness, throbbing, or other sign of irritation occur in the perinæum, a free incision should be made into the part, so as to afford a ready outlet for any urine that may have been effused.

If the Surgeon find it impossible to introduce a catheter into the bladder, he should pass a grooved staff as far as it will go, and then, putting the patient in the lithotomy position, make a free incision in the middle line of the perinæum on to the end of the instrument. The seat of the laceration is freely exposed by holding apart the edges of the wound with retractors, clearing

away all blood-clot and arresting such hæmorrhage as may be still continuing. The staff is now withdrawn and a full-sized catheter passed along the urethra and guided if possible into the proximal end. This is often extremely difficult. If the floor of the urethra only have been torn, it may be accomplished by keeping the point of the catheter well against the upper wall of the canal; but if the urethra have been completely torn across, it will tax all the skill of the Surgeon to direct the instrument into the vesical end of the canal. Teale of Leeds recommends that a director should be first introduced into the proximal end of the opening in the urethra, over which a dilator may be passed; the director being then withdrawn, the catheter is readily introduced through the dilator. In some cases the difficulty appears to arise from the proximal end of the urethra being drawn upwards by the distended bladder. If this happens the bladder may be partially emptied by suprapubic aspiration. Should the Surgeon fail to introduce a catheter he will usually find that the urine drains away from the perineal incision, so that he can wait a day or two before making another attempt. It may however be found necessary to aspirate the bladder once or twice above the pubes. Failing all other means suprapubic cystotomy has been performed and the proximal end of the divided urethra found by passing a curved staff along it from the bladder. This is however a severe measure, to be avoided if possible. Suture of the urethra over a catheter should be practised, whenever practicable.

VAGINA AND RECTUM.—**Foreign Bodies** are occasionally thrust forcibly into or impacted in the vagina or rectum. When a foreign body, such as a stick, or a broom-handle, or the leg of a chair, is thrust forcibly up the rectum by a person falling on it, two injuries may result—extensive laceration of the sphincter ani and the perineum, with hæmorrhage: or transfixion of the gut and wound of the peritoneum, with consecutive inflammation of that membrane, which almost invariably terminates fatally. The consequences of such an injury present nothing very special, and require to be treated on ordinary principles. If in the fall the foreign body have been forcibly thrust into the vagina, there may be injury to the bladder or peritoneum; but the most common source of danger is laceration of the labium, and free hæmorrhage from this source. I have several times seen enormous quantities of blood thus lost. This hæmorrhage is best arrested by plugging firmly with lint soaked in a solution of the perchloride of iron, and by the pressure of a bandage.

A variety of things, such as pieces of stick, glass-bottles, gallipots, tumblers, &c., have been introduced into and impacted in these canals. Their extraction is often very difficult, in consequence of the swelling of the mucous membrane over and around them, and the depth to which they have been pushed. In order to remove them, the use of lithotomy or necrosis forceps may be required. In some cases the foreign body produces ulceration into the bladder; and it has been found to transfix the wall of the canal in which it is lodged, and, by penetrating the peritoneum, has speedily caused death. A remarkable case of this kind occurred in my practice, in which a cedar pencil, five inches long, and cut to a point, had been forced up by the patient herself, a young woman, through the posterior wall of the vagina into the abdominal cavity. Here it transfixed two coils of the small intestine, and after being fixed there for eight months, I extracted it by an incision through the anterior abdominal wall, midway between the umbilicus and Poupart's ligament, where its point

was engaged in the fascia transversalis. It had occasioned repeated attacks of peritonitis; and, after extraction, death resulted from that cause.

LACERATION OF THE PERINÆUM.—The perinæum is occasionally ruptured during parturition. The extent of the laceration varies greatly, and influences materially the ultimate issue of the case. In some cases there is merely a slight rent at the fourchette; in others, the whole perinæum has given way as far as the sphincter ani; in others the sphincter also is torn; or the rent may extend into the recto-vaginal septum. The worst cases are those in which the perinæum has been torn, and the recto-vaginal septum destroyed by sloughing from prolonged pressure of the fetal head. In such cases, the loss of soft tissues and the existence of dense cicatricial bands render complete union by operation very uncertain. When the sphincter ani or the recto-vaginal septum has given way, incontinence of feces forms the most troublesome symptom. The neighbouring parts are from this cause liable to excoriation; and not unfrequently the rectal mucous membrane becomes prolapsed or hæmorrhoidal.

The operation for the closure of ruptured perinæum is comparatively modern. Although it had been done in France by Guillemeau in the 16th century, and in this country by Smellie in the 18th, little attention was paid to the subject until Rouse, in 1834, published five cases, in four of which he had effected a cure by means of the quilled suture. From that time the operation took its place in surgery.

The operation may be done at two distinct periods after the occurrence of the laceration, viz., immediately or remotely.

Operation for Ruptured Perinæum.—The **immediate** operation is done as soon as possible after the occurrence of the accident. Anæsthesia is unnecessary except in those cases in which the tear is complete and passes into the rectum. The patient lying on the left side, the vagina is to be plugged with a sponge or a tampon of wool or gauze. The raw surface is then cleared of blood-clot, and closed with silver-wire or silk-worm-gut sutures. These are introduced with a large fully-curved needle on a handle. The needle is made to enter the skin just beyond one lateral extremity of the raw surface, and passing across completely buried, emerges at a corresponding point on the opposite side; it is then threaded and withdrawn. Two or three sutures passed in this way are usually sufficient, and when all have been inserted the ends of each are twisted or tied together. The risk of perforating the anterior wall of the rectum during the passage of the needle may be obviated by introducing one finger into the bowel. In the more severe cases in which the sphincter ani is torn through, it will be necessary to employ additional sutures for the purpose of bringing together the ends of the muscle. These should consist of fine silver wire which can be passed with a half-curved needle. The needle is first introduced just to one side of the apex of the tear in the anterior wall of the rectum, accurately at the torn edge of the mucous membrane. It is passed forwards to a spot about half an inch from the point of entry; here it emerges into the wound, and being re-introduced at the corresponding point on the opposite side is carried backwards into the rectum in a similar manner. The ends are then twisted together, and other sutures are passed in the same way, each one being introduced rather further out and embracing a slightly greater extent of tissue than the preceding one. After the suturing has been completed the vaginal plug is removed. A vaginal douche of Condy's fluid or

boric acid lotion must be given twice daily. It is as a rule unnecessary to resort to the use of the catheter, provided that the parts be thoroughly cleaned and dried as often as they become soiled. The only dressing required is a small pad of antiseptic gauze or wool which should be changed frequently. The sutures may be left in position for a week or ten days.

The **remote** operation is undertaken for the cure of those cases in which healing has occurred without approximation of the parts by the immediate method above described. Of the very numerous operations which have been devised for this purpose, one of the simplest and most efficient is that recommended by Lawson Tait. The basis of the principle upon which Tait's operation is performed is that the thin white line of the cicatrix extends transversely to the axis of the rent, which was of course at right angles to the plane of the perinæum. The scheme of the operation "is to restore the old rent and unite it at right angles to its representative cicatrix—that is, at right angles to the plane of the perinæum." No tissue is removed, "and therefore if the operation fails the parts simply return to their abnormal state, not to one which is more unlikely to be remedied." The steps of the operation are briefly as follows, and are described almost in Tait's own words.

The folds of the buttocks being held firmly apart so that the cicatrix is put on the stretch, it is divided with scissors from end to end. The incision is about three eighths of an inch deep and forms two flaps, a rectal and a vaginal. From each end of the incision it is carried forwards into the tissue of the labium for about an inch, and again backwards beside the rectum for about a third of an inch. The vaginal flap is held forwards and the rectal flap backwards, so that the raw surface assumes a somewhat quadrilateral shape. Silk-worm-gut sutures are employed and are passed with a stout-handled and well-curved needle. Each suture is entered at a point about an eighth of an inch within the lateral margin of the wound, and emerges at the corresponding point on the opposite side. The needle is buried deeply in the tissues except at the upper angle of the wound where it appears on the surface. When a sufficient number of stitches have been passed they are tied, and thus the edges of the wound are drawn together in such a way that the resulting cicatrix is antero-posterior. Tait does not recommend the use of separate rectal sutures, but should the Surgeon think it advisable to use them, they may be inserted in the way described in the immediate operation. The sutures can be left in position for three or four weeks, and the rectum and vagina are washed out daily. The bowels should be opened at the end of a week by an aperient and a simple oil enema. The same remarks apply to the dressing of the wound and the use of the catheter as after the immediate operation.

DIVISION THIRD.

SURGICAL DISEASES.

DISEASES AFFECTING THE TISSUES GENERALLY.

CHAPTER XXX.

MORTIFICATION, OR GANGRENE.

THE death of a part of the body is, in surgical language, termed **Mortification** or **Gangrene**. In pathological language the term **Necrosis** is applied to local death generally, in whatever part or tissue it occurs; but in surgical practice it is customary to confine it to affections of the bones or cartilages: when limited to the soft tissues of a limb it is spoken of as **Sphacelation**; and when accompanied by ulceration, it is called **Sloughing**. Many other varieties of gangrene are recognized by Surgeons. Like most other diseases, it may be **Acute** or **Chronic** in its duration. As the parts affected are moist and swollen, or dry and shrivelled, it may be divided into the **Moist** and the **Dry** or **Mummified** gangrene; so again, according to its cause, it is spoken of as **Spontaneous** or **Traumatic**; and very frequently, it is arranged according to the nature of its cause under the denominations of **Constitutional** and **Local**. Besides these, various **Specific** forms of the disease are met with, which will require special consideration.

LOCAL SIGNS.—Certain local phenomena are common to all varieties of gangrene. The part becomes colder than natural, the temperature falling to that of the external air. Its sensibility is lost, and it may be touched, pricked, or cut without feeling. In some cases the sensibility is greatly increased just before gangrene sets in, agonizing pain of a burning or neuralgic character being experienced, which soon gives way to complete insensibility. The natural functions of the affected parts are abolished. Thus the muscles no longer contract, and all motion of the part itself ceases. The changes that subsequently take place in the tissues of the gangrenous part are of two kinds, giving rise to the division of gangrene into *dry* and *moist*. In the *moist* variety death of the part takes place while the tissues are engorged with blood, either from inflammation or from obstruction to the circulation through the veins or capillaries. In this form the skin of the dead part becomes discoloured, usually greyish or greenish, the

cuticle separates, and when pressed upon obliquely slides away under the finger, leaving the moist and slippery cutis exposed. The colour gradually darkens to a dull purplish greenish black, mottled in patches with reddish-brown spots: and after a time an odour of putrescence is evolved, very commonly with an emphysematous crackling from evolution of gas in the gangrenous tissues. This shows that putrefactive changes have taken place in the dead tissues. The *dry* variety occurs as a consequence of some obstruction to the supply of blood to the part, so that at the time it sets in the tissues contain less blood than natural. In it the colour is often at first of a pale tallowy white, mottled, with dusky spots. The skin soon becomes dry, horny, and semi-transparent, and eventually assumes a brown wrinkled appearance, and the whole gangrenous part becomes shrivelled and dry like the limb of a mummy.

CONSTITUTIONAL SYMPTOMS.—These vary greatly. When the disease is strictly local, affecting a part of but limited extent, and perhaps of no great importance to the economy, they are not very strongly marked. If, however, the gangrene, although limited, implicate important organs, as a knuckle of intestine for example, marked symptoms declare themselves.

The full invasion of the gangrene, if it affect any considerable extent of tissue or any important organ is always attended with great depression of the system. The countenance is dull and anxious and the pulse feeble, quick, and easily compressible; the tongue is brown, and the lips and teeth loaded with sordes. In moist gangrene the constitutional disturbance is aggravated in some cases by absorption of the products of the unhealthy inflammation from which the death of the part has resulted, and in others of the products of putrefaction from the decomposing slough. Death may in fact occur from this cause with all the symptoms of septic poisoning. In dry gangrene these symptoms are usually much less marked. When gangrene affects an internal organ the depression is always very great, and the special symptoms will vary with the part affected.

CAUSES.—The causes of gangrene are *predisposing* and *immediate*. Anything that tends to lower the vitality of the tissues must necessarily bring them into a state in which a comparatively slight injury may cause their death. These conditions have already been fully discussed in the chapter on inflammation (p. 172 *et seq.*). The predisposing causes of inflammation, when acting more powerfully, predispose to gangrene.

Immediate Causes of Gangrene.—These may be divided thus:—

1. **Causes acting primarily by arrest of the Circulation.**—These may again be divided into:—

(a.) *Arrest of the Supply of Arterial Blood to a part.*—This is a common cause of gangrene. It may be produced by accident, by ligature or other surgical operation, or by thrombosis or embolism of the arteries.

(b.) *Obstruction of the Circulation through a part.*—This is seldom a primary cause of gangrene, and as such arises only from pressure either from within, as from the growth of a tumour, or from without, as in the formation of bed-sores or sloughs beneath splints. Obstruction to the capillary circulation necessarily accompanies all acute inflammations, and often forms an important element in the production of gangrene; but in inflammation it is not a primary cause, being secondary to the damage done to the tissues directly by the irritant causing the inflammatory process.

(c.) *Obstruction to the Return of Venous Blood from a part.*—This seldom forms the sole cause of gangrene, even when important veins are occluded by thrombosis or pressure. As an accessory cause, it frequently aids in the production of gangrene, when the main artery is obstructed at the same time.

(d.) *Diminished Vis a Tergo from extreme weakness of the heart's action.*—This is a powerful accessory cause when there is any obstruction either to the arterial flow or to the venous return. It may result from extreme debility from fever or from starvation. The gangrene that accompanies ergot-poisoning is supposed to be due partly to relaxation of the veins by which a large quantity of blood is withdrawn from the circulation, and partly to weakness of the heart's action. Great loss of blood may in the same way aid in producing gangrene.

2. Causes acting directly on the Tissues:—

(a.) *Traumatic Causes.*—The production of gangrene by mechanical violence, heat and cold, and caustic fluids has already been fully discussed, and needs no further notice here.

(b.) *Causes giving rise to acute inflammation.*—Any acute inflammation as already pointed out in the chapter on inflammation, may terminate in gangrene, if the irritant which causes it is of sufficient intensity or the tissues upon which it acts are of abnormally low vitality.

In certain forms of specific infective inflammation gangrene forms the principal characteristic of the process, as in hospital gangrene, cancrum oris, carbuncle, malignant pustule, and spreading traumatic gangrene.

Amongst the causes, some are **Constitutional**, others **Local**, in their action. Those forms of gangrene are said to be *constitutional* which arise from obstruction of the circulation in consequence of disease of the heart and vessels. The constitutional state also frequently forms an important predisposing cause of gangrene in cases in which the immediate cause is local. Bright's disease and diabetes are amongst the most frequent conditions which act in this way. Those varieties of gangrene are *local* which arise from injuries of all kinds, whether applied to the part itself, or to the main artery leading to it, by its ligature or wound.

The forms of gangrene which arise from traumatic causes, have already been described in previous chapters (see pp. 336, 404, 461); while those that are due to obstructed circulation to or through a part, or that take the form of specific disease, are left for consideration here.

GANGRENE FROM ARREST OF THE SUPPLY OF ARTERIAL BLOOD.—Whenever a part of the body is deprived of its proper supply of blood, mortification may ensue. Most commonly when the principal trunk of an artery is obstructed, the collateral circulation is sufficient to maintain the vitality of the part; but, should this be interfered with, gangrene results. Indeed, the sudden loss of a large quantity of blood from the system may occasion the death of some of those parts in which the circulation is naturally most languid. Thus Brodie relates the case of a drunken man, who, being bled to an inordinate extent, was seized with gangrene of both feet.

Obstruction to the flow of blood through the arteries may be occasioned by two primary sets of causes:—*a*, from *injury* or *operation*, as wound or ligature of the main trunk; *b*, from *disease*, as by *thrombosis* and *embolism*, or by *calcification*, and subsequent occlusion of the vessel. Gangrene from arterial

cuticle separates, and when pressed upon obliquely slides away under the finger, leaving the moist and slippery cutis exposed. The colour gradually darkens to a dull purplish greenish black, mottled in patches with reddish-brown spots; and after a time an odour of putrescence is evolved, very commonly with an emphysematous crackling from evolution of gas in the gangrenous tissues. This shows that putrefactive changes have taken place in the dead tissues. The *dry* variety occurs as a consequence of some obstruction to the supply of blood to the part, so that at the time it sets in the tissues contain less blood than natural. In it the colour is often at first of a pale tallowy white, mottled, with dusky spots. The skin soon becomes dry, horny, and semi-transparent, and eventually assumes a brown wrinkled appearance, and the whole gangrenous part becomes shrivelled and dry like the limb of a mummy.

CONSTITUTIONAL SYMPTOMS.—These vary greatly. When the disease is strictly local, affecting a part of but limited extent, and perhaps of no great importance to the economy, they are not very strongly marked. If, however, the gangrene, although limited, implicate important organs, as a knuckle of intestine for example, marked symptoms declare themselves.

The full invasion of the gangrene, if it affect any considerable extent of tissue or any important organ is always attended with great depression of the system. The countenance is dull and anxious and the pulse feeble, quick, and easily compressible; the tongue is brown, and the lips and teeth loaded with sordes. In moist gangrene the constitutional disturbance is aggravated in some cases by absorption of the products of the unhealthy inflammation from which the death of the part has resulted, and in others of the products of putrefaction from the decomposing slough. Death may in fact occur from this cause with all the symptoms of septic poisoning. In dry gangrene these symptoms are usually much less marked. When gangrene affects an internal organ the depression is always very great, and the special symptoms will vary with the part affected.

CAUSES.—The causes of gangrene are *predisposing* and *immediate*. Anything that tends to lower the vitality of the tissues must necessarily bring them into a state in which a comparatively slight injury may cause their death. These conditions have already been fully discussed in the chapter on inflammation (p. 172 *et seq.*). The predisposing causes of inflammation, when acting more powerfully, predispose to gangrene.

Immediate Causes of Gangrene.—These may be divided thus:—

1. **Causes acting primarily by arrest of the Circulation.**—These may again be divided into:—

(a.) *Arrest of the Supply of Arterial Blood to a part.*—This is a common cause of gangrene. It may be produced by accident, by ligature or other surgical operation, or by thrombosis or embolism of the arteries.

(b.) *Obstruction of the Circulation through a part.*—This is seldom a primary cause of gangrene, and as such arises only from pressure either from within, as from the growth of a tumour, or from without, as in the formation of bed-sores or sloughs beneath splints. Obstruction to the capillary circulation necessarily accompanies all acute inflammations, and often forms an important element in the production of gangrene; but in inflammation it is not a primary cause, being secondary to the damage done to the tissues directly by the irritant causing the inflammatory process.

(c.) *Obstruction to the Return of Venous Blood from a part.*—This seldom forms the sole cause of gangrene, even when important veins are occluded by thrombosis or pressure. As an accessory cause, it frequently aids in the production of gangrene, when the main artery is obstructed at the same time.

(d.) *Diminished Vis a Tergo from extreme weakness of the heart's action.*—This is a powerful accessory cause when there is any obstruction either to the arterial flow or to the venous return. It may result from extreme debility from fever or from starvation. The gangrene that accompanies ergot-poisoning is supposed to be due partly to relaxation of the veins by which a large quantity of blood is withdrawn from the circulation, and partly to weakness of the heart's action. Great loss of blood may in the same way aid in producing gangrene.

2. Causes acting directly on the Tissues:—

(a.) *Traumatic Causes.*—The production of gangrene by mechanical violence, heat and cold, and caustic fluids has already been fully discussed, and needs no further notice here.

(b.) *Causes giving rise to acute inflammation.*—Any acute inflammation as already pointed out in the chapter on inflammation, may terminate in gangrene, if the irritant which causes it is of sufficient intensity or the tissues upon which it acts are of abnormally low vitality.

In certain forms of specific infective inflammation gangrene forms the principal characteristic of the process, as in hospital gangrene, *cancrem oris*, carbuncle, malignant pustule, and spreading traumatic gangrene.

Amongst the causes, some are **Constitutional**, others **Local**, in their action. Those forms of gangrene are said to be *constitutional* which arise from obstruction of the circulation in consequence of disease of the heart and vessels. The constitutional state also frequently forms an important predisposing cause of gangrene in cases in which the immediate cause is local. Bright's disease and diabetes are amongst the most frequent conditions which act in this way. Those varieties of gangrene are *local* which arise from injuries of all kinds, whether applied to the part itself, or to the main artery leading to it, by its ligature or wound.

The forms of gangrene which arise from traumatic causes, have already been described in previous chapters (see pp. 336, 404, 461); while those that are due to obstructed circulation to or through a part, or that take the form of specific disease, are left for consideration here.

GANGRENE FROM ARREST OF THE SUPPLY OF ARTERIAL BLOOD.—Whenever a part of the body is deprived of its proper supply of blood, mortification may ensue. Most commonly when the principal trunk of an artery is obstructed, the collateral circulation is sufficient to maintain the vitality of the part; but, should this be interfered with, gangrene results. Indeed, the sudden loss of a large quantity of blood from the system may occasion the death of some of those parts in which the circulation is naturally most languid. Thus Brodie relates the case of a drunken man, who, being bled to an inordinate extent, was seized with gangrene of both feet.

Obstruction to the flow of blood through the arteries may be occasioned by two primary sets of causes:—a, from *injury* or *operation*, as wound or ligature of the main trunk; b, from *disease*, as by *thrombosis* and *embolism*, or by *calcification*, and *subsequent occlusion of the vessel*. Gangrene from arterial

obstruction varies materially in its symptoms, prognosis, and treatment, according as it arises from one or other of these causes. When the obstruction in the arteries is very complete, the gangrene will be of the dry kind; but if some blood still finds its way into the part, and if there is at the same time an impediment to the return of blood through the veins, the disease will partake more or less of the characters of the moist variety.

(a.) A limb gangrenous in consequence of the **Ligature or Wound of its Main Artery**, without any other injury to the vascular system, becomes cold, feels heavy, and loses its sensibility; at the same time it assumes a dull tallowy white colour, mottled with greyish or brownish streaks. This state of things is met with chiefly in the lower extremity. In a short time the pallid colour is lost, the part becoming brown or blackish; the integuments of the foot become semi-transparent and horny-looking where they are stretched over the tendons of the instep, and the part presents a shrivelled appearance. This form of gangrene may invade the whole of the lower limb, but most commonly is limited to the foot, stopping either just above the ankle, or if not there, immediately below the knee, as Guthrie has observed; the arrest taking place in one or other of these two spots, on account of the greater freedom of the collateral circulation here than in other parts of the limb. If any of the large venous trunks become obstructed or otherwise implicated, so that the return of blood through them is interfered with at the same time that the supply by the arteries is arrested, the limb generally assumes a greenish-blue colour, and rapidly runs into putrefaction. In some of these cases it happens that sloughs of the integument and subcutaneous areolar tissue form, although the limb generally preserves its vitality. The treatment of these forms of gangrene, which are strictly local, is described in the chapter on the Arrest of Arterial Hæmorrhage.

(b.) Gangrene may occur from the arrest of the circulation through an artery as the result of *disease of the coats of the vessel*. This is the variety that is commonly called *spontaneous*.

Spontaneous gangrene is termed **Senile** when it occurs in old people in consequence of the arteries becoming rigid and their calibre narrowed by **Atheroma or Calcification of their Coats**. The pathology of these affections of the arteries will be more fully discussed in the chapter on Diseases of the Blood-vessels in Volume II. It is sufficient here to state that these changes render the arteries unable to maintain the proper circulation of blood through the limb, and further from the roughening of the inner coat predispose them to thrombosis, that is to say, to the deposit of fibrin by which the vessel may become completely obliterated. The want of a due supply of arterial blood in these cases is owing not only to the diseased state of the arteries, but also in a great measure to the weak propulsive power of the heart, and the consequent feebleness of the circulation especially through the lower limbs. When the circulation is so far interrupted as to lower the nutrition of the limb, the following premonitory symptoms are observed. The patient complains of a sensation of weight in the limb, with coldness, itching, and tingling in the foot, and cramps in the calf. The circulation of the part is habitually defective, the pulsation of the tibials being scarcely perceptible. In some cases cutaneous ulcerations ensue. These symptoms commonly exist for a considerable length of time before gangrene actually comes on, and should always be looked upon with anxiety in old people.

When the circulation becomes arrested from the conjoined influences of diminished cardiac power and arterial obstruction, gangrene inevitably results. It is met with in the lower extremities of people past the middle period of life, and the tendency to it increases as age advances.

Senile gangrene may set in in different ways. In many instances it commences without any apparent exciting cause. The toes and foot simply shrivel, without any sign of local inflammation and with but little constitutional disturbance. The part that is destroyed becomes black, dry, and shrunken, resembling in appearance the limb of a mummy; hence the change is often termed **Mummification** (Fig. 336). The toes often look like the shrivelled skins of over-ripe or sucked-out black grapes. This form of gangrene is usually due to the complete occlusion of a previously diseased artery by thrombosis.

In other cases the gangrene is the immediate result of some slight inflammation accidentally induced, as from the excoriation produced by a tight boot, or from a trivial wound in cutting a corn or toe-nail. In these cases the slight injury, which in healthy tissues would be harmless, causes the formation of a small slough. This decomposes, and the products of putrefaction acting on the surrounding tissues give rise to a spreading inflammation, which, owing to the greatly diminished vitality of the part, terminates in gangrene, and the process thus started may spread until it reaches tissues of sufficient vitality to resist its progress. In other instances, again, the disease is ushered in by more acute symptoms. The whole foot becomes swollen, oedematous, and red; inflammation, apparently of a gouty character, being set up in it. The gangrene may at first affect only one toe, or it may from the commencement involve several toes. It generally begins as a purple or blackish-red spot on the side of one of the toes, usually the inner side of the great toe; this spot may be surrounded by an inflamed areola, and accompanied by much smarting and burning pain of a paroxysmal character; it spreads by gradually involving the inflamed areola, which continues to extend in proportion as the gangrene progresses. The pain, which is often of the

Fig. 335. Popliteal and Tibial Arteries obstructed by Thrombosis.

Fig. 336. Senile Gangrene: Exposure of Bones of Foot.

most intense character, subsides when the gangrene becomes complete.

In whichever way the gangrene commences the affection gradually extends, invading perhaps one toe after another, involving the instep (Fig. 336), or the sole of the foot and the heel; and unless it terminate by the formation of the line of demarcation, or death put an end to the patient's sufferings, it may extend up to the ankle or leg. In other instances, the gangrene being limited to a small extent, as to the toes only, the patient may recover with the loss of the fore part of the foot.

The constitutional symptoms vary with the mode of invasion. In the

inflammatory form there is usually considerable constitutional disturbance with some fever at first, subsequently sinking into marked depression with subnormal temperature as the patient becomes poisoned by absorption of the products of putrefaction: and the disease may thus often prove fatal in from a month to six weeks. On the other hand, in the dry form of gangrene, I have known the disease to continue with very little constitutional disturbance for more than twelve months, slowly creeping on during that time. In all forms of spontaneous gangrene there is a marked improvement in the constitutional state as soon as a distinct line of demarcation forms between the dead and the living tissues.

The thin skin on the anterior part of the leg at its middle and lower third is apt to fall into a state of gangrene in old people as the result of very slight injuries, and occasionally without any obvious external cause. In these cases a bleb forms which on breaking leaves a slough which gradually dries, becomes black and extends as the neighbouring parts are killed by a process of painful inflammation.

Diabetes is a fertile cause of gangrene of the toes and feet. It most commonly occurs in middle-aged well-nourished diabetics, and is rarely met with in the acute form of the disease in young subjects. Diabetes is associated with a general state of malnutrition of the tissues, but it is probable that this alone is never the cause of gangrene, although it favours the spread of the disease when it has once started. Cellulitis is especially liable to follow slight wounds in patients suffering from diabetes, and in some cases this is the starting point of the gangrenous process. Further, it has been shown by Billroth, Frerichs and others, that diabetes is frequently associated with extensive arterial degeneration. This is undoubtedly a most important element in the causation of diabetic gangrene, which is thus closely allied to senile gangrene, differing chiefly in its greater tendency to spread on account of the unusually feeble vitality of the tissues. Lastly, it is now recognised that diabetes is occasionally a cause of peripheral neuritis, and this may be one element at least in the production of gangrene, particularly of the slowly-spreading variety which begins in a perforating ulcer similar to that occurring in locomotor ataxy.

The disease usually commences with a large bleb which forms on the under surface of the foot or at the end of one of the toes. This bleb contains fluid which speedily becomes turbid, and is surrounded by a dusky purple areola. From this the gangrene slowly spreads, and unless the diabetes can be checked, may largely invade and destroy the foot.

Thrombosis of an artery (Fig. 335) occurs only as a consequence of previous disease of its inner coat, so, although it is frequently the immediate cause of gangrene, by obstructing an atheromatous or otherwise diseased vessel, it is never the primary cause of the disease.

Embolism is more frequent as an immediate cause of gangrene. An embolus is a solid body, which, having entered the circulation, is carried onwards by the blood-stream until it lodges in some vessel which is too narrow to allow it to pass. Emboli, if of any size, almost invariably lodge at the point at which a main trunk bifurcates or gives off a large branch. If very small they may pass on into the capillaries, causing capillary embolism. When an embolus has lodged in an artery, a clot forms upon it, reaching as high as the first branch above the point of obstruction. Fibrin which has been deposited

upon a diseased part of a large vessel, or in a fusiform aneurism, and vegetations from the valves of the left side of the heart, are the most common sources of embolism in the systemic arteries; but occasionally a fragment of a tumour which has penetrated the coats of a large artery may be washed away into the blood-stream and form an embolus.

Gangrene from embolism is most common in the lower limb, and the bifurcation of the popliteal artery is the usual place at which the embolus lodges. If it be so small as to pass into one of the tibials, the circulation is maintained by the unobstructed artery; and gangrene does not occur. Gangrene from embolism is, however, also met with in the upper limb. In these cases the gangrene develops suddenly, the whole of the parts deprived of blood perishing simultaneously, there being no tendency for the mischief to spread; pulsation ceases in the terminal branches of the obstructed artery, and intense superficial pain is felt in the limb, ceasing after about a week. The limb is at first pale, but soon undergoes the characteristic changes in colour, when decomposition commences. The gangrene is always of the dry variety. In the leg, as Billroth points out, the foot soon becomes mummified, while near the line of demarcation the parts remain more moist. The line of demarcation forms in these cases immediately below the knee. Gangrene from embolism may prove fatal from septic poisoning before any attempt can be made by nature to separate the mortified part. After death, the affected vessel is found firmly plugged by the embolus, above which is a dense coagulum reaching as high as the next branch.

The accompanying drawing (Fig. 337) represents the bifurcation of the common femoral artery occupied by a fibrinous plug, taken from a man aged 32, who died of gangrene of the left leg. In this case the patient, after recovering from rheumatic endocarditis, whilst straining at stool, suddenly felt his left leg tingle painfully, then become numb and cold. The circulation in it ceased, and gangrene speedily supervened, which extended as high as the knee. Death followed amputation of the limb. Here there can be little doubt that the sudden supervention of gangrene was the result of obstruction to the arterial circulation of the lower extremity, consequent on the detachment of a vegetation from the valves of the heart, and its arrest at the bifurcation of the femoral artery.

Fig. 337.—Obstruction of Femoral Artery at its Bifurcation by an Embolus and ascending Thrombosis.

In addition to the varieties of spontaneous gangrene just described, some other rarer forms are occasionally met with. Von Winiwarter has described a peculiar form of overgrowth of the endothelial cells of the inner coat of both arteries and veins—**endarteritis and endophlebitis proliferans**—by which their lumen becomes obliterated. Thrombi are formed in the affected vessels, and these become organized and penetrated by new vessels, as in the closure of a ligatured artery. This affection is said to be caused by syphilis and alcoholism, and occurs usually at an earlier age than ordinary senile gangrene. According to Billroth the signs of imperfect blood-supply may be present for some years before gangrene takes place. When gangrene does set in, it is usually of the moist variety. Examples of gangrene of this variety are described in Chap. XLII.

Raynaud has described a rare form of **symmetrical gangrene** which attacks

the fingers, and sometimes the toes. The premonitory symptoms are that the fingers readily become "dead," often from very slight exposure to cold, and are slow in recovering. In the more advanced conditions the fingers become of a livid colour, cold and insensitive, but intensely painful, a condition described by Raynaud under the name of "local asphyxia." This may pass off after a few hours, and the circulation may be restored, or a bleb may form at the end of one or more of the fingers, beneath which a slough is found when the cuticle is removed, or in extreme cases the whole ungual phalanx may become mummified. The corresponding fingers of the opposite hand may be affected simultaneously or at a later period. The affection is most common in women between 18 and 30. It resembles severe chilblains in some respects, but differs in the intensity of the pain, the character of the gangrene, and the age of the patient. In some recorded cases there has been a history of ague; it is occasionally associated with paroxysmal hæmoglobinuria. It is supposed to be due to vaso-motor disturbance consequent upon central mischief situated in the cord; but its pathology is uncertain.

Gangrene from Venous Obstruction.—Obstruction to the veins by pressure or thrombosis is scarcely ever the sole cause of gangrene; but if at the same time the main artery is occluded, as when it and the vein are compressed together, or when the femoral vein is wounded accidentally at the time when the artery is ligatured, mortification is especially apt to take place. Gangrene from this cause is always of the moist kind, attended with much cedema, discoloration, and rapid putrefaction of the part.

Gangrene from arrest of the Circulation by Strangulation.—A part is often purposely strangled by a Surgeon in operative procedures; or its circulation may in this way be arrested as the result of certain accidents or diseased conditions. (See p. 313.) In either case, the strangulation acts by stopping more or less completely the whole of the circulation through the part. If the strangulation be sufficiently severe, it may kill the tissues outright: for instance, when a nævus or a pile is tied, all flow of blood to or from the part is suddenly arrested, and its vitality is destroyed, the tissues that have been strangled shrivelling and separating by ulceration along the line of ligature. When the strangulation is not so severe as this, great congestion ensues, consequent on the amount of blood sent into the part being greater than can escape by the veins, which are more affected by the constricting force than the arteries; the part strangled becomes dark and congested, and effusion takes place into its tissue. If it be a superficial part, blebs arise on the skin. As the part swells the compression of the vessels becomes more powerful, till finally the flow through the arteries is arrested as well as that through the veins; the circulation is completely stopped, and thus sloughing arises. All this we find in the constricted gut in a strangulated hernia.

Gangrene as a termination of Inflammation.—It has already been pointed out (see the chapter on Inflammation) that all the causes of inflammation are agents which tend to lower the vitality of the parts upon which they act, and that, if acting with sufficient intensity, they bring the process of inflammation to an end by killing the tissues upon which they are exerting their influence. The effect produced by an irritant is dependent: first, on the intensity of the irritant itself; secondly, in many cases on the duration of its action; and thirdly, on the power of resistance, or in other words, on the

vitality of the tissues upon which it is acting. Thus, to take an example, a mustard plaster if applied for a short time on a healthy part causes simple inflammation without destruction of tissue ; if it be of sufficient strength and be kept on a longer time, it will cause death of the skin upon which it is acting. Supposing it, however, to be applied to the skin of a part, the vitality of which is lowered either by constitutional causes of mal-nutrition, such as diabetes or Bright's disease, or from local interference with nutrition, or from degeneration of the arteries, sloughing may result. It has also been pointed out that an irritant of sufficient intensity causes arrest of the circulation, by stasis, in the vessels of the part upon which it acts, and that this condition, unless relieved, must terminate in gangrene. Lastly, all acute inflammations are attended with migration of leucocytes, with abundant coagulable exudation, which distends the lymph-spaces, and presses on the vessels of the inflamed part, thus still further impeding the circulation through it. In gangrene as a termination of inflammation there are thus three causes involved : first, the direct injury done to the tissues, including the walls of the vessels, by the irritant which causes the process ; secondly, obstruction to the circulation from within by stasis ; and thirdly, obstruction from without by the pressure of the inflammatory exudation.

The relative part taken by these different causes varies in different forms of gangrenous inflammation. In some the irritant that causes the process is so powerful in its action, or as it is more commonly expressed in clinical language, the intensity of the inflammation is so great as to kill the part almost directly, however healthy its texture or sound the constitution of the patient may be. More commonly, however, it is not so much the actual as the relative intensity of the inflammation that destroys the part ; there being some debility, local or constitutional, by which the resisting power is lessened. Thus gangrene arises especially in persons whose tissues have degenerated in consequence of old age, defective food, or habitual intemperance. It is remarkable to observe what slight injuries will induce gangrenous inflammation under these circumstances. The nature of the tissue also exercises considerable influence : thus areolar tissue and fasciæ slough more readily than the skin or muscles, whilst the proper tissue of glands is seldom affected. As a rule, the least vascular tissues slough most readily. The pressure of the exudation exerts a marked influence in many forms of spreading gangrenous inflammation of the areolar tissue. Thus in phlegmonous erysipelas free incisions may avert the danger of sloughing of the skin and subcutaneous tissue by relieving tension and allowing a ready exit for the inflammatory exudation.

Gangrene may form the termination of inflammation arising from simple mechanical, physical, or chemical irritants. It is then localized, and has little tendency to spread beyond the area directly injured. It is much more frequently met with as a characteristic feature of certain forms of infective inflammation, as in phlegmonous erysipelas, sloughing phagedæna, hospital gangrene, spreading gangrene, cancrum oris, or malignant pustule. The special features of infective inflammations have been already pointed out (p. 183 *et seq.*). In the gangrenous forms of infective inflammation, death of the tissues may be due directly to the intensity of the virus, as in hospital gangrene, in which the parts are destroyed as if by the action of a powerful caustic ; or to the disturbance of the circulation by the extent and abundance

of the exudation, as in phlegmonous erysipelas, in which, if free vent be provided and tension relieved by incision, the death of the tissue may be prevented. Some forms of gangrenous inflammation are intensely contagious, as hospital gangrene; others, as malignant pustule, are communicable solely by inoculation; and others again, as *cancrem oris*, although having the characters of an infective inflammation, are not capable of being carried from one patient to another.

Gangrene consequent on inflammation is of the moist or acute kind, being always connected with a retention of blood in the part affected. We may regard it as impending in a part that has become inflamed from injury or other cause, if we find that the redness becomes of a dusky or purplish hue; that bullæ filled with dark fluid rise upon the surface; that the swelling, at first hard, tense, and brawny, becomes of a pulpy or doughy character; that the pain is of a dull, heavy, or burning kind; and that the temperature of the part, at first greatly increased, gradually sinks. We know that gangrene has taken place when there is a total loss of the sensibility of the part, even to pricking or pinching; that the motion of the part itself ceases; that its colour changes to a peculiar mottled, purplish-red, or greenish-black hue, unlike anything else in the body; and that the temperature falls to a level with that of the surrounding air. There is likewise an extremely offensive odour evolved differing from that of ordinary *post-mortem* decomposition.

The *Constitutional Symptoms* are always those of fever, with marked depression, often assuming the character of septic poisoning.

ARREST OF GANGRENE.—Certain forms of gangrene consequent upon infective inflammatory processes have a tendency to extend indefinitely until the patient succumbs to the disease. In all forms of spontaneous gangrene, and in that due to direct injury to the tissues, the progress of the mortification is in most cases arrested, and the dead parts are separated from the living. When the gangrene reaches a part of which the vitality is too great to be destroyed by the operation of the causes which have produced death in the tissues beyond, a **line of demarcation** is formed. The process by which the separation of the dead from the living

FIG. 388.—Senile Gangrene of Foot: Line of Separation.

tissues is accomplished has been fully described in the chapter on Ulceration (see p. 271). The dead parts are not thrown off merely by disintegration, but by a vital process, that of ulceration, occurring in the living tissues. The line of ulceration is termed the **line of separation**, and extends along the extreme margin of the living tissues (Fig. 388).

This process of separation, commencing at the edge of the slough, slowly extends downwards to the whole depth of the gangrene; if this affect the entire thickness of the limb, the ulceration will find its way completely across it. If the slough be more superficial, the ulceration extends beneath it, and detaches it gradually. The line of separation is usually oblique, the soft parts being first divided, and the hard tissues then ulcerated through, until the ligamentous or osseous structures, which are slowly acted upon,

are severed. As the ulceration extends across the limb, the largest arteries and veins are cut through by it, without the occurrence of hæmorrhage, owing to the thrombosis, which blocks them from the line of separation to the nearest large collateral branch above it. The period required for the detachment of gangrenous parts varies according to their extent. Small sloughs may be detached in a few days, whilst many weeks are required for the separation of a limb. The action is most rapid in soft vascular tissues and in young subjects. After the separation of the gangrenous part, a more or less irregular ulcerated surface is left, which, if not too extensive, and if the patient's reparative powers are in a favourable state, will cicatrize by the same process as ordinary ulcers.

DIAGNOSIS.—The diagnosis is readily made when gangrene is fully developed: but in the early stages, before it is positively declared, it is not always easy to determine its existence. The ecchymosis and discoloration of a bruise, the collapse and lividity that result from cold, or the dark purple hue occasioned by long-continued congestion, may readily be confounded with impending gangrene. In these cases of doubt, the Surgeon should not be in too great a hurry to pronounce an unfavourable opinion, and still less to act upon it; for not uncommonly parts of the body which have to all appearance lost their vitality, may, under proper treatment, regain it.

PROGNOSIS.—The prognosis as to the part itself is always bad; though occasionally, when gangrene has not been fully established, partial recovery may unexpectedly take place. So far as the life of the patient is concerned, much will depend on the cause of the affection, and on the age and strength of the individual; at advanced periods of life, and in a feeble state of system, the result is always unfavourable. Also whilst the gangrene is spreading, the prognosis is bad, as it is impossible to say where the morbid process may stop; but when a "line of demarcation" has formed, indicating the possession of a certain vigour of constitution, the principal danger is over, and the result will depend on the strength of the patient, and the support that can be given during the processes of separation and of repair.

TREATMENT.—As gangrene proceeds from a great variety of causes, it is evident that no one plan of treatment can be universally applied; and it becomes necessary to modify our therapeutical and operative measures, not only according to the cause of the disease, but also with reference to the constitution of the patient, and to the stage in which we meet with the gangrene; and, indeed, it often requires great experience to accommodate the treatment to the varying phases of the disease.

The **Constitutional Treatment** of gangrene is of the highest importance, more especially in the spontaneous forms of the affection. It has three principal aims: 1. To remove the cause if possible, and thus to arrest the gangrene. 2. To support the powers of the system during the process of the separation of the dead tissues; and 3. To lessen the irritability of the nervous system.

1. In attempting to remove the constitutional cause we must bear in mind that constitutional conditions most commonly act only as predisposing causes of gangrene, the death of the part being determined by some local affection. The constitutional conditions which predispose to gangrene, such as want of food, diabetes, Bright's disease, fevers, feebleness of the heart's action, or general arterial degeneration, are all associated with debility. Depressing

remedies must therefore be avoided even in the inflammatory forms of the affection.

Inflammatory fever, however high it may be in the early stages, rapidly gives way, after gangrene has set in, to symptoms of an asthenic type. It is only before the occurrence and during the spread of gangrene, that the use of lowering remedies could possibly be suggested; for, when once gangrene has ceased to extend, however high the fever may have been that accompanied its progress, all the powers of the constitution will be required to maintain the process of separation of the sloughs, if they be extensive and deep. Venesection is never required in any form of gangrenous inflammation. In the forms of gangrene consequent upon specific infective inflammation, however acute the symptoms may be, depletion is never necessary. It would only render the tissues less able to withstand the effects of the specific irritant which is causing the process. In all inflammatory forms of gangrene the diet should be light but nutritious; and the patient should be put to bed, with the affected part elevated, and in many cases a brisk purgative at the commencement of the treatment enables him to take his food better. As the disease advances mild tonics may be given, and in the later periods, when the constitutional symptoms become asthenic, stimulants should be administered. The best stimulants are wine or porter, according to the patient's habits of life; and these should be given in combination with nourishment, so as not merely to raise the pulse, but to produce a more permanent tonic influence on the system generally. If much depression occur, the medicinal stimulants, especially ether, ammonia, and camphor, are of material service. The only tonics that are of much value here are the preparations of cinchona bark and some of the vegetable bitters, as gentian and cascarrilla; and though the specific virtues that were formerly attributed to them can no longer be accorded, yet when they do not irritate the stomach, they are of unquestionable service in combating the asthenic symptoms, and improving the digestive powers. In these cases I look upon cinchona bark, in combination with chlorate of potash and ammonia, as of undoubted value.

As a great part of the constitutional disturbance in most cases is due to the absorption of the products of putrefaction from the dead tissues, much can be done to relieve the symptoms by the efficient local use of antiseptics.

2. After the proper employment of means calculated to remove the constitutional cause of the gangrene, the system must be supported against the debilitating influences that accompany the process of ulceration and of exquaration necessary for the separation of the mortified parts. During this period, there is less fever but more debility, and stronger tonics and stimulants can be borne; but we should be careful not to overstimulate the patient. On this point it is extremely difficult to lay down any precise rule: every possible variety as to the quantity and quality of food and stimulant being required by different individuals. The safest guides are the state of the pulse and tongue: if they improve, the means employed agree. At the same time hygienic measures should be carefully attended to: cleanliness and free ventilation, with the abundant use of disinfectants, are of the first importance.

3. The third indication, that of lessening the irritability of the system which always supervenes, and which is partly owing to the severity of the pain, and partly to the shaken and depressed state of the nervous system, is best carried

out by the administration of opium; and although this drug may not act as a specific, as Pott supposed, yet in many cases, and especially in the gangrene of the toes and feet of old people, it is undoubtedly a remedy of the greatest value. A grain of solid opium may advantageously be administered every sixth, eighth, or twelfth hour, according to the effect which it is found to produce; care being taken that the bowels do not become confined. The hiccup, which is often depressing, is best remedied by the administration of spirits of chloroform and camphor. The effect of opium in diabetic gangrene is often most striking. It must be given in the largest amount the patient can bear, and in most cases as soon as the patient is fully under its influence, the progress of the disease ceases.

Local Treatment.—Gangrene, when threatening as the result of inflammation, may often be prevented by free incisions into the inflamed and tense tissues. Punctures are not sufficient, but free incisions two or three inches long, should be made, which by gaping widely allow the escape of blood and other fluids, and thus effectually relieve the vessels and the tissues. This is more especially the case where there is much loose areolar tissue, as in the penis or scrotum; or indeed in any part in which much tension results from the inflammation. The *relief of local tension* is of the first importance in cases of inflammation threatening to terminate in gangrene. By a free incision through the structures so affected, as in phlegmonous erysipelas, not only may the vitality of the affected tissues be preserved, but the extension of gangrene, if it have already set in, may be arrested, and the constitutional disturbance at once lessened. By incision, also, irritating effusions and infiltrations are discharged, and thus one cause of sloughing is removed.

In the non-inflammatory form of the disease, as soon as it is evident that a part is about to become gangrenous it should be carefully washed with warm carbolic acid lotion (1 in 40). This solution is not of sufficient strength to cause any irritation of the unbroken skin. Having thus rendered the surface as far as possible aseptic, the whole limb should be thickly wrapped in salicylic wool, or it may be sprinkled with iodoform and afterwards covered with iodoform-wool. By this treatment offensive decomposition may often be prevented. Carbolic acid dressings should not be applied, as they are too irritating and might cause extension of the mischief. The dressing should not be disturbed unless the smell indicates that decomposition is taking place beneath it. At a later stage the same treatment may be continued, or the parts that are already gangrenous may be enveloped in lint soaked in warm solutions of carbolic acid, boric acid, chloride of zinc, or creosote, or they may be dusted with charcoal powder and covered with a layer of wadding. No poultices should be applied if the sloughs be large, for heat and moisture hasten decomposition. *The separation of the sloughs* should be left as much as possible to nature. The vitality of the tissues in the proximity of and above the line of separation is very low, and may readily be destroyed by any operative interference. Hence no attempt should be made to remove sloughs not already separated, nor should stimulants be applied to the living tissues. It matters little what is done to parts already dead, which, when loosened, may be cut away; but we must not meddle with those that are living. Hæmorrhage seldom occurs before the separation of the sloughs, but there is always danger of its happening during that process. If it occur, pressure or the actual cautery will be found the best means to arrest it; and, if these fail,

ligature of the artery higher up the limb, or amputation when practicable, might be required.

Parts that are quite dead, but that do not readily separate, such as tendons, ligaments, and bones, may be cut through, and thus many weeks or months saved in their separation. It may occasionally be necessary in doing this to encroach on the living tissues; this should be done as carefully and as sparingly as possible, for reasons already stated.

The line of separation should be dressed with some mild antiseptic lotion or ointment, in order to keep the surface clean and to prevent the absorption of septic discharges. If sloughs do not readily separate, the balsam of Peru, either pure or diluted with yolk of egg, or very dilute nitric acid and opiate lotions are useful applications. After the separation of the sloughs, the ulcerated surface must be treated on general principles.

Having thus briefly considered the treatment of gangrene in general, it remains to indicate certain special points in the treatment of the most important varieties. The question of **Amputation** in cases of gangrene of the limbs is of great importance to the practical Surgeon, and requires our attention.

In the treatment of *local gangrene*, such as that following severe injury, it is a general rule to amputate before the occurrence of the line of demarcation. There are, however, two exceptions to this rule; viz., gangrene from frost-bite, and that from severe burns. In these injuries it is better to wait for the formation of the line of separation, and then to fashion the stump just above it as the circumstances of the case may require. The rule of early amputation also applies to cases of gangrene resulting from wound or ligature of an artery.

The question of amputation in those forms of *gangrene consequent on specific infective processes*, as phlegmonous erysipelas, spreading traumatic gangrene, or hospital gangrene, will be fully considered with those diseases. Such operations often give the only chance of life, but their results are on the whole very unfavourable, the patient usually sinking from a recurrence of the disease in the stump, or from the constitutional disturbance that had previously set in.

In *spontaneous gangrene* from disease of the arteries, it was until recently a golden rule in Surgery never to amputate until the line of separation had formed, and not indeed until the ulceration had extended so deeply into the tissues that there was no chance of the gangrene overleaping the barrier. This rule, which was founded on the fact that it may be impossible in such cases to determine to what height in the limb the gangrene will spread, was justified by the excellent results often obtained. In following this plan of treatment means must be taken to maintain the patient's strength by the administration of tonics, nourishing food, &c., during the process of separation. As soon as all the soft parts, except the ligaments, have been ulcerated through, the mortified part should be separated by cutting through the remaining osseous, ligamentous, or tendinous structures, and then means should be taken to fashion the stump that has been formed by nature. In some cases this will be sufficiently regular to serve every useful purpose after it has cicatrized. In most instances, however, the stump is more irregular and unsightly (of which Fig. 339 is a good illustration) and the bones protrude to such an extent that it is necessary, in order to give the patient a useful limb, to amputate through the face of the stump, or

higher up. All this must be left to the discretion of the Surgeon: but no procedures of this kind should be undertaken until the patient's strength has been restored sufficiently to bear the operation.

The tedious process of separation of the gangrenous part is however by no means devoid of serious risk to the patient, and thus it has come about that attempts have been made to hasten the cure of such cases by amputation through a part of the limb in which the circulation appears to be still active. This method of treatment will be considered in connexion with senile gangrene, in which it has been followed by excellent results. In a remarkable

Fig. 339.—Spontaneous Amputation in gangrene of Right Foot and Left Leg from Embolism.

case recorded by Pearce Gould of symmetrical gangrene of both feet from obliterative disease of the arteries and veins amputation was successfully performed through the knee-joints before a line of demarcation had formed.

In *gangrene from embolism*, the amputation may as a rule be performed at an early period, provided the patient's general condition is such as to justify the operation, but it should not be undertaken until the supply of blood to the tissues immediately above the gangrenous parts is fully restored, and a distinct line of demarcation has formed, close to which the incisions may safely be carried.

In *senile gangrene* the constitutional treatment is important, and although depletory measures are never admissible, we must guard against over-stimulation of the patient. Senile gangrene commonly occurs in individuals belonging to the wealthier classes of society, who have lived high, taken insufficient exercise, and consequently induced an irritable, plethoric, but enfeebled state of system. In many cases the patients are of a gouty habit, and occasionally the inflammation that precedes the development of the gangrene appears to be of this nature. In this condition stimulants and the more powerful tonics are not well borne; they accelerate the pulse and interfere with digestion. As Brodie observes, it is of great importance in this disease to attend to the state of the digestive organs, in order that nutrition may go on, and that blood of a proper quality may be made. In order to accomplish this, a light nourishing diet, partly animal and partly vegetable, should be given, and a moderate quantity of wine, beer, or brandy allowed. The bowels must be relieved from time to time by a saline aperient, a rhubarb draught, or simple aperient pill. Mercury depresses the patient, and hence it should not be used as an aperient in any form in this disease, unless the state of the liver imperatively demand it. If the digestion become impaired, a stomachic, as the infusion of cascarrilla or the compound infusion of gentian with a little ammonia, may be given.

The administration of opium in these cases, as originally recommended by Pott, has received the sanction of almost every practical Surgeon. Brodie's opinion on this point is especially valuable; he says, "If I am not greatly mistaken, the result of a particular case will very much depend on this—whether opium does or does not agree with the patient." From two to four grains of opium may be administered in divided doses in the course of twenty-four hours; the quantity being increased as the system becomes accustomed to its effects. If, however, it disturb the stomach and occasion headache, notwithstanding the use of aperients, as will often happen when there is febrile disturbance in persons of a full habit of body, it must be discontinued. The pain in the foot, which is often very severe during the progress of the disease, usually ceases when the mortification is complete; before this, it is but little influenced by sedatives, whether constitutionally or locally applied.

It may be stated generally that in those cases in which there is much fever, in which the tongue is loaded, the pulse quick, and the skin hot, in which the spread of the gangrene is preceded by a red angry blush, with much pain and heat, moderate diet and mild tonics will be most useful; whilst on the other hand, when it is simply a shrivelling of the toes and feet, without any pressing local inflammation, or febrile disturbance, a decided tonic or stimulating plan will succeed best.

If the gangrene be limited to one or more of the toes the local treatment should consist in maintaining the temperature of the part and endeavouring to prevent putrefaction of the dead tissues. This is best done by surrounding the part in a sheet of antiseptic wool, which need not be changed more than once or twice a week. Should the gangrene be of the moist variety the dead part may be painted with carbolic acid and glycerine (1 in 5), or some such powerful antiseptic, before being covered with wool. When the soft parts have been separated, the bone may be cut through and the sore dressed with some antiseptic lotion or stimulating ointment.

If however the gangrene be more extensive and involve the foot much danger inevitably attends the separation of the dead parts. To avoid this amputation may in suitable cases be performed without waiting for the formation of a line of demarcation. This practice has been successfully adopted by Garlike, James of Exeter, Jonathan Hutchinson, and others, and certainly is a justifiable proceeding in well selected cases in which the health is otherwise good, the constitution tolerably sound, and the gangrene so extensive as to make it very doubtful if the patient would survive the process of natural separation of the dead parts. In gangrene of the foot the amputation should be done immediately above the knee, as if performed lower down there would be great danger of sloughing of the flaps. The circular method should always be adopted, as it makes the smallest wound, and avoids the danger of sloughing attending a flap operation. A convenient mode of amputation in such cases has been described on p. 138. The operation must be performed with strict antiseptic precautions, and some form of lasting antiseptic dressing will be found most convenient in the after-treatment. Amputation should not be undertaken merely to give a patient a "last chance," when he is already dying of exhaustion or septic poisoning, as when performed under these circumstances it has usually been fatal within twenty-four hours.

In *diabetic gangrene* the administration of opium or codon and the exclusion of starchy and saccharine matter from the diet may in some cases arrest the

gangrenous process. König, however, showed, and the statement has been confirmed by others, that the gangrenous inflammation may cause an increase in the amount of sugar and intensify the other symptoms, and that under these circumstances anti-diabetic treatment is likely to fail.

Until recent years the question of amputation for diabetic gangrene did not present itself. Experience has, however, shewn that extensive wounds will often heal quite satisfactorily in patients suffering from diabetes if strict asepsis can be maintained. This has been especially insisted upon by König, and amputation for diabetic gangrene has also been advocated by Roser and Kuster, and recently in this country by Godlee and Spencer. It has already been pointed out that arterial disease is doubtless a most important factor in the production of the gangrene of diabetes, and indeed in cases which appear to be of this variety the same rules of local treatment may guide the Surgeon as in senile gangrene. If high amputation be undertaken no pains must be spared to keep the wound aseptic. In the more chronic and painless forms of this affection, which are probably, in part at least, dependent on changes in the nerves, Godlee suggests that the case may more safely be left for the chance of separation by natural means. The high amputation is under these circumstances hardly likely to be called for; and if removal of the limb be practised, it may be done a short distance above the gangrenous part.

In the treatment of *Raynaud's disease* gangrene must if possible be prevented by improving the nutrition of the limb, for which purpose shampooing and galvanism have proved of service. Barlow recommends that the extremity of the affected limb be immersed in a basin of salt water, whilst one pole of a constant-current battery is placed on the upper part of the limb, and the other in the basin. The strength of the current should be such as the patient can comfortably bear, and it should be made and broken frequently. If gangrene occurs and is limited to the fingers or toes Raynaud strongly recommends that the dead part should be allowed to separate by natural means. It is only in those rare cases in which the process is more extensive that the advisability of amputation will have to be considered on the same grounds as in other forms of spontaneous gangrene.

BED-SORES.

When a part of the body is compressed too severely, or for too long a time, even in a healthy person, it loses its vitality, and a limited slough results: this separates, and an ulcer is left, which cicatrizes in the usual way. But in certain deranged states of the health, more especially when the blood is vitiated, and the constitutional powers lowered, as during fever, or when the heart is diseased and weakened, more particularly if the patient be old and debilitated, or if innervation be acutely affected, and he be paralysed, the skin covering those points of the body that are necessarily pressed upon in the recumbent position, such as the sacrum, the trochanters, the elbows, shoulders, and heels, becomes congested and inflamed, assuming a dull reddish-brown colour, and speedily becomes excoriated, often without any pain being felt by the patient. One great cause of bed-sores is undoubtedly bad nursing. It would not be just to say that a bed-sore is always the result of negligent nursing, but it may truly be said that the chance of the formation of bed-sores, and their severity when formed, will be increased or diminished in the

exact ratio of the negligence or care of the nurse. It is not so much the actual severity of the pressure that occasions a bed-sore, as moderate long-continued pressure applied to a part congested by position in a patient enfeebled by disease. If means be not taken to relieve the part from the injurious compression to which it is subjected, and more especially if it be allowed to become irritated by the contact of feces or urine, the subcutaneous areolar tissue corresponding to the inflamed patch will be converted, with the skin covering it, into a tough greyish slough, from under which a thin ichorous pus exudes. This slough may extend by a process of undermining of the integuments covering it; and on its separation extensive mischief will be disclosed, the fascia and muscles being exposed, or the bones even laid bare, and soon becoming roughened and carious. In some cases even the inferior aperture of the spinal canal may be laid open, and death result from septic meningitis. In other cases, the patient is worn out by discharge and irritation, or succumbs to pyæmia or septicæmia.

TREATMENT.—This is in a great measure preventive. When a patient is likely to be confined to bed for many weeks, especially by exhausting disease, steps should be taken by proper arrangement of the pillows, and by the use of a water-bed or cushions, to prevent pressure from being injuriously exercised upon any one part. If the patient be unable to move himself his position should be changed by the nurse at regular intervals. At the same time, cleanliness and dryness should be carefully provided for by proper nursing, by the use of a draw-sheet, and by furnishing the bedstead with the necessary arrangements for using the bed-pan, &c. The back should be periodically examined by the Surgeon himself. The skin on the exposed parts may be protected by the application of collodion or soap-plaster spread upon wash-leather or amadou, or isinglass on felt; or, what is better, it may be strengthened by being washed with spirits of wine. In some cases much benefit is derived from frictions of brandy and glycerine in equal parts. If the skin has become reddened it should be painted with a solution of nitrate of silver, of gr. v. to 3j.

If the skin have become chafed, the removal of pressure is imperative, and the abrasion may be washed over with collodion. If a sore have formed it may be dressed with boric acid ointment, or balsam of Peru, spread upon lint. In some cases the prone couch may occasionally be advantageously substituted for the ordinary bed previously employed. When sloughs have formed, their separation must be facilitated by the use of moist antiseptic dressings, as boric acid lint and lotion, and the ulcers that are left should be treated on ordinary principles, the utmost attention being paid to cleanliness by the use of antiseptic lotions; but no dressing that the Surgeon can apply will cause these ulcers to clean, and still less to heal, unless pressure be removed and the patient's general health improve, when they will speedily cicatrize under the most simple treatment.

BOILS.

A **BOIL** OR **FURUNCLE** is a localized inflammation affecting the skin and subcutaneous tissue terminating in the formation of a small conical slough of areolar tissue called the *core*, around which suppuration takes place, the dead tissue being finally separated and discharged by an opening through the skin.

The inflammation starts in connection with a hair, but whether from the follicle itself or from the sebaceous gland is uncertain: probably it may commence in either situation. It begins as a small red pimple, through the middle of which the hair may often be seen protruding. From this the inflammation extends into the subcutaneous tissue; it is accompanied by abundant conglutable exudation, so that the inflamed area becomes raised above the surrounding parts, forming a hard circumscribed tumour of a purplish-red colour, conical in form, but flattened at the top. On the summit of this a vesicle forms which bursts, leaving a grey slough exposed, which is gradually loosened by suppuration around it, and discharged usually by a single opening, after which the small cavity heals rapidly. In the early stages there are itching and tenderness, but as the tension and hardness increase the boil becomes extremely painful. Boils are always seated on parts provided with hair, the most common situations being the back of the neck, the shoulders, nates, and hands. They seldom occur singly, one usually following another for some weeks or even months. The nearest lymphatic glands are usually swollen, but very rarely suppurate. In some cases the inflammation subsides without suppuration, and the boil is then said to be *blind*.

Predisposing Causes.—Boils most frequently occur in young people, but are common enough at all ages. They are met with sometimes in very plethoric, and sometimes in enfeebled, constitutions, often following some of the more severe febrile diseases, and attending convalescence from them: they are not uncommon in diabetic subjects. The boils which often break out during training for athletic contests are supposed to be due to a too exclusively animal diet. Sometimes boils may be traced to exposure to sewer-gas. In other cases, the system appears to have fallen into a cachectic state, often without any evident cause, and this terminates by a critical eruption of boils. A sudden change in the habits of life, as from sedentary to active pursuits, a course of sea-bathing, &c., will also occasion them. They are commonly met with in the spring of the year, but may occur at all seasons, and are occasionally epidemic.

Immediate Causes.—Many years ago Pasteur showed that a micrococcus was always present in the discharge that could be obtained from a boil by puncturing it and squeezing it at an early stage. This organism has since been identified as the staphylococcus pyogenes so commonly found in all acute suppurations. That it can act as a cause of boils has been shown by Giarré, who rubbed a gelatine cultivation of the staphylococcus obtained from a case of acute necrosis of bone into his own arm, with the result of producing a closely set crop of boils. Boils are also well known to be common on the hands from the contact of decomposing animal matter in *post-mortem* examinations. Friction seems an important local cause, as they are most common on the neck at the part rubbed by the collar, and are often met with on the nates from rowing.

Treatment.—If any definite constitutional condition can be discovered upon which the boils seem to be dependent it must be attended to. The urine should always be tested for sugar and albumen. The drains of the house in which the patient lives should be examined as the disease may be due to poisoning by sewer-gas. Boils may occur in the most opposite conditions of health, and different modes of treatment are consequently necessary. If the patient be debilitated and cachectic, iron, quinine, and cod-liver oil; if he be

plethoric, and the system loaded, purgatives, salines, and liquor potassæ will be appropriate. In the one case an abundant nourishing diet, in the other case a spare and simple one, with avoidance of stimulants, will be required. Change of air is often very beneficial. In some cases empirical means are of service. Thus, when the disease is associated with pompholyx, or preceded by painful vesicles, arsenic may be of benefit. In other instances, yeast or charcoal has been advantageously given. Ringer strongly recommends the administration of sulphide of calcium both for preventing the formation of fresh boils and hastening the separation of the slough in those that have already appeared. A tenth of a grain may be given hourly or a third of a grain four times a day.

The *Local Treatment* is simple. When the boil is in its earliest stage, if a hair can be seen projecting through the pimple, it should be pulled out with forceps. The development may in some cases be arrested also by touching it with nitrate of silver, or with a saturated solution of perchloride of mercury. When the boil is evidently forming the red area around it should be painted with equal parts of glycerine and belladonna. This usually relieves the pain and protects the skin from the irritation of the poultices or other applications. Hot, moist applications must then be employed; four layers of wet boric acid lint covered with oiled silk and cotton-wool, or a linseed meal poultice well greased on the surface, forms the best application. Poultices, however, in many cases irritate the surrounding skin, and encourage the formation of a fresh crop of boils. Nothing will be found to give so much relief or to hasten suppuration more than the application of a sponge squeezed out of water, as hot as the patient can bear it, and changed every few minutes. If the patient is confined to the house, he can carry out this treatment himself for several hours during the day. Most commonly a boil may be allowed to break, but the Surgeon may in some cases find it necessary to incise it when it is large, and does not appear disposed to break of itself.

CARBUNCLE.

A **CARBUNCLE** is a specific spreading inflammation of the subcutaneous areolar tissue, implicating the skin and terminating in death of the affected tissues, with the formation of a pulpy greyish or ash-coloured slough. Whether it commences in the deep layers of the true skin—possibly in the sebaceous glands, or in the subcutaneous areolar tissue—has not been definitively determined.

Signs.—A carbuncle begins as a flat or very slightly conical inflammatory swelling of the skin, the base of which is hard, and the edges clearly defined: it is of a dusky-red colour and is accompanied from the first by a burning, stinging, heavy, or throbbing pain in the part, out of proportion to the apparent gravity of the disease. The inflamed base steadily enlarges and implicates the subcutaneous tissue more deeply, forming a flat, slightly elevated, hard, circumscribed swelling, gradually becoming doughy as sloughing sets in. As it increases in size, the swelling maintains its flattened circular or oval shape, and the skin covering it assumes a purple or brownish-red tint. Vesicles form on it at several points, which speedily become pustular and burst, exposing openings beneath in the cutis, through which the ash-grey sloughs appear, and from which unhealthy purulent discharge scantily issues. The openings in

the thin undermined skin gradually melt into each other, and the slough slowly separates. In most cases, the whole thickness of the subcutaneous fat is not destroyed; but occasionally when the slough comes away the deep fascia or even the muscles may be exposed.

The size of the swelling varies from one to six inches in diameter; most commonly it is about two inches across. Carbuncles are generally met with on the posterior part of the trunk, more especially about the shoulders and the nape of the neck; being rarely seen anteriorly, or on the extremities. I have, however, had to treat very large carbuncles on the abdomen, and have met with them on the shin, forearm, and forehead. A carbuncle is almost invariably single; but some years ago I had under my care a patient in whom a large carbuncle was followed by the appearance of about a dozen smaller ones scattered over the back, in spite of which he finally recovered.

The **Constitutional Disturbance** attending this disease is always of the asthenic type; the complexion is often peculiarly sallow or yellow, the pulse feeble, and the tongue loaded; and if the carbuncle be large, or be seated on the head, death may take place, the patient frequently sinking from septicæmia or pyæmia.

Causes.—A carbuncle arises usually without any assignable local exciting cause; but in some cases it is evidently occasioned by the introduction of some poisonous matter into a puncture in the skin or into a hair-follicle. In all cases it is associated with and dependent upon a disordered state of the constitution, and any condition that lowers the powers of the system will predispose to it. Habitually bad and insufficient food, the exhaustion induced by chronic wasting diseases, especially diabetes, or the debility resulting from acute febrile diseases—more particularly typhus—may all occasion it. Carbuncles are more common in men than in women, and in the old than in the young, being very rare under twenty. They occur more frequently in some years than in others. Micrococci are abundantly present in the diseased tissues, but no specific organism definitely related to the disease has been discovered.

Diagnosis.—A carbuncle resembles a *boil* in many points, yet differs in its greater size, in the dusky-red colour of the inflamed integument, in its broad flat form, and in the large quantity of contained slough in proportion to the small amount of purulent discharge in the numerous openings on the surface, as well as in the conditions in which it generally occurs. It differs from a boil also in its tendency to spread. A boil "comes to a head," bursts, and discharges pus and slough; a carbuncle will be discharging and sloughing at one part, whilst it spreads, hard and brawny, at another. A carbuncle is almost invariably single; boils most commonly appear in crops.

The **Prognosis** in carbuncle will depend on its size and situation, and on the state of the patient's constitution, more particularly on that of his kidneys. The most dangerous carbuncles are those that are large, and situated or encroaching on the scalp; in fact, the more this structure is involved the greater the danger. If the constitution be good, even these may be recovered from; but if the kidneys be unsound, or if there be saccharine diabetes, the progress of the disease cannot readily be checked, and the patient will usually sink.

Treatment.—The **Constitutional Treatment** of carbuncle must be guided by the constitutional state that accompanies the local disease. If the

carbuncle occur in a debilitated person, the tincture of the perchloride of iron in small and frequent doses, with a moderate allowance of alcoholic stimulants and a good diet, will be necessary. If the patient be diabetic, opium must be freely administered, unless chronic bronchitis or albumen in the urine should contra-indicate it. If the carbuncle occur in a person of advanced years addicted to high living, and possibly not temperate in habits, the ordinary treatment of inflammation of a sloughing character must be adopted. The bowels having been freely cleared out, ammonia and bark, or quinine, must be given. Alcoholic stimulants may be more freely administered. But they must be administered medicinally in measured quantities, and at intervals of longer or shorter duration according to the need of the patient as determined by his pulse and temperature. Port-wine used to be the favourite remedy. It is considered less necessary at the present day than it was a generation or two back, and brandy or whiskey with milk or eggs is commonly substituted for it. But whatever stimulant be given, too much care cannot be taken in regulating its doses and times of administration, which must not be left to the discretion of the non-medical attendant. In addition to stimulants, good and abundant nourishment should be given; meat, if the patient can digest it; if not, soups, such as strong beef-tea, essence of meat, or turtle-soup.

Local Treatment.—In the very early stage the progress of a carbuncle may be arrested by destroying it with a pointed stick of potassa cum calce. If the carbuncle have attained a somewhat larger size, though still small, it may be covered with a piece of soap-plaster spread on leather, having a hole cut in the centre, through which the pus and sloughy matters may be discharged. When the carbuncle is of still larger size the question will arise whether it should be incised or not. Some Surgeons uniformly adopt incisions; others, with equal constancy, reject them. I think that the exclusive adoption of either method is erroneous, and that the most successful treatment consists in allowing the question of early incision to be determined by the amount of tension existing in and around the carbuncle. Should the parts be soft, relaxed, and comparatively painless, an incision is not necessary; but, on the other hand if the tension be considerable, the pain great, and the constitutional disturbance dependent on both proportionately intense, nothing gives such immediate relief, local and constitutional, as early and free incision. The crucial incision which has been largely employed is sometimes convenient, but often presents no advantages over a single straight one. The bleeding may be free, and as the patient is seldom in a state to lose blood it must at once be restrained by dry cotton-wool and pressure. Hueter advises that if the patient is strong enough to stand the necessary loss of blood, and if the carbuncle be not too large, the whole slough should be scraped or dissected away at the time the incision is made. The cavity thus left should be well scrubbed out with some powerful antiseptic lotion and dressed antiseptically. In this way extension is arrested and the fever due to the presence of the slough immediately subdued.

Should incision of the carbuncle not have been performed early, it may become necessary at a later period, in order to prevent the confinement of the pus and sloughs. Pyæmia is so frequent a cause of death in bad cases of carbuncle, that it becomes very important to prevent putrefaction in the sloughs, if possible. If an incision be made before the skin has given way,

it should be done with antiseptic precautions. The surrounding skin should be washed with carbolic lotion, and as soon as the incision has been made an antiseptic dressing should be applied. At subsequent dressings the surface must be irrigated with some antiseptic lotion. Iodoform sprinkled on the sore is often most useful. Poultices should be avoided as tending to encourage putrefaction. If warmth and moisture are required, a thick layer of boric acid lint wetted with a concentrated solution of boric acid or salicylic wool moistened with warm water, will be found the most convenient application; or if these be not at hand, the carbuncle may be covered with some lint soaked in carbolic oil (1 in 10), or terebene and oil, or some other antiseptic dressing, over which a fomentation may be applied. As the sloughs loosen, they should be separated; and the granulating surface which is left, and which will usually be found to be sluggish in healing, should be dressed with some of the more stimulating ointments, such as those of elemi, resin, or balsam of Peru.

FACIAL CARBUNCLE.—Under this name has been described by Ludlow, T. Smith and others, a somewhat rare form of gangrenous inflammation of the face. It appears first as a pustule or vesicle on the lip—according to Smith, most commonly on the upper lip. It is surrounded by a red blush, and the tissues beneath are swollen and oedematous. The swelling spreads rapidly, often involving a great part of one side of the face; in a few days its edge is less clearly defined, and the swollen tissues are more oedematous and less brawny than in a common carbuncle. Suppuration takes place after two or three days, in patches scattered through the swollen tissues. The skin in the central part becomes dusky in colour, and the subcutaneous tissue breaks down into soft shreddy sloughs soaked in pus. The constitutional symptoms are of the gravest kind; there is considerable elevation of temperature at first, with dry tongue and great prostration. Should the patient survive to the period of sloughing and suppuration, death may take place from pyæmia or septicæmia. Embolic pyæmia is very common following septic thrombosis of the large veins on the side of the face.

In rare cases the disease may commence about the nose and extend to the eyelids. It may then be fatal by septic thrombosis extending backwards by the ophthalmic vein to the cavernous sinus. In this condition there is great swelling of the eyelids, and pus may form deeply in the orbit. It is speedily fatal from meningitis or pyæmia. The exact relation of this affection to true carbuncle is doubtful. T. Smith believes it to differ only in the greater acuteness and intensity of the process, but I do not think it can be considered a carbuncular inflammation. Its whole course and the appearance of the inflamed part rather indicate its alliance to phlegmonous erysipelas. Death ensues usually in from forty-eight hours to five or six days after invasion. It is a very grave, but not a hopeless affection.

Diagnosis.—The disease somewhat resembles malignant pustule, with which it has often been confounded. The black slough surrounded by vesicles which is so characteristic of the latter disease, is, however, wanting in facial carbuncle. Moreover, in malignant pustule the slough is dry, while in facial carbuncle it is soaked in pus.

Treatment.—Abundance of liquid nourishment and stimulants are required, and Paget recommends the administration of quinine in large doses. Locally, incisions seem to have been of but little use; the application of hot

carbuncle occur in a debilitated person, the tincture of the perchloride of iron in small and frequent doses, with a moderate allowance of alcoholic stimulants and a good diet, will be necessary. If the patient be diabetic, opium must be freely administered, unless chronic bronchitis or albumen in the urine should contra-indicate it. If the carbuncle occur in a person of advanced years addicted to high living, and possibly not temperate in habits, the ordinary treatment of inflammation of a sloughing character must be adopted. The bowels having been freely cleared out, ammonia and bark, or quinine, must be given. Alcoholic stimulants may be more freely administered. But they must be administered medicinally in measured quantities, and at intervals of longer or shorter duration according to the need of the patient as determined by his pulse and temperature. Port-wine used to be the favourite remedy. It is considered less necessary at the present day than it was a generation or two back, and brandy or whiskey with milk or eggs is commonly substituted for it. But whatever stimulant be given, too much care cannot be taken in regulating its doses and times of administration, which must not be left to the discretion of the non-medical attendant. In addition to stimulants, good and abundant nourishment should be given; meat, if the patient can digest it; if not, soups, such as strong beef-tea, essence of meat, or turtle-soup.

Local Treatment.—In the very early stage the progress of a carbuncle may be arrested by destroying it with a pointed stick of potassa cum calce. If the carbuncle have attained a somewhat larger size, though still small, it may be covered with a piece of soap-plaster spread on leather, having a hole cut in the centre, through which the pus and sloughy matters may be discharged. When the carbuncle is of still larger size the question will arise whether it should be incised or not. Some Surgeons uniformly adopt incisions; others, with equal constancy, reject them. I think that the exclusive adoption of either method is erroneous, and that the most successful treatment consists in allowing the question of early incision to be determined by the amount of tension existing in and around the carbuncle. Should the parts be soft, relaxed, and comparatively painless, an incision is not necessary; but, on the other hand if the tension be considerable, the pain great, and the constitutional disturbance dependent on both proportionately intense, nothing gives such immediate relief, local and constitutional, as early and free incision. The crucial incision which has been largely employed is sometimes convenient, but often presents no advantages over a single straight one. The bleeding may be free, and as the patient is seldom in a state to lose blood it must at once be restrained by dry cotton-wool and pressure. Hueter advises that if the patient is strong enough to stand the necessary loss of blood, and if the carbuncle be not too large, the whole slough should be scraped or dissected away at the time the incision is made. The cavity thus left should be well scrubbed out with some powerful antiseptic lotion and dressed antiseptically. In this way extension is arrested and the fever due to the presence of the slough immediately subdued.

Should incision of the carbuncle not have been performed early, it may become necessary at a later period, in order to prevent the confinement of the pus and sloughs. Pyæmia is so frequent a cause of death in bad cases of carbuncle, that it becomes very important to prevent putrefaction in the sloughs, if possible. If an incision be made before the skin has given way,

it should be done with antiseptic precautions. The surrounding skin should be washed with carbolic lotion, and as soon as the incision has been made an antiseptic dressing should be applied. At subsequent dressings the surface must be irrigated with some antiseptic lotion. Iodoform sprinkled on the sore is often most useful. Poultices should be avoided as tending to encourage putrefaction. If warmth and moisture are required, a thick layer of boric acid lint wetted with a concentrated solution of boric acid or salicylic wool moistened with warm water, will be found the most convenient application; or if these be not at hand, the carbuncle may be covered with some lint soaked in carbolic oil (1 in 10), or terebene and oil, or some other antiseptic dressing, over which a fomentation may be applied. As the sloughs loosen, they should be separated; and the granulating surface which is left, and which will usually be found to be sluggish in healing, should be dressed with some of the more stimulating ointments, such as those of elemi, resin, or balsam of Peru.

FACIAL CARBUNCLE.—Under this name has been described by Ludlow, T. Smith and others, a somewhat rare form of gangrenous inflammation of the face. It appears first as a pustule or vesicle on the lip—according to Smith, most commonly on the upper lip. It is surrounded by a red blush, and the tissues beneath are swollen and œdematous. The swelling spreads rapidly, often involving a great part of one side of the face: in a few days its edge is less clearly defined, and the swollen tissues are more œdematous and less brawny than in a common carbuncle. Suppuration takes place after two or three days, in patches scattered through the swollen tissues. The skin in the central part becomes dusky in colour, and the subcutaneous tissue breaks down into soft shreddy sloughs soaked in pus. The constitutional symptoms are of the gravest kind; there is considerable elevation of temperature at first, with dry tongue and great prostration. Should the patient survive to the period of sloughing and suppuration, death may take place from pyæmia or septicæmia. Embolic pyæmia is very common following septic thrombosis of the large veins on the side of the face.

In rare cases the disease may commence about the nose and extend to the eyelids. It may then be fatal by septic thrombosis extending backwards by the ophthalmic vein to the cavernous sinus. In this condition there is great swelling of the eyelids, and pus may form deeply in the orbit. It is speedily fatal from meningitis or pyæmia. The exact relation of this affection to true carbuncle is doubtful. T. Smith believes it to differ only in the greater acuteness and intensity of the process, but I do not think it can be considered a carbuncular inflammation. Its whole course and the appearance of the inflamed part rather indicate its alliance to phlegmonous erysipelas. Death ensues usually in from forty-eight hours to five or six days after invasion. It is a very grave, but not a hopeless affection.

Diagnosis.—The disease somewhat resembles malignant pustule, with which it has often been confounded. The black slough surrounded by vesicles which is so characteristic of the latter disease, is, however, wanting in facial carbuncle. Moreover, in malignant pustule the slough is dry, while in facial carbuncle it is soaked in pus.

Treatment. Abundance of liquid nourishment and stimulants are required, and Paget recommends the administration of quinine in large doses. Locally, incisions seem to have been of but little use; the application of hot

fomentations, followed by antiseptic dressings when sloughing has taken place, is all that can be done in most cases.

CANCERUM ORIS. OR NOMA.

Cancerum oris is a rapidly spreading gangrenous inflammation attacking the inside of the cheek, most frequently between the second and sixth years of life. It is met with usually in ill-fed, sickly children who have been living under bad hygienic conditions. It commonly occurs during convalescence from some acute specific fever, most frequently measles; or after the incautious administration of mercury during a weak state of the system.

Symptoms.—One of the cheeks becomes red, swollen, brawny, tense, and shining, being excessively hard. It is often difficult to open the mouth: but if the Surgeon can gain a view of its inside, he will see a deep and excavated foul ulcer opposite to the centre of the external swelling, covered with a brown pulpy slough. The gums are turgid, dark and ulcerated; the saliva is mixed with putrescent matters. By the second day a dark purple spot appears in the middle of the red external swelling over which the epithelium separates and the skin quickly becomes gangrenous. The sloughing extends rapidly, until by the third or fourth day a large gangrenous cavity is formed, opening externally through the cheek and internally laying bare the alveolar borders of the jaw. The child suffers little, and, as the disease advances, it commonly becomes drowsy, and at last dies comatose, usually within a week. This affection is most fatal. Rilliet and Barthez state that not more than one case in twenty recovers. Should recovery take place, a large portion of the cheek may be lost, opening the mouth half way back to the ear, or a dense cicatricial band may form between the jaws, making it impossible to open the mouth.

Pathology.—The exact cause of the ulceration is still uncertain. In the ulcerative stomatitis of calves, which in many respects closely resembles cancerum oris, Lingard and Batt have found the line of junction of the necrotic and healthy tissues occupied by a "mass of bacilli having the appearance of a dense phalanx advancing upon the healthy tissues." These were cultivated out of the body, and found capable of causing a spreading necrosis when inoculated on other animals. In one case of cancerum oris which he had the opportunity of examining, Lingard found similar organisms with the same arrangement.

Treatment.—The child must be put under chloroform, and the sloughing mass deeply cauterized. The sloughs should be scraped or scrubbed away before the caustic is applied. Nitric acid is usually recommended in these cases. The actual cautery may also be used, especially when the cheek is already perforated. If the slough appears on the surface externally, it may be cut away before applying the caustic. After cauterization the mouth should be syringed out with diluted Condy's fluid, and the ulcerating surface dusted with iodoform. The strength must be supported with beef-tea, wine, and ammonia. If recovery take place, some plastic operation may be necessary at a later period, in order either to close the gap in the cheek or to enable the child to open its mouth.

NOMA OF THE VULVA—GANGRENOUS VULVITIS.

Gangrenous Inflammation of the Vulva of a character much resembling cancrum oris, and occurring under similar conditions, is occasionally met with in unhealthy, ill-fed female children, and is not uncommonly fatal. It usually attacks the surface of one labium, but soon extends to the other by contact. The parts round are swollen and inflamed, and in the centre is an ash-grey slough, which rapidly extends. The **Treatment** consists in wiping or scraping away the slough and applying fuming nitric acid. After this the child should be kept for some hours every day in a bath of warm boric acid lotion. When in bed, a piece of lint soaked in a solution of boric acid in glycerine and water should be placed between the labia.

CHAPTER XXXI.

DISEASES ARISING FROM SEPTIC AND INFECTIVE
PROCESSES IN WOUNDS.

THIS group of diseases, including septicæmia, pyæmia, anthrax, tetanus, rabies, erysipelas, hospital gangrene and some others of less importance, has been investigated of recent years by numberless observers with an energy and ability probably never exceeded in any branch of science. As the means of observation were improved and new methods of investigation invented, so the conviction in the minds of the majority of pathologists became more and more confirmed that all these unhealthy processes are directly caused by the action of living micro-organisms. We are still very far from knowing all the conditions which, as predisposing or accessory causes, take part in the development of these diseases, or the exact mode in which the organisms give rise to the various morbid processes with which they are associated; but that their relation to them is, in some forms of disease at least, actually one of cause and effect, may be said to be no longer a mere hypothesis.

The relations of microscopic organisms to unhealthy inflammations, and the nature of a true infective process have already been discussed in the chapter on Inflammation, p. 177, *et seq.*

It will be remembered that it was there pointed out that a clear distinction must be drawn between simple putrefaction and infective processes. Simple putrefaction is a fermentative change taking place in dead matter only, and the products of the fermentation may excite inflammation and suppuration locally, and if absorbed give rise to a definite constitutional disturbance; but the organized ferment which determines the process cannot act on living tissues, consequently there is no true infection, either locally or of the system in general. It is to processes of this kind that the term "septic" should be limited, the word then being synonymous with "putrid."

In a true infective process the virus infects the living tissues, increasing in quantity amongst them, and gives rise to unhealthy processes in them. These may be local, the accompanying constitutional disturbance being merely the result of the absorption of the chemical products resulting from the growth of the organisms; or general, when the virus enters the blood-stream and multiplies in it. The former is called a *local*, and the latter a *general infective process*.

In simple septic processes the fungi which are supposed to cause them are said to be non-pathogenic or non-parasitic; in infective processes they are spoken of as pathogenic or parasitic. The term "mycosis" is often used to signify the infection of the living tissues by fungoid organisms.

Although these septic and infective processes are distinct from each other they are nearly related; infective processes very rarely starting from wounds, unless the discharges are in a septic condition. This fact has been explained by supposing that non-pathogenic organisms may develop pathogenic pro-

been already described in Chapter XI.; tetanus will be considered in a subsequent Chapter.

It is impossible here to discuss fully the evidence for and against the micro-parasitic origin of these diseases. It is essential to bear in mind the four postulates which, according to Koch, must be fulfilled, before the causal relation of a micro-organism to any given disease can be taken as proved. First, the organism must be constantly present in cases of the disease; secondly, the organism must be capable of cultivation outside the body; thirdly, the disease must be capable of production by inoculation with the pure cultivation; and fourthly, the same organism must be capable of demonstration in the disease thus produced. Anthrax and cutaneous erysipelas may be quoted as instances in which these necessary conditions have been fulfilled, and, judging by analogy, the probability is great that in allied diseases the same proof will eventually be forthcoming. Further, the course of such diseases, the modifications produced by altered conditions in the body and in its surroundings, and lastly, the modes of prevention are all in keeping with the hypothesis of a living virus.

The chief arguments urged against it are the following. In the first place, it has been urged that many processes, dissimilar in every respect, are found to be associated with the presence of organisms apparently perfectly similar. Thus micrococci are found in a simple acute abscess, in erysipelas and in pyæmia; but with bodies of such extreme minuteness differences may readily exist which it is beyond our power to recognize. Cohn, while referring to this question, called attention to the external similarity of the sweet and bitter almond, which yet differ from each other so widely in their chemical properties. A much more important objection, which is pointed out by Koch himself, is that in many cases in the human subject the number of microscopic organisms found has been singularly small, so small in fact as to make it difficult to understand how they could be the cause of such grave disease. Lastly, it has been maintained that the microscopic organisms are merely an accidental accompaniment of the process and not the cause, or that at most they serve merely as carriers of the virus and are not the producers of it. It is difficult to refute this assertion with the means at present at our command. When, however, as in the case of erysipelas, the organism may be cultivated for twenty generations out of the body in an artificial medium, and finally, on being inoculated on another individual will produce a genuine attack of the disease, it seems difficult to regard it as other than an essential factor in the production of the specific inflammation.

It must be acknowledged therefore, that, although it is highly probable that all the diseases in this group arise directly from the action of micro-organisms, the evidence is not as yet sufficient to furnish in every case demonstrative proof of the truth of this theory.

Supposing, however, that the fungoid theory of infective processes in wounds were proved beyond a doubt, this would in no way disprove the facts previously known as to the influence of bad hygienic conditions in the development of these diseases. The experience of generations of Surgeons has taught us that, although inflammation and suppuration with febrile disturbance result from contact with the raw surfaces of wounds of such simple septic products as must form in all dead tissues or putrescible animal fluids exposed to the ordinary air of a dwelling-house, the graver infective processes are of

extreme rarity in cases treated in pure air and in the isolation of a private house. On the other hand, it has been established incontestably that if the cubic capacity of a ward be taken, and the rate of ventilation through it determined, a Surgeon may with certainty foretell how many suppurating wounds it will require, in the absence of antiseptic treatment, to generate infective disease in it.

Thus, although in the prevention of these diseases the use of antiseptics must take the first place as attacking the evil at its source, a strict attention to the laws of hygiene as regards cubic space, ventilation, and general cleanliness, is also necessary to exclude those accessory conditions that favour its development. By these means combined all this group of diseases can be prevented; their occurrence is the result in almost all cases of some definite error in the treatment of the wound, or of some infringement of sanitary rules. They are not accidental; they are preventable and ought to be prevented. Should a case arise, our knowledge of the nature of the diseases shows clearly how they may be carried from one individual to another, and efficient means to prevent their spread should at once be adopted. The whole subject of the relation of these diseases to general hygienic conditions has already been discussed (pp. 7 *et seq.*), and need not be further considered here.

The view is steadily gaining ground that the local and constitutional symptoms produced in septic and infective processes are the result of the action of chemical products developed during the growth of the micro-organisms. In the investigation of the nature of these chemical products much valuable work has recently been done and is still in progress. The most important fact, which may be taken as definitively established, is that in certain instances, the injection into the body of an animal of a culture of a pathogenic organism, from which the organism itself has been separated by filtration or destroyed by the action of heat, is still followed by the typical symptoms of the disease. This was first demonstrated by Pasteur in 1880, in connexion with chicken cholera; the symptoms of the disease followed the injection of the sterilized products of the bacillus.

In the consideration of Tetanus in the next chapter it will be seen that the characteristic symptoms of the disease can be produced by the injection of the "*toxines*" obtained from a pure cultivation of the tetanus bacillus. It may further be mentioned that paralysis has been produced in animals by the chemical products of the bacillus of diphtheria; coma, swelling of the spleen, etc., by those of the bacillus anthracis; and fatal septic intoxication by a definite chemical body obtained from putrefying blood.

The chemical products themselves belong to two chief classes: first, basic substances, which seem to be closely allied to alkaloids in their chemical composition; and secondly, toxic albumins, especially albumoses.

The relation of these chemical substances elaborated by the growth of pathogenic micro-organisms to the production of acquired immunity is one of great interest, but can only very briefly be referred to here. Pasteur supposed that immunity conferred by a previous attack of an infective disease resulted from the exhaustion of some nutritive material necessary for the growth of the micro-organism. Chauveau, on the other hand, held that it resulted from the retention in the blood of certain products produced by the organism and inimical to its own growth.

At the present day two chief views are held on this important subject.

According to Metchnikoff and his followers immunity is the result of certain changes imposed upon the living cells which act as phagocytes. In the Chapter on Inflammation (pp. 160 *et seq.*), it has been seen that the behaviour of leucocytes towards invading micro-organisms is possibly determined by the chemical products of the latter. If these are positively chemiotactic the leucocytes are attracted and the organisms destroyed by them; if on the other hand the chemical substances are negatively chemiotactic, the leucocytes are repelled and the micro-organisms gain the day. The same chemical product which in a susceptible animal acts negatively is supposed in the immune animal to act in a positive manner, and thus death of the invading organisms results.

On the other hand, Buchner and others believe that a bacteria-killing substance exists in the blood of immune animals, and that phagocytes play only a secondary part in the process, being attracted to the organisms which are already dead. Hankin has suggested that certain substances, which he speaks of as "protective proteids," are the essential agents, and are persistently in process of formation in the body of the immune animal.

LOCAL INFECTIVE PROCESSES IN WOUNDS.

WOUND-DIPHTHERIA.

This name has been applied by French and German writers to an unhealthy condition assumed by granulating wounds, in which they become covered by an opaque, white, or yellowish-white membranous layer closely resembling the false membrane of diphtheria. By English Surgeons it has more commonly been described as a mild form of phagedænic ulceration. It arises invariably in connection with decomposing discharges, and is not uncommon in wounds over which urine is flowing. The granulating sore which may have been in a healthy condition up to the time of the attack, becomes dark in colour, and here and there small hæmorrhages may be noticed amongst the granulations. The healthy discharge of pus ceases, and is replaced by a very slight serous exudation. Then an opaque white patch appears and soon spreads over the surface. The surrounding skin becomes reddened and slightly swollen, the edges are raised and sharply cut, and the sore may slowly spread and deepen. The opaque white layer on the surface is difficult to remove, but if a small piece be peeled off and examined microscopically it will be found to be composed of the superficial layers of the granulation cells which have perished and become finely granular, mixed with a coagulated exudation. Throughout the whole layer are abundant micrococci, singly, in chains, and in colonies. There is usually some slight febrile disturbance, and the nearest lymphatic glands are swollen.

Causes.—This unhealthy process is always the consequence of local neglect of cleanliness and general imperfection of hygienic arrangements. It may affect several wounds in a ward, but its contagiousness is not very clearly marked, and it frequently occurs in isolated cases. It has no relation to diphtheria. It is true that a similar unhealthy condition has been observed in wounds when the patient has been attacked by genuine diphtheria; but the constitutional condition is then entirely different. Diphtheritic inflammation in the throat does not lead to the progressive destruction of tissue

observed in the so-called wound-diphtheria. Wound-diphtheria is much more nearly allied to hospital gangrene; in fact, the term is extended by many writers on the Continent to that process, the affection here described being regarded as the mildest form of the same disease. It is well, however, to separate the process above described from genuine hospital gangrene, on account of its less evident contagiousness and its comparatively harmless character.

Treatment.—This is very simple. It is only necessary to apply some strong antiseptic lotion, such as chloride of zinc (gr. 40 to ʒj), carbolic acid (1 in 20), or the surface may be rubbed over with solid nitrate of silver or sulphate of copper. When a wound assumes this condition the hygienic surroundings of the patient should be carefully investigated, and any faults of ventilation, cleanliness or drainage corrected. In the mildest cases dusting the surface with iodoform may be sufficient to arrest the unhealthy process.

HOSPITAL GANGRENE.

This affection is also known by the names of contagious or pulpy gangrene, or sloughing phagedæna, and by some French and German writers the term wound-diphtheria is extended to it. It is characterized by a rapidly destructive and spreading infective inflammation, the affected wound becoming covered by an adherent slough as the process extends. It attacks open sores and wounds. It is rarely met with in its fullest extent, except in military practice; the accumulation of a large number of wounded persons with foul suppurating sores under one roof, and the want of proper cleanliness and attention during an active campaign, disposing to it.

LOCAL SIGNS.—When hospital gangrene invades a wound or open sore that has hitherto been perfectly healthy, grey soft points of slough appear upon it, which rapidly spread, until the whole of the surface is affected. At the same time the sore increases rapidly in superficial extent, and commonly in depth; the surrounding integument becomes oedematous, swollen, and of a livid red colour; the edges of the ulcer are everted, sharp-cut, and assume a circular outline; and its surface is covered with a thick pulpy greyish-green tenacious mass, which is firmly adherent. There is usually some dirty yellowish-green or brownish discharge, and occasionally some bleeding; the pain is of a severe burning character; and the foetor from the surface is great. The ravages of this disease, when fully developed, are very extensive. The soft parts, such as the muscles, areolar tissue, and vessels are transformed into a grey pulpy mass, and the bones are denuded and necrosed. The larger blood-vessels resist the progress of the disease longer than any other parts, but may at last be exposed, pulsating at the bottom of the deep and foul chasm. There is, however, little risk of hæmorrhage in the early stages; but, when the sloughs are separating, an artery may give way, and bleeding to a dangerous or fatal extent ensue. Hennen states that there is most danger of this about the eleventh day. When the sloughs are thrown off, in the form of reddish-brown or greyish-green, viscid, and pulpy masses, a very sensitive granulating surface is left, having a great tendency to bleed, and to be again invaded by the gangrenous process.

Blackadder has described a form of this affection, in which a vesicle containing a bloody ichor forms, with a hot stinging pain; this breaks, leaving a

circular ulcer of about the size of a split pea. The ulcer once formed, rapidly extends by sharp-cut edges into the surrounding integument.

CONSTITUTIONAL SYMPTOMS.—In the early stage there may be active febrile disturbance, with high temperature and quick pulse. But these symptoms soon subside into those of prostration. In the majority of cases the constitutional symptoms follow the local invasion of the wound. This was certainly so on the two occasions in which in former years I had an opportunity of observing outbreaks of the disease in University College Hospital; and the same has been noted by Delpech, Blackadder and others.

CAUSES.—All wounds and sores are liable to be attacked in this way, but the disease most frequently affects those that are of recent origin. Hutchinson believes that it is specially prone to originate in syphilitic subjects. The experience of many wars has led incontestably to the conclusion that hospital gangrene will certainly be developed amongst the wounded if they are crowded in too great numbers under one roof, however large may be the building; whilst, amongst the wounded who are treated in the open, or in "hut hospitals"—mere temporary sheds—it is all but unknown. In many German hospitals in which it was formerly of very frequent occurrence, it has been entirely excluded by the adoption of antiseptic methods of treating wounds, all other conditions remaining unchanged. It is evident, therefore, that the disease is primarily due to two causes, the overcrowding of patients in a ward and the putrefaction of the discharges from their wounds. The last outbreak that occurred at University College Hospital, more than twenty-five years ago, was evidently due to these causes. In one of my wards, which was intended to contain 15 or 16 patients only, owing to accidental and unavoidable circumstances, 21 patients were admitted, and slept for one night, many of them having suppurating wounds. The result was an outbreak of hospital gangrene, which spread through the institution, and was most serious and persistent. But though it commonly has its origin in this way, especially in the crowding of military hospitals after a hard-fought action, it is met with out of hospitals. Well-marked cases of this affection, some of a very severe character, have at times occurred amongst the out-patients of University College Hospital. In these cases, as in many others, it is probable that the disease was occasioned by the neglect of hygienic conditions, in the close and ill-ventilated houses of the poor, aided possibly by some atmospheric or epidemic influence; erysipelas and phlebitis being also very prevalent at the time. This had been observed during the first occurrence of the disease at our Hospital, in 1841; and it is impossible not to recognize a similarity of cause in these different affections. Hospital gangrene is highly contagious, and when once it has broken out it will readily spread from patient to patient by contact with nurses' or Surgeons' fingers, instruments, dressings, and above all if the pernicious custom of using sponges in cleaning sores be adopted. It is impossible to be too careful in these respects. The disease may also be carried by the air, and may thus be said to be "infectious."

Pathological Anatomy.—The slough is composed of the tissues of the part infiltrated with inflammatory products, the fluids having undergone coagulation. The individual cells are not recognizable, the whole presenting a finely granular appearance. When stained and properly prepared, innumerable micrococci are seen amongst the granules; they are in colonies or chains, or single. The perishing tissues immediately beneath the slough are

CHAPTER XXXI.

DISEASES ARISING FROM SEPTIC AND INFECTIVE
PROCESSES IN WOUNDS.

THIS group of diseases, including septicæmia, pyæmia, anthrax, tetanus, rabies, erysipelas, hospital gangrene and some others of less importance, has been investigated of recent years by numberless observers with an energy and ability probably never exceeded in any branch of science. As the means of observation were improved and new methods of investigation invented, so the conviction in the minds of the majority of pathologists became more and more confirmed that all these unhealthy processes are directly caused by the action of living micro-organisms. We are still very far from knowing all the conditions which, as predisposing or accessory causes, take part in the development of these diseases, or the exact mode in which the organisms give rise to the various morbid processes with which they are associated; but that their relation to them is, in some forms of disease at least, actually one of cause and effect, may be said to be no longer a mere hypothesis.

The relations of microscopic organisms to unhealthy inflammations, and the nature of a true infective process have already been discussed in the chapter on Inflammation, p. 177, *et seq.*

It will be remembered that it was there pointed out that a clear distinction must be drawn between simple putrefaction and infective processes. Simple putrefaction is a fermentative change taking place in dead matter only, and the products of the fermentation may excite inflammation and suppuration locally, and if absorbed give rise to a definite constitutional disturbance; but the organized ferment which determines the process cannot act on living tissues, consequently there is no true infection, either locally or of the system in general. It is to processes of this kind that the term "septic" should be limited, the word then being synonymous with "putrid."

In a true infective process the virus infects the living tissues, increasing in quantity amongst them, and gives rise to unhealthy processes in them. These may be local, the accompanying constitutional disturbance being merely the result of the absorption of the chemical products resulting from the growth of the organisms; or general, when the virus enters the blood-stream and multiplies in it. The former is called a *local*, and the latter a *general infective process*.

In simple septic processes the fungi which are supposed to cause them are said to be non-pathogenic or non-parasitic; in infective processes they are spoken of as pathogenic or parasitic. The term "mycosis" is often used to signify the infection of the living tissues by fungoid organisms.

Although these septic and infective processes are distinct from each other they are nearly related; infective processes very rarely starting from wounds, unless the discharges are in a septic condition. This fact has been explained by supposing that non-pathogenic organisms may develop pathogenic pro-

perties when growing in a suitable medium, such as the discharges of an unhealthy wound are assumed to be. Evidence is, however, wanting to prove this. The more generally received opinion is that the specific infective processes are each due to a special form of organism, and that putrefaction serves only as a predisposing cause of infection: first by exciting inflammation and suppuration, and thus providing a suitable medium—the inflammatory exudation or pus—in which the pathogenic organisms may develop; and secondly, by lowering the vitality of the tissues, in consequence of which they are more readily invaded by the pathogenic or parasitic fungi.

However this may be, the practical fact remains that the prevention of putrefaction is also the most certain means of preventing infection.

The mode of entrance of the virus has already been discussed (p. 181). In infective processes attacking wounds there is no doubt that in the great majority of cases, so great in fact that we may almost say in all cases, the virus enters the wound directly from without, and the surest means of prevention are those directed to protect the wound from external influences.

The local and general affections consequent upon septic processes in or infection of wounds may be thus briefly classified:—

I. The Effects of Putrefaction.—True Septic Processes.—The poison is generated solely in dead matter, and is associated with the presence of bacteria, bacilli, and micrococci of various forms.

a. Local.—*Septic inflammation and suppuration* dependent on the local irritation caused by the chemical products of putrefaction. It is a non-infective process (p. 182).

b. General.—A febrile affection dependent upon the absorption of the chemical products of putrefaction from the wound. It is a non-infective process, and varies in intensity with the dose of the poison. If the dose be small and the period during which absorption lasts be short, the resulting affection is known as *Septic Traumatic Fever* (p. 307); if the dose be small and absorption continue for months, it gives rise to *Hectic Fever* (p. 250). If the dose be very large and rapidly absorbed it may be speedily fatal, the affection then forming one variety of septicaemia—*Septic Poisoning*—or *Septic Intoxication*, or as it is sometimes called *Septæmia*.

II. Infective Processes.

1. Local Processes leading to a Spreading Destruction of the Affected Tissues.

a. Wound-diphtheria.—This name has been applied by the Germans to a superficial infective process usually attacking granulating sores. The surface becomes covered with an opaque tough membranous layer, beneath which progressive destruction of the granulations takes place. There is febrile disturbance, but no specific constitutional affection accompanying it. It is contagious, and is associated with the growth of micrococci.

b. Hospital Gangrene.—A rapidly spreading gangrenous inflammation, attacking recent or granulating wounds. The gangrene follows closely on the inflammation, the dead tissues forming a pulpy adherent slough. There is febrile disturbance, but no specific infection of the whole system. It is associated with the growth of micrococci, and is intensely contagious.

c. Spreading Traumatic Gangrene.—An acute rapidly spreading inflammation terminating in death of the affected tissues. The inflammation extends a considerable distance beyond the dead tissues, and the gangrenous process is

accompanied by the evolution of gas and offensive decomposition. There is constitutional disturbance of the type of septic poisoning, but there is no evidence of a general specific infection of the blood. It is associated with the presence of rod-shaped organisms, but is not known to be contagious.

d. Phlegmonous Erysipelas.—An acute rapidly spreading inflammation of the subcutaneous areolar tissue, secondarily affecting the skin. It is accompanied by very abundant exudation, and the gangrene that complicates it seems to be due chiefly to the tension caused by this. So far as is known it is not accompanied by any specific infection of the system, and its contagiousness is doubtful. It is associated with the presence of micrococci in chains (*streptococcus*).

e. Cutaneous Erysipelas.—An acute infective disease characterized by a superficial inflammation spreading in the skin from the wound, and by a general febrile disturbance of a specific character. It is supposed by some that the poison infects the whole system as well as the local seat of inflammation, but this is doubtful. It is associated with the presence of micrococci in the affected skin, and according to some observers, also in the blood.

2. General Infective Processes.

a. Septic Infection.—An acute general infective process, rapidly terminating in death without the development of secondary centres of inflammation. The poison infects the whole system and increases in it, the fatal result being apparently directly due to alteration in the blood consequent upon the development of the virus in it. The local affection may be insignificant. The disease is rare in man. In animals it is easily induced experimentally, and in them it is always found to be associated with a definite organism in the blood, differing in different species. It is most intensely contagious. By many writers it is spoken of as *septicæmia*, its name being derived from the fact that in animals it is capable of being caused by the injection of small doses of putrid matter under the skin. The term *septic infection* is here used to distinguish it from *septic poisoning* caused by the chemical products of putrefaction, which by many writers is also spoken of as "*septicæmia*."

b. Pyæmia.—A general infective process, almost invariably starting from a wound which has reached the stage of suppuration; hence its name. It is characterized by the formation of secondary centres of inflammation and suppuration disseminated throughout the body. It is associated with the presence of micrococci in the blood and in the secondary centres of inflammation. It is believed to be contagious. It presents several varieties, which will be described when treating of the disease.

In actual practice it will be found that the distinction between these various affections is not always clearly defined, and this has given rise to the view that some of them at least are merely modifications of one disease. This apparent confusion may, however, be equally well explained by the co-existence of more than one form in the same case. Thus a patient may suffer from phlegmonous erysipelas with sloughing of the subcutaneous areolar tissue; decomposition of the sloughs may follow and give rise to septic poisoning, and, finally, death may take place from pyæmia.

c. Anthrax, Glanders, Hydrophobia, and Tetanus.—General infective diseases, the result of the presence in the body of a specific virus usually obtaining entrance in a wound. The three first-mentioned diseases have

been already described in Chapter XI.; tetanus will be considered in a subsequent Chapter.

It is impossible here to discuss fully the evidence for and against the micro-parasitic origin of these diseases. It is essential to bear in mind the four postulates which, according to Koch, must be fulfilled, before the causal relation of a micro-organism to any given disease can be taken as proved. First, the organism must be constantly present in cases of the disease; secondly, the organism must be capable of cultivation outside the body; thirdly, the disease must be capable of production by inoculation with the pure cultivation; and fourthly, the same organism must be capable of demonstration in the disease thus produced. Anthrax and cutaneous erysipelas may be quoted as instances in which these necessary conditions have been fulfilled, and, judging by analogy, the probability is great that in allied diseases the same proof will eventually be forthcoming. Further, the course of such diseases, the modifications produced by altered conditions in the body and in its surroundings, and lastly, the modes of prevention are all in keeping with the hypothesis of a living virus.

The chief arguments urged against it are the following. In the first place, it has been urged that many processes, dissimilar in every respect, are found to be associated with the presence of organisms apparently perfectly similar. Thus micrococci are found in a simple acute abscess, in erysipelas and in pyæmia; but with bodies of such extreme minuteness differences may readily exist which it is beyond our power to recognize. Cohn, while referring to this question, called attention to the external similarity of the sweet and bitter almond, which yet differ from each other so widely in their chemical properties. A much more important objection, which is pointed out by Koch himself, is that in many cases in the human subject the number of microscopic organisms found has been singularly small, so small in fact as to make it difficult to understand how they could be the cause of such grave disease. Lastly, it has been maintained that the microscopic organisms are merely an accidental accompaniment of the process and not the cause, or that at most they serve merely as carriers of the virus and are not the producers of it. It is difficult to refute this assertion with the means at present at our command. When, however, as in the case of erysipelas, the organism may be cultivated for twenty generations out of the body in an artificial medium, and finally, on being inoculated on another individual will produce a genuine attack of the disease, it seems difficult to regard it as other than an essential factor in the production of the specific inflammation.

It must be acknowledged therefore, that, although it is highly probable that all the diseases in this group arise directly from the action of micro-organisms, the evidence is not as yet sufficient to furnish in every case demonstrative proof of the truth of this theory.

Supposing, however, that the fungoid theory of infective processes in wounds were proved beyond a doubt, this would in no way disprove the facts previously known as to the influence of bad hygienic conditions in the development of these diseases. The experience of generations of Surgeons has taught us that, although inflammation and suppuration with febrile disturbance result from contact with the raw surfaces of wounds of such simple septic products as must form in all dead tissues or putrescible animal fluids exposed to the ordinary air of a dwelling-house, the graver infective processes are of

extreme rarity in cases treated in pure air and in the isolation of a private house. On the other hand, it has been established incontestably that if the cubic capacity of a ward be taken, and the rate of ventilation through it determined, a Surgeon may with certainty foretell how many suppurating wounds it will require, in the absence of antiseptic treatment, to generate infective disease in it.

Thus, although in the prevention of these diseases the use of antiseptics must take the first place as attacking the evil at its source, a strict attention to the laws of hygiene as regards cubic space, ventilation, and general cleanliness, is also necessary to exclude those necessary conditions that favour its development. By these means combined all this group of diseases can be prevented: their occurrence is the result in almost all cases of some definite error in the treatment of the wound, or of some infringement of sanitary rules. They are not accidental; they are preventable and ought to be prevented. Should a case arise, our knowledge of the nature of the diseases shows clearly how they may be carried from one individual to another, and efficient means to prevent their spread should at once be adopted. The whole subject of the relation of these diseases to general hygienic conditions has already been discussed (pp. 7 *et seq.*), and need not be further considered here.

The view is steadily gaining ground that the local and constitutional symptoms produced in septic and infective processes are the result of the action of chemical products developed during the growth of the micro-organisms. In the investigation of the nature of these chemical products much valuable work has recently been done and is still in progress. The most important fact, which may be taken as definitively established, is that in certain instances, the injection into the body of an animal of a culture of a pathogenic organism, from which the organism itself has been separated by filtration or destroyed by the action of heat, is still followed by the typical symptoms of the disease. This was first demonstrated by Pasteur in 1880, in connexion with chicken cholera; the symptoms of the disease followed the injection of the sterilized products of the bacillus.

In the consideration of Tetanus in the next chapter it will be seen that the characteristic symptoms of the disease can be produced by the injection of the "toxines" obtained from a pure cultivation of the tetanus bacillus. It may further be mentioned that paralysis has been produced in animals by the chemical products of the bacillus of diphtheria; coma, swelling of the spleen, etc., by those of the bacillus anthracis; and fatal septic intoxication by a definite chemical body obtained from putrefying blood.

The chemical products themselves belong to two chief classes: first, base substances, which seem to be closely allied to alkaloids in their chemical composition; and secondly, toxic albumins, especially albumoses.

The relation of these chemical substances elaborated by the growth of pathogenic micro-organisms to the production of acquired immunity is one of great interest, but can only very briefly be referred to here. Pasteur supposed that immunity conferred by a previous attack of an infective disease resulted from the exhaustion of some nutritive material necessary for the growth of the micro-organism. Chauveau, on the other hand, held that it resulted from the retention in the blood of certain products produced by the organism and inimical to its own growth.

At the present day two chief views are held on this important subject.

According to Metchnikoff and his followers immunity is the result of certain changes imposed upon the living cells which act as phagocytes. In the Chapter on Inflammation (pp. 160 *et seq.*), it has been seen that the behaviour of leucocytes towards invading micro-organisms is possibly determined by the chemical products of the latter. If these are positively chemiotactic the leucocytes are attracted and the organisms destroyed by them; if on the other hand the chemical substances are negatively chemiotactic, the leucocytes are repelled and the micro-organisms gain the day. The same chemical product which in a susceptible animal acts negatively is supposed in the immune animal to act in a positive manner, and thus death of the invading organisms results.

On the other hand, Buchner and others believe that a bacteria-killing substance exists in the blood of immune animals, and that phagocytes play only a secondary part in the process, being attracted to the organisms which are already dead. Hankin has suggested that certain substances, which he speaks of as "protective proteids," are the essential agents, and are persistently in process of formation in the body of the immune animal.

LOCAL INFECTIVE PROCESSES IN WOUNDS.

WOUND-DIPHTHERIA.

This name has been applied by French and German writers to an unhealthy condition assumed by granulating wounds, in which they become covered by an opaque, white, or yellowish-white membranous layer closely resembling the false membrane of diphtheria. By English Surgeons it has more commonly been described as a mild form of phagedenic ulceration. It arises invariably in connection with decomposing discharges, and is not uncommon in wounds over which urine is flowing. The granulating sore which may have been in a healthy condition up to the time of the attack, becomes dark in colour, and here and there small hæmorrhages may be noticed amongst the granulations. The healthy discharge of pus ceases, and is replaced by a very slight serous exudation. Then an opaque white patch appears and soon spreads over the surface. The surrounding skin becomes reddened and slightly swollen, the edges are raised and sharply cut, and the sore may slowly spread and deepen. The opaque white layer on the surface is difficult to remove, but if a small piece be peeled off and examined microscopically it will be found to be composed of the superficial layers of the granulation cells which have perished and become finely granular, mixed with a coagulated exudation. Throughout the whole layer are abundant micrococci, singly, in chains, and in colonies. There is usually some slight febrile disturbance, and the nearest lymphatic glands are swollen.

Causes.—This unhealthy process is always the consequence of local neglect of cleanliness and general imperfection of hygienic arrangements. It may affect several wounds in a ward, but its contagiousness is not very clearly marked, and it frequently occurs in isolated cases. It has no relation to diphtheria. It is true that a similar unhealthy condition has been observed in wounds when the patient has been attacked by genuine diphtheria; but the constitutional condition is then entirely different. Diphtheritic inflammation in the throat does not lead to the progressive destruction of tissue

observed in the so-called wound-diphtheria. Wound-diphtheria is much more nearly allied to hospital gangrene; in fact, the term is extended by many writers on the Continent to that process, the affection here described being regarded as the mildest form of the same disease. It is well, however, to separate the process above described from genuine hospital gangrene, on account of its less evident contagiousness and its comparatively harmless character.

Treatment.—This is very simple. It is only necessary to apply some strong antiseptic lotion, such as chloride of zinc (gr. 40 to 3j), carbolic acid (1 in 20), or the surface may be rubbed over with solid nitrate of silver or sulphate of copper. When a wound assumes this condition the hygiene surroundings of the patient should be carefully investigated, and any faults of ventilation, cleanliness or drainage corrected. In the mildest cases dusting the surface with iodoform may be sufficient to arrest the unhealthy process.

HOSPITAL GANGRENE.

This affection is also known by the names of contagious or pulpy gangrene, or sloughing phagedæna, and by some French and German writers the term wound-diphtheria is extended to it. It is characterized by a rapidly destructive and spreading infective inflammation, the affected wound becoming covered by an adherent slough as the process extends. It attacks open sores and wounds. It is rarely met with in its fullest extent, except in military practice; the accumulation of a large number of wounded persons with foul suppurating sores under one roof, and the want of proper cleanliness and attention during an active campaign, disposing to it.

LOCAL SIGNS.—When hospital gangrene invades a wound or open sore that has hitherto been perfectly healthy, grey soft points of slough appear upon it, which rapidly spread, until the whole of the surface is affected. At the same time the sore increases rapidly in superficial extent, and commonly in depth; the surrounding integument becomes oedematous, swollen, and of a livid red colour; the edges of the ulcer are everted, sharp-cut, and assume a circular outline; and its surface is covered with a thick pulpy greyish-green tenacious mass, which is firmly adherent. There is usually some dirty yellowish-green or brownish discharge, and occasionally some bleeding; the pain is of a severe burning character; and the foetor from the surface is great. The ravages of this disease, when fully developed, are very extensive. The soft parts, such as the muscles, areolar tissue, and vessels are transformed into a grey pulpy mass, and the bones are denuded and necrosed. The larger blood-vessels resist the progress of the disease longer than any other parts, but may at last be exposed, pulsating at the bottom of the deep and foul chasm. There is, however, little risk of hæmorrhage in the early stages; but, when the sloughs are separating, an artery may give way, and bleeding to a dangerous or fatal extent ensue. Hennen states that there is most danger of this about the eleventh day. When the sloughs are thrown off, in the form of reddish-brown or greyish-green, viscid, and pulpy masses, a very sensitive granulating surface is left, having a great tendency to bleed, and to be again invaded by the gangrenous process.

Blackadder has described a form of this affection, in which a vesicle containing a bloody ichor forms, with a hot stinging pain: this breaks, leaving a

circular ulcer of about the size of a split pea. The ulcer once formed, rapidly extends by sharp-cut edges into the surrounding integument.

CONSTITUTIONAL SYMPTOMS.—In the early stage there may be active febrile disturbance, with high temperature and quick pulse. But these symptoms soon subside into those of prostration. In the majority of cases the constitutional symptoms follow the local invasion of the wound. This was certainly so on the two occasions in which in former years I had an opportunity of observing outbreaks of the disease in University College Hospital; and the same has been noted by Delpech, Blackadder and others.

CAUSES.—All wounds and sores are liable to be attacked in this way, but the disease most frequently affects those that are of recent origin. Hutchinson believes that it is specially prone to originate in syphilitic subjects. The experience of many wars has led incontestably to the conclusion that hospital gangrene will certainly be developed amongst the wounded if they are crowded in too great numbers under one roof, however large may be the building; whilst, amongst the wounded who are treated in the open, or in "hut hospitals"—mere temporary sheds—it is all but unknown. In many German hospitals in which it was formerly of very frequent occurrence, it has been entirely excluded by the adoption of antiseptic methods of treating wounds, all other conditions remaining unchanged. It is evident, therefore, that the disease is primarily due to two causes, the overcrowding of patients in a ward and the putrefaction of the discharges from their wounds. The last outbreak that occurred at University College Hospital, more than twenty-five years ago, was evidently due to these causes. In one of my wards, which was intended to contain 15 or 16 patients only, owing to accidental and unavoidable circumstances, 21 patients were admitted, and slept for one night, many of them having suppurating wounds. The result was an outbreak of hospital gangrene, which spread through the institution, and was most serious and persistent. But though it commonly has its origin in this way, especially in the crowding of military hospitals after a hard-fought action, it is met with out of hospitals. Well-marked cases of this affection, some of a very severe character, have at times occurred amongst the out-patients of University College Hospital. In these cases, as in many others, it is probable that the disease was occasioned by the neglect of hygienic conditions, in the close and ill-ventilated houses of the poor, aided possibly by some atmospheric or epidemic influence; erysipelas and phlebitis being also very prevalent at the time. This had been observed during the first occurrence of the disease at our Hospital, in 1841; and it is impossible not to recognize a similarity of cause in these different affections. Hospital gangrene is highly contagious, and when once it has broken out it will readily spread from patient to patient by contact with nurses' or Surgeons' fingers, instruments, dressings, and above all if the pernicious custom of using sponges in cleaning sores be adopted. It is impossible to be too careful in these respects. The disease may also be carried by the air, and may thus be said to be "infectious."

Pathological Anatomy.—The slough is composed of the tissues of the part infiltrated with inflammatory products, the fluids having undergone coagulation. The individual cells are not recognizable, the whole presenting a finely granular appearance. When stained and properly prepared, innumerable micrococci are seen amongst the granules; they are in colonies or chains, or single. The perishing tissues immediately beneath the slough are

infiltrated with migrating cells, which press upon the vessels, some of which are obliterated, and others filled with clots. Micrococci are recognizable in this region also, and are almost certainly directly concerned in causing the unhealthy process. Koch succeeded in inducing in mice a gangrenous process closely resembling hospital gangrene by the inoculation of a form of micrococcus which showed a regular mode of growth in chains. The infective process was purely local, death occurring without infection of the blood. The micrococci were originally obtained from putrid blood, but subsequent inoculations from one animal to another were constantly followed by the same form of gangrenous inflammation, and the development of the same definite form of micrococcus.

TREATMENT.—The **preventive treatment** of hospital gangrene may be deduced from a consideration of the causes that give rise to it. The experience of many German surgeons, and especially of Nussbaum, of Munich, has shown, that by the introduction of the antiseptic treatment the disease has been banished from hospitals in which, owing to faulty hygiene, it formerly existed to a fearful extent. On the other hand, it had practically been banished from English hospitals by attention to ordinary cleanliness, and general hygienic rules as to cubic space per patient, ventilation, drainage, &c., long before the introduction of antiseptic surgery, although occasional outbreaks still occurred. Now it is unknown in any properly managed civil hospital. In military practice antiseptic treatment is often impossible, and overcrowding unavoidable. The disease may then be prevented almost to a certainty by treating the wounded under canvas, in "hut hospitals," or in the open. Should it break out, the building in which it has developed itself should at once be abandoned or destroyed. The spread of the disease may be prevented by at once isolating the affected patient, treating him in the open, and allowing no contact between his attendants and other patients. Should it have broken out in a civil hospital, the first point to attend to is to *prevent the extension of the disease* to patients who are not as yet affected. This may be done by separating those who have been seized with it from the healthy, by preventing overcrowding of the hospital, ventilating the wards, washing the floors with a solution of chloride of zinc, whitening the walls, and fumigating the apartment with chlorine gas.

Local Treatment.—The first step in the local treatment is, to clean away the slough till the living tissues are exposed, the patient being under the influence of an anæsthetic. This must be done by means of scissors and forceps, by scraping with a sharp spoon, and by forcibly rubbing the surface with a sponge or a piece of tow. The metal instruments used for this purpose must afterwards be disinfected by being held in the flame of a spirit lamp, or put in a bath of carbolic lotion (1 in 20); the sponge or tow must *immediately* be burnt. The raw surface must then be freely cauterized by the application of fuming nitric acid, chloride of zinc, or the actual cautery. I prefer nitric acid, if strong and freely applied, the surface and edges being well sponged with it. The actual cautery is, however, very useful in those cases in which the surface to be destroyed is very extensive, or if there be a tendency to hæmorrhage. Should it not reach the deeper portions of the sore, nitric acid may be freely sponged into them. It is important to bear in mind that these escharotic applications will be fruitlessly expended in charring the tenacious grey pulpy slough, unless this have been previously cleared away. After the

application of the caustic, the parts may be dressed with carbolic oil, terebene and oil, or some moist antiseptic dressing. The German Surgeons, who until recently had unusual opportunities of studying this affection, mostly preferred chloride of zinc. König recommends the following treatment. The sloughs having been cleared away, the surrounding skin must be washed with carbolic acid lotion (1 in 20), or chloride of zinc (20 gr. to $\frac{3}{4}$ j). Some dry chloride of zinc is then moistened with water till it dissolves into an oily liquid; cotton-wool soaked in this is laid on the raw surface, and pushed into any irregular hollows or cavities of the wound, and allowed to lie there for from five to twenty minutes, according to the severity of the case. It is then removed, and some efficient form of antiseptic dressing applied. The pain is usually severe, and a hypodermic injection of morphia should be given to relieve it. The slough formed by the chloride of zinc will separate in from three to ten days, leaving a healthy granulating surface beneath, which may be treated on ordinary principles. In military practice, in which alone it is probable that hospital gangrene will be met with in the future, chloride of zinc is by far the most convenient caustic, as it is carried in the solid state, while fuming nitric acid is dangerous and difficult to transport.

Should *arterial hæmorrhage* occur, it may be arrested by the application of a ligature to the bleeding point; but if this do not hold, as will probably be the case owing to the softened state of the tissues, the actual cautery must be applied; or the limb must be removed if all other means fail.

In some cases, though the sloughing is checked at one part of the surface, it has a tendency to spread at another. When this is the case, it may be necessary to apply the caustic or cautery repeatedly. In other instances, the sloughing cannot be stopped, but opens large arteries, and destroys the greater part of the soft tissues of a limb; and then it may be a question whether amputation should be performed during the spread of the disease, or the patient left to die of hæmorrhage or exhaustion. Such a contingency is not of common occurrence; yet it may happen and the operation be successful as appears from the following case, though there would necessarily be great danger of a recurrence of the disease in the stump. The wife of a butcher applied at the Hospital, with a slight wound of the forearm, inflicted by a foul hook. It was dressed in the ordinary way, but in the course of a few days she returned with extensive sloughing phagedæna of the part. She was immediately admitted, and the disease was arrested by the energetic employment of the local treatment above described; not, however, until after considerable destruction of the tissues on the inside of the forearm had taken place. She left the Hospital before the wound was completely cicatrized, and returned in a few days with a fresh attack of the disease, more extensive and severe than the first; this time the process could not be permanently stopped, either by the actual cautery or by nitric acid. The radial artery was opened and required ligature, and the whole of the soft parts, from the wrist to the elbow, were totally disorganized, and the bones exposed. There was now very severe constitutional disturbance, and the case was evidently fast hastening to a fatal termination. In these circumstances I amputated the arm midway between the shoulder and the elbow; and, notwithstanding that the local disease was progressing at the time of the operation, and that the constitutional disturbance was very great, the patient having a pulse of 160 to 170, at which it continued for more than a fortnight, she made a good recovery. To

this the free administration of quinine and stimulants greatly contributed.

The **Constitutional Treatment** consists in as nourishing a diet as the patient will take, with a liberal supply of stimulants; and these may be increased by the addition of the brandy-and-egg mixture, or of ammonia, in proportion as depression comes on. From five to seven grains of the sulphate of quinine should be given every four or six hours, with a full dose of opium at bed-time, and more frequently if there be much pain and irritation.

SPREADING TRAUMATIC OR EMPHYSEMATOUS GANGRENE.

Spreading Traumatic Gangrene, Emphysematous Gangrene, or the *gangrène foudroyante* of Maisonneuve, is a most acute and fatal form of infective inflammation usually following contused or lacerated wounds, particularly when complicated with fractures or when opening a joint.

Causes.—The causes of the disease are not certainly known. The cases occur sporadically and there is no evidence of infection from case to case. It is met with at all ages. On examination of the affected tissues, rod-shaped organisms — bacteria — are found in great abundance, and these are doubtless connected with the rapid formation of offensive gas in the gangrenous parts which forms so characteristic a feature of the disease. They have also been found in the blood, probably not in an active state, but being merely accidentally present. In the great majority of

Fig. 340.—Bacteria cultivated on a potato from a case of emphysematous gangrene.

cases the wound from which the gangrene has originated has not only been lacerated but has had mud or dirt, especially street mud, ground into it. This is known to contain rod-shaped organisms, both bacilli and bacteria, capable of setting up various unhealthy local and general processes if inoculated on animals, and it is very probable that this is the source of infection in cases of emphysematous gangrene. The conditions favourable for the development of the disease are the presence of the lacerated wound opening a cavity such as a joint or communicating with a crushed bone. It is especially liable to occur if the wound be injudiciously closed by sutures without proper drainage or antiseptic precautions.

It is most common after contused or lacerated wounds of the foot with considerable subcutaneous extravasation; it also occasionally follows similar injuries of the hand.

Symptoms.—Spreading gangrene always sets in before suppuration is established, usually on the second or third day. At first the symptoms appear to be merely those of ordinary septic inflammation, the result of pent-up decomposing discharges. There is febrile disturbance of the septic type, with pain and swelling in the wound, and a blush of redness extending for some distance on each side of it. The true nature of the affection, however, speedily becomes apparent. The wounded limb at the seat of injury swells, becomes dusky-red, and is the seat of a deep-seated, burning pain. The

swelling, redness, and tension spread upwards, and are speedily followed by a dusky purplish tint, by a soft doughy feeling of the parts, and in the course of a few more hours by a deep blackish-purple discoloration, which spreads uniformly and with great rapidity through all the tissues affected. This is accompanied or immediately followed by emphysematous crackling, due to the presence of gases which are developed by the decomposition of the parts attacked by the gangrene. The changes, which are of a putrefactive nature, first develop in the wound itself, and speedily extend from it to the surrounding parts. That portion of the limb which is below the gangrenous part becomes pale, cold, and cedematous. The portion which is above becomes rapidly infiltrated by serous exudation, which runs up the inner side of the limb to the axilla or groin, as the case may be. The part immediately above the limit of the tissues that are actually mortified is swollen by cedematous infiltration, tense, pitting slightly on pressure, and usually of a dusky brownish-red colour; and frequently beyond the edge of the advancing redness, there is a brownish discoloration, apparently due to pigment liberated by the breaking up of the red corpuscles in the gangrenous tissues and diffused beyond the area of inflammation. The process has no tendency to limit itself; the œdema and peculiar discoloration extend higher along the inner side of the limb, where they always first reach the trunk. Emphysematous crackling rapidly spreads along the same parts, and the gangrene here travels with great rapidity, hopelessly involving the tissues and entering into the areolar planes of the axilla or groin in a very few hours. As the gangrene advances, the parts affected are transformed into a soft, pulpy, black mass. On making an incision into the parts so affected, it will be found that the gangrenous inflammation is primarily seated in the areolar planes of the limb, and that the muscles are not affected in the first instance. It will be observed also that the disease extends through the areolar tissue, the skin falling secondarily into slough.

The constitutional symptoms early assume the character of acute septic poisoning, the patient sinking into a prostrate condition, and the temperature falling below normal. Unless relieved by treatment, death almost invariably ensues in three or four days after the invasion of the disease, and always shortly after the gangrene has reached the trunk.

Treatment.—The preventive treatment consists in very carefully cleaning any wound into which mud or dirt has been ground with a powerful antiseptic fluid, perchloride of mercury (1 in 500) perhaps being the best. Should emphysematous gangrene appear the Surgeon will be placed in a great difficulty. If he trust to constitutional treatment, in the hope of a line of demarcation forming, he will certainly be disappointed, the gangrene rapidly spreading up to the trunk; and if he amputate, he will probably lose his patient by the stump becoming affected. Yet amputation should, in my opinion, be performed at once. For, although this operation is necessarily very unfavourable when practised in these cases, yet it must be remembered that, if the Surgeon wait for the line of demarcation or trust to other means such as incisions or general treatment, the patient will certainly die. The only chance of safety, then, lies in amputating early, and removing the limb high above the part affected; thus, in spreading gangrene of the arm, at the shoulder-joint; and of the leg, in the upper part of the thigh. In most cases it will be found that the infiltration precursory to the gangrenous mischief runs up one side of the

limb—the inner or posterior—to a much greater extent than the other. In amputating under such circumstances, the Surgeon may often very advantageously so fashion his flaps as to exclude as much as possible of the affected part or side of the limb, forming them chiefly from that least affected. The principal source of danger, after amputation in these cases, is recurrence of the morbid condition in the stump, more particularly in the lower extremity. Out of twelve cases in which I have seen or done amputation for this disease this recurrence happened in seven instances. The tendency will be increased by the proximity of the line of amputation to the gangrenous limit. But, even under the most unfavourable circumstances, recovery will sometimes take place. Thus I have seen the flaps in amputation for spreading gangrene infiltrated with gelatinous-looking fluid, and yet recovery take place. In a man whose arm I amputated at the shoulder-joint for spreading gangrene of the limb, the infiltration had extended as high as the scapula; yet he made an excellent recovery. In the lower extremity the liability to recurrence of the gangrene is, however, very much greater; and there can be but very little prospect of saving the patient if the thigh has once become reddened and infiltrated, even though the gangrene do not extend above the knee—invasion of the stump ensuing under such circumstances with almost absolute certainty.

Much of the success of the case will depend on the after-treatment. This must consist principally of antiseptic dressings to the stump, full doses of liquor opii, and the early and free administration of stimulants, more particularly brandy and wine; attention to these points will often bring the patient through, though usually not without much difficulty and great constitutional disturbance.

CHAPTER XXXII.

ERYSIPELAS. CELLULITIS. WHITLOW.

THE term "erysipelas," or "erysipelatos inflammation," is applied to a group of infective inflammatory processes affecting the skin, the subcutaneous areolar tissue, intermuscular or subfascial areolar tissue, mucous membranes and submucous tissue, serous membranes and lymphatic vessels, and having one feature in common, *the tendency to spread with great rapidity by continuity of tissue, or in other words, to assume a "diffuse" form.* Erysipelas is due to the action of a virus, which infects the part attacked, increases in quantity in it by a process analogous to fermentation, and diffuses itself by means of the lymph-spaces and lymphatic vessels, exciting a characteristic form of inflammation as it spreads. The virus most commonly enters the body by a wound, causing a local inflammation accompanied by a definite febrile disturbance; but some forms of erysipelatos inflammation arise when no apparent wound exists, and it is probable that in such cases the poison enters the system from the alimentary canal or the respiratory tract, and is carried by the blood to the spot at which the local inflammation appears. There is no evidence of a true general infection in any of the forms of erysipelas; it is probable that the virus may be carried by the blood, but cannot multiply in it as in a true general infective process.

Erysipelatos inflammation may attack a wound of any size or of any age; but the statistics of University College Hospital show that it most commonly arises in suppurating wounds, about two-thirds of the cases beginning after the tenth day, and very few before the fourth.

The different forms of erysipelatos inflammation are most conveniently described as they affect different tissues and organs. With this view, we may divide them primarily into External and Internal Erysipelas.

External Erysipelas is that variety which affects the skin and subcutaneous areolar tissue. The inflammatory process may affect either or both of these structures and thus erysipelas has been divided, as first suggested by Nunneley, into three forms: 1. **Cutaneous**; 2. **Cellulo-cutaneous**; 3. **Cellulitis**. The cellulo-cutaneous form is the **Phlegmonous Erysipelas** of Lawrence; whilst the cellular variety is often spoken of as **Diffuse Cellulitis**.

It is a fact of much importance that the cutaneous variety of erysipelas is characterized by the absence of pus formation, whilst on the other hand the cellulo-cutaneous and cellular varieties are essentially processes of diffuse suppuration. We shall indeed see shortly that there is strong clinical and pathological support for the view that cutaneous erysipelas is a specific inflammation of the skin, and that the conditions known as cellulo-cutaneous and cellular erysipelas are quite distinct affections resulting from infection of the tissues with pyogenic organisms, and differing from each other chiefly in the exact seat of the suppuration.

The statistics of University College Hospital give the following results, showing the relative frequency of these affections. During a period of ten years 196 cases were admitted under the care of the Surgeons or arose in the surgical wards. Of these 148 were cutaneous, 24 cellulocutaneous or phlegmonous, and 24 cellular (or cellulitis). To these may be added 36 cases of so-called idiopathic cutaneous erysipelas admitted under the care of the Physicians, making a total of 184 cases of the cutaneous form out of 232, or nearly 80 per cent.

CAUSES.—The causes of erysipelatous inflammations are : first, the *essential cause*, the virus or contagium ; and secondly, the *predisposing causes*, which may be divided into those that are *intrinsic* to the patient, including such local or constitutional conditions as predispose him to receive the virus, and those that are *extrinsic*, such as the meteorological and hygienic conditions to which he is exposed before he is attacked by the disease. The extrinsic causes may act by favouring the development of the virus out of the body or its transmission from one individual to another, or by impairing the health of the patient and thus rendering him more ready to receive the poison.

1. The **Essential Cause.**—It has been proved to demonstration that *cutaneous erysipelas* is the result of the growth of a micrococcus in the lymphatic spaces of the skin. The organism occurs most commonly in pairs or chains, and is known as the *Streptococcus erysipelatosus*. Fehleisen first succeeded in cultivating these organisms on gelatine and coagulated serum. A small piece of the affected skin was removed and placed on the prepared gelatine ; after a short time the white film, which the microscope showed to be composed of micrococci, spread over the surface of the gelatine. A small speck of this was then planted on another gelatine surface and again the film formed. The process was repeated many times, in one instance to thirty generations, until it might reasonably be supposed that any chemical poison which might theoretically have been adhering to the original organisms taken from the skin was perfectly

Fig. 341.—*Streptococcus erysipelatosus*. (From a pure cultivation on gelatine.)

eliminated. The fungi were then inoculated on rabbits, and gave rise to a spreading inflammation, exactly resembling cutaneous erysipelas. Afterwards similar inoculations were made on eight patients in cases of cancer, sarcoma, and lupus, with the view of exerting the reputed curative action of erysipelas on these affections. Seven out of the eight patients, after a period of incubation of from fifteen to sixty hours, were affected by genuine erysipelas, with all the characteristic local and constitutional symptoms. In the one case in which the inoculation failed, the patient had recently recovered from a spontaneous attack of the disease. At the Congress of German Surgeons in 1883, Fehleisen exhibited a patient in whom genuine cutaneous erysipelas had been produced by the inoculation of micrococci which were thirty generations removed from the original organisms obtained from the skin, the cultivation having been continued on gelatine from August, 1882, to April, 1883.

According to Koch and Fehleisen, the micrococci are not found in the

blood-vessels or blood. Hiller states that if the blood be examined numerous white corpuscles in a state of degeneration are found, having become converted into masses of highly refracting granules. Busk has described the occurrence of plugs of such corpuscles in the capillaries of the lung, and Bastian has observed a similar condition in the brain.

In *phlegmonous erysipelas* and in *diffuse cellulitis* a micrococcus is also found—the *Streptococcus pyogenes*—which has already been described on p. 244.

Much discussion has taken place as to the possible identity of these two organisms—the *Streptococcus erysipelatosus* and the *Streptococcus pyogenes*. In their microscopic characters and in their behaviour in artificial cultivations the two organisms are practically indistinguishable. The results of inoculation experiments have been

somewhat contradictory; thus while several observers have obtained similar results with the two organisms, others have found that the *Streptococcus erysipelatosus* constantly causes a spreading inflammation of the skin, but that the *Streptococcus pyogenes* causes marked inflammatory swelling with a tendency to supuration. Baumgarten and others who believe that the organisms are identical suggest that the clinical differences between cutaneous erysipelas and the suppurative processes are dependent upon the varying virulence of the organism, the mode of infection and the idiosyncrasy of the patient. On the whole it seems probable that the two organisms, although morphologically alike, are not the same. Watson Cheyne, who inclines to this view, suggests that cases in which cutaneous erysipelas and supuration are associated may be the result of mixed infection.

It is an important fact to guide us in the prevention of these diseases that the organisms are killed in 45 seconds by a 1 in 80 solution of carbolic acid, or in 15 seconds by a 1 in 1000 solution of corrosive sublimate.

Cutaneous Erysipelas is undoubtedly *contagious*, and instances have repeatedly fallen under my own observation, in which erysipelas, often unfortunately fatal, has been communicated to the servants, nurses, or relatives of patients affected by it. A remarkable proof of the contagious nature of erysipelas occurred in the winter of 1851, in one of my wards at University College Hospital. The Hospital had been free from any cases of the kind for a considerable time, when, on the 15th of January, at about noon, a man was admitted under my care with gangrenous erysipelas of the legs, and placed in Brundrett Ward. On my visit two hours after his admission, I ordered him to be removed to a separate room, and directed that the chlorides should be freely used in the ward from which he had been taken. Notwithstanding these precautions, two days after this, a patient, from whom a necrosed portion of ilium had been removed a few weeks previously, and who was lying in the bed adjoining that in which the patient with erysipelas had been temporarily placed, was seized with erysipelas, of which he speedily died. The disease then spread to almost every case in the ward, and proved fatal to several patients who had recently been operated upon.

Phlegmonous erysipelas and diffuse cellulitis on the other hand do not spread by infection if a case be admitted into a general ward; nevertheless, on

Fig. 342.—Pus from a case of Phlegmonous Erysipelas, containing the *Streptococcus pyogenes*.

account of the somewhat uncertain state of our knowledge concerning these affections, the patient should if possible be isolated.

2. **Predisposing Causes.**—Certain local and constitutional intrinsic causes predispose the patient to receive the virus.

Local.—Of these the most important is certainly *the presence of a wound or raw surface*. The statistics of University College Hospital show that erysipelatous inflammation may attack a wound at any time from its infliction to its healing. This is especially true of the cutaneous forms; other varieties of erysipelatous inflammation more commonly start from recent wounds. The presence of decomposing discharges in the wound is undoubtedly an important predisposing cause, and antiseptic treatment has done much to prevent it. When erysipelas is epidemic, it is well for the Surgeon not to perform any operation that can conveniently be postponed; and in no case should a patient on whom an operation has recently been performed be put in a neighbouring bed to a case of erysipelas, or even in the same ward. The size of the wound has little influence on the occurrence of erysipelas, which will as readily follow a puncture as an amputation wound. Lacerated wounds are, however, more liable to be followed by erysipelas than clean-cut incisions. The depth of the wound also influences in an important manner the kind and the degree of the erysipelatous inflammation, the phlegmonous and the cellular forms arising most commonly from those injuries that penetrate the deep fascia of a limb. In such cases the disease may spread widely and fatally through the deeper subaponeurotic and intermuscular planes of areolar tissue. It is important in these cases not to confound a simple septic inflammation due to the presence of decomposing matter in an ill-drained wound, with genuine erysipelatous inflammation. Injuries about the head and hands are said to be more liable to be attacked by erysipelatous inflammation than those of other parts.

Constitutional.—Some persons appear to be *naturally predisposed* to erysipelas to such a degree that it readily follows the application of cold, or stomach disorder, or a trivial superficial injury. This predisposition is most generally acquired by habitual derangement of health, more especially as the result of the excessive use of alcoholic stimulants. The condition is met with amongst the labouring poor as the result of privation of the necessities of life, and amongst the wealthier classes as a consequence of high living, want of exercise, and luxurious habits.

Some *morbid states of the blood*, consequent upon visceral disease, appear to predispose, in the highest degree, to the supervention of erysipelas. This is especially the case in diabetes, and in disease of the kidneys attended with albuminuria. As a consequence of renal disease, erysipelas often occurs from the most trivial causes; such as a scratch, the sting of an insect, or any of the minor operations in surgery, more especially about the lower part of the body. Not only is it readily induced in this way, but it will extend in an uncontrollable manner in these states of the system, and will often assume a gangrenous form, there being apparently an utter want of power in the tissues to resist the influence of the virus. Persons of a plethoric habit, with a tendency to gout, are predisposed to erysipelas. The blood-degeneration that attends malignant disease peculiarly disposes to erysipelas, which accordingly more frequently takes place after operations on persons suffering from such diseases than after the removal of simple tumours.

Persons whose *nervous systems* are habitually depressed, the semi-idiotic and idiotic for instance, are very prone to inflammations of an erysipelatous form. A person who has once suffered from erysipelas is said to be more liable to the disease. Fehleisen states that his inoculation experiments showed that after an attack of cutaneous erysipelas there is a short period of immunity, lasting a few weeks or months.

2. **Extrinsic Causes.**—Amongst the circumstances that surround the patient and that favour the production of this disease, the season of the year and atmospheric changes exercise a marked influence. Erysipelas is usually supposed to be more frequent in the spring and autumn, and the experience at University College Hospital tends to confirm this idea. Thus we find that during the years 1871 to 1890, 471 cases of erysipelas were treated in the Hospital, including those admitted for the disease and those affected by it while undergoing treatment for other affections. Of these, 126 occurred during the cold months of December, January, and February; 129 during March, April and May; 74 during the hot months of June, July, and August; and 142 during September, October, and November. It has frequently been asserted that erysipelas often breaks out on the setting in of cold easterly winds or on sudden atmospheric changes. Observations were made during one year (1872) at University College Hospital with the view of testing the truth of this assertion; but, as they were not continued after that year, the time over which they extend is not sufficient to exclude the influence of chance. As far as they went, however, they tended to show that mild damp weather, with westerly winds, is a more powerful predisposing cause of erysipelas and allied conditions than cold dry weather with easterly winds, which is exactly the reverse of the generally received opinion. The subject is one of great interest, and is well worthy of further investigation. Erysipelas often becomes epidemic as the result of peculiar, but at present unexplained, conditions of the atmosphere. Thus at University College Hospital the number of cases occurring during the four years 1871 to 1874 was as follows: in 1871, 29; in 1872, 29; in 1873, 26; in 1874, 67. And not only was it at University College Hospital that this excess of erysipelas was noticed, but every similar institution in London suffered in the same way. It will usually be found that, when erysipelas is very abundant among the in-patients of a hospital, similar cases present themselves for treatment in the out-patient department; and at the same time it is generally noticed that phlebitis of varicose veins, epidemic catarrh, acute tonsilitis, and other allied affections prevail. Epidemic erysipelas may vary in its type. Thus the epidemic of 1874 was chiefly of the cutaneous variety, and was accompanied by comparatively slight tendency to gangrene or sloughing; while that of 1872, in Edinburgh, was of a violent phlegmonous type, usually attacking the subcutaneous tissue and leading to extensive diffuse sloughing and suppuration.

The great predisposing cause of erysipelas is, however, to be sought for and will be found in a *want of attention to hygienic conditions*. It is one of the penalties inflicted by nature on those who neglect those prime requisites of health—temperance and cleanliness—or who are incapable of obtaining good food and pure air. Were the laws of hygiene obeyed as they should be, erysipelas and the allied diffuse inflammations would rarely be met with in surgical practice. *Overcrowding* of hospitals, and *want of proper ventilation* in wards and rooms, are fertile sources of erysipelas, and of the allied processes.

Erysipelas, however, cannot be as certainly generated in this way as some other unhealthy processes in wounds, such as hospital gangrene, or pyæmia. This has frequently been observed in military practice. Thus, after the battle of Sedan, although the wounded in some hospitals were almost decimated by pyæmia, erysipelas was very rarely met with. In the American War it is stated to have occurred in 0·4 per cent. of the wounded. It generally broke out in badly ventilated hospitals, and spread rapidly from one patient to another. It was less frequent in cases treated in tents, but occasionally it made its appearance under the most favourable hygienic conditions. These facts tend to confirm the view that genuine erysipelas is due to a specific virus which is not universally present. In old hospital buildings in which the disease has frequently occurred, the poison may be constantly present, waiting only for favourable conditions to manifest itself.

Fehleisen has shown that the streptococci of cutaneous erysipelas can be cultivated at ordinary temperatures, not only in gelatine and blood-serum, but on potatoes, and it seems probable that the virus will increase readily whenever there is dead animal or vegetable matter in which it can develop. This explains the way in which the disease is not unfrequently originated in hospitals, by dressers going directly from the dead-house, and especially from the examination of the bodies of those who have died of diffuse inflammations, to the bedside of patients, without taking sufficient care to clean their hands or change their clothes. For this reason also the same instruments should never be used for practising operations on the dead and performing them on the living body. The apparent origin of the disease from air passing over an ash-heap on which kitchen refuse has been thrown, which has been more than once recorded, may be due to the cultivation of the specific streptococcus on decaying vegetable matter.

The varieties of external erysipelatous inflammation will be separately discussed in some detail.

1. **CUTANEOUS ERYSIPELAS** is a specific spreading inflammation of the skin, accompanied by constitutional symptoms which are secondary to the local disturbance.

Local Symptoms.—If there be a wound, its surface becomes dry, and the margins become slightly swollen, and the characteristic rash spreads away from them into the surrounding skin. The disease may also appear to occur idiopathically; that is to say, it may apparently originate in the unbroken skin. Trousseau, and others, have asserted that even in these cases it always starts from some slight abrasion which has been overlooked. When arising in this way it commences most commonly at the junction of mucous membrane and skin, as at the angle of the mouth, the ala of the nose, the corner of the eye, the meatus of the ear, or the margin of the anus. In rare cases it may arise spontaneously on the limbs. I have seen it commence in the unbroken skin over an abscess. This so-called idiopathic erysipelas is the same disease as that in which the rash starts from a wound, although this has been doubted. During an outbreak of erysipelas in a surgical ward the two forms may arise in different cases as the result of the same infection.

The *rash* is of a uniform, vivid rosy-red hue, sometimes becoming dusky, and always disappearing on pressure, leaving a slightly yellowish tint behind; when advancing, it is characterized by a sharply-defined border slightly raised above the healthy skin, but when subsiding it fades away into the colour of the

healthy skin. It is accompanied by some slight oedematous swelling, frequently recognizable only by the permanent impression left by the finger-nail pressed on the skin, but often considerable where the areolar tissue is loose, as in the eyelids and scrotum; and there is usually a sense of stiffness with a burning sensation in the part, and not unfrequently greatly increased sensibility. Vesicles or bullæ often form, containing a clear serum, which speedily becomes turbid, and dries into fine branny desquamation. The redness may spread rapidly along the limb or trunk, or if the face be affected, may travel quickly from one side to the other, causing such swelling of the eyelids as to close them, and giving rise to swelling and much tensive pain in the ears. The disease is invariably accompanied by enlargement and tenderness of the lymphatic glands. In some cases this may even precede the rash.

A form termed *erratic erysipelas* has been described occurring in connection with pyæmia, in which the eruption disappears from one part of the body and reappears in another. It is a very dangerous condition, often indicating the approach of death. It is very doubtful if it is in any way related to genuine cutaneous erysipelas.

The inflammation in cutaneous erysipelas has no tendency to terminate in suppuration. In some parts in which the areolar tissue is very loose, especially in the eyelids, suppuration occasionally takes place, but it then seems to be the result rather of the tension caused by the effusion than of the irritation of the specific virus.

When the inflammation is passing off the pain abates, the colour fades, the swelling subsides, the cuticle, which has been detached by the serous transudation, flakes off in thin layers, and the skin returns to its normal state. In other cases, cedema of the part continues, with some irritability and redness of the skin and peeling of the cuticle; and in some rare cases the simple erysipelas seems to take on a gangrenous or sloughing character, especially about the umbilicus and genitals of young children.

Constitutional Symptoms.—The fever of cutaneous erysipelas continues as long as the rash is spreading. The invasion is marked by alternate chills and flushes, but seldom by a distinct rigor. The temperature seldom rises to 106° F., more commonly it keeps below 104° F. There are no marked variations beyond the ordinary morning fall and evening rise met with in all febrile affections. The pulse may at first be full and strong, but it soon falls in force and becomes more frequent. Headache is a common symptom. There is frequently some delirium, which in the early stages may be violent, but later on becomes feeble and muttering. Delirium is especially marked in erysipelas of the head, and was formerly supposed to be due to affection of the membranes of the brain. It has been shown, however, by *post-mortem* examination of fatal cases, that meningitis is very rare except in cases of erysipelas attacking a compound fracture of the skull, or spreading into the fat of the orbit. The delirium is usually due to the blood-condition, and is always a grave sign. The tongue is at first much coated, and soon becomes dry and brown; there is also in most cases a good deal of derangement of the digestive organs, with tenderness about the epigastrium, complete loss of appetite and nausea; the evacuations are dark and offensive, and not unfrequently there is diarrhoea.

Cutaneous erysipelas is a most depressing disease, the patient being frequently much reduced in strength, anæmic, and emaciated even after a comparatively slight attack.

The duration of an attack of cutaneous erysipelas is very uncertain : it may last from three days to three weeks, and relapses by which it may be prolonged to a month or more are very common.

Pathology.—After death the red tint fades, leaving the skin of a yellowish tint ; if it be cut into, it is found to contain an excess of serous fluid. The internal organs present nothing that is characteristic. As in all diseases accompanied by high fever and general blood-poisoning, the epithelium of the kidneys and liver is found in a state of cloudy swelling, and the spleen is in some cases enlarged. The lungs are usually congested. Sometimes marked *post-mortem* staining of the blood-vessels and organs is found very soon after death, and occasionally small petechiæ are scattered beneath the serous membranes.

If the most advanced edge of the spreading margin be examined microscopically, the lymph-spaces of the cutis are found to contain numerous streptococci, as was first pointed out by Lukomsky and v. Recklinghausen. These may be packed so closely as to form an opaque granular mass, but if they are less crowded together they can be seen to form pairs or

Fig. 343.—Streptococci in the lymph spaces of the skin from a case of cutaneous erysipelas. The dark patch in the upper right hand corner is the deeper layer of the epidermis. (From a photograph by Koch.)

chains (see p. 244). The zone in which they can be recognized easily is very narrow, as they are soon hidden by numerous migrating leucocytes which fill the spaces of the fibrous tissue, and accumulate round the vessels and in the lymph-spaces. No micrococci can be found when the rash is receding, nor in those parts over which it has passed. The theory of the disease founded on these observations is that the micro-organisms invade the healthy tissues, and by their presence or by the chemical products of their growth, excite inflammation with migration of the colourless corpuscles. The organisms are then destroyed by the migrated corpuscles, and thus are present only in the advancing margin.

Two views have been held concerning the essential nature of cutaneous erysipelas. First, that it is a general specific disease, of which the rash is merely a local manifestation, the wound serving merely as the determining point at which the eruption shall appear ; and, secondly, that it is a local infective inflammation and that the fever and other constitutional symptoms are entirely secondary. The arguments in favour of the first view are briefly as follows :—1. Like other acute specific diseases it occurs in epidemics. 2. In

some cases the fever distinctly precedes the appearance of the rash, sometimes by as much as 48 hours. Moreover, I have seen a constitutional disturbance of the same type as that accompanying the local inflammation occur without any such complication. This I had special occasion to observe in a very fatal outbreak of erysipelas that took place in one of my wards in 1851. On that occasion, all the cases in which the cutaneous form of erysipelas appeared were marked by severe constitutional disturbance, attended with much gastro-intestinal irritation. But precisely the same type of general febrile symptoms occurred in patients in the same ward in whom no local manifestation of the disease took place. 3. The severe constitutional disturbance accompanying the disease is often apparently out of proportion to the local mischief. 4. In many cases the disease seems to break out without any breach of surface at which inoculation could have occurred. In some cases it has been known to commence at the edge of a carbolic acid dressing, and not at the wound. 5. As is the case with other acute specific diseases, an attack confers a temporary immunity from the disease; and 6. The fact of its inoculability is no argument against the theory that it is a general disease, for we see the same in small-pox and syphilis. In favour of the local theory the following facts are urged:—1. Local diseases as well as general occur in an epidemic form. 2. When the fever appears to precede the eruption careful observation will always show some local disturbance; either the wound has become red and dry or the lymphatic glands nearest it are tender and swollen. When gastro-intestinal disturbance occurs in many patients in a ward, some of whom develop erysipelas while others do not, the disordered health is not due to the specific virus but to some unhealthy state of the ward which may act as a predisposing cause of erysipelas. 3. The fever continues as long as the rash is extending, and ceases at once when its progress is arrested. In inoculation erysipelas in the rabbit's ear, all constitutional symptoms disappear at once if the ear is amputated. 4. The breach of surface necessary for inoculation is merely microscopic, and consequently it is impossible ever to say with certainty that none existed. Slight excoriations of the skin are very common at the edge of antiseptic dressings, and may readily serve as points of inoculation. 5. Temporary immunity against a second attack is believed to be conferred in other diseases which are primarily local, as in some forms of dissection-wound. The immunity in erysipelas is of very short duration, and patients are frequently met with who are liable to repeated attacks of the disease. 6. Erysipelas differs from acute specific diseases in having no appreciable period of incubation, and no definite course or duration. 7. Lastly, the characteristic organism has not been demonstrated in the blood or cultivated from it either in animals or in man.

The balance of evidence is therefore in favour of the local theory of the disease, and although it cannot be denied that the virus, through not multiplying in the blood, may possibly, under exceptional circumstances, enter from the lungs or alimentary canal, and be carried to the wound by the blood, yet this is not the rule, and we may hope to prevent the occurrence of this most serious complication of wounds by means calculated to protect the raw surface from the virus.

DIAGNOSIS.—The diagnosis of cutaneous erysipelas is generally easy. From the *exanthemata*, it is distinguished by the character of the eruption; by the way in which it spreads from a single spot, usually a wound or raw surface;

and especially by the characteristic sharply defined margin. It is most commonly confounded with the red blush surrounding a wound in which septic matter is pent up: in this, however, the margin of the redness is not sharply defined: the enlargement of the lymphatic glands and the definite invasion are usually absent. From inflammation of the veins or of the lymphatics, the diagnosis is not always easy, more especially as the two conditions frequently co-exist. If a vein is inflamed, the general absence of cutaneous redness, the existence of a hard round cord, and the tenderness along the course of the vessel, are sufficient to establish the diagnosis. In inflammation of the lymphatic vessels the redness is not uniform, but consists of a number of small and separate red streaks, running in the direction of the lymphatics, and affecting the glands towards which they course. These two affections—erysipelas of the skin and inflammation of the lymphatics—are so frequently conjoined that a differential diagnosis is not of much importance.

PROGNOSIS.—The prognosis in uncomplicated cutaneous erysipelas is by no means grave. Of 36 cases of idiopathic erysipelas admitted under the care of the physicians in University College Hospital during a period of ten years, only two died, and one of these was suffering from chronic Bright's disease. When traumatic the disease is far more dangerous. Of 148 cases admitted under the Surgeons or breaking out in the surgical wards during a similar period 35 died. In only five is no special complication mentioned in the report, and one of these was an infant. Two died of pneumonia, seven of pyæmia which attacked the patient after the erysipelas had subsided, two of meningitis from injury to the head: two suffered from Bright's disease, two from severe constitutional syphilis, one from general albumenoid degeneration, two from advanced cancer of the breast, one from cancer of the liver, one from heart disease, two from suppuration of the kidneys secondary to cystitis: one had a large cavity in the lung: one was an habitual drunkard, one was in very bad health, and one was dying at the time of invasion: one died from bed-sores, one from secondary hæmorrhage, one from an abscess, and one from thrombosis of the veins of the leg and sloughing of the skin after the specific disease had subsided. These statistics show that cutaneous erysipelas rarely proves fatal unless it attacks an individual previously suffering from grave constitutional disease, but that by exhausting the strength it may leave the patient liable to fall a victim to other complications of wounds such as pyæmic Disease of the kidneys is always a most serious complication. High fever, violent delirium, profuse diarrhoea and early prostration are grave signs during the progress of the case. Traumatic erysipelas is more dangerous than idiopathic, as other unhealthy processes are apt to follow in the wound: on the other hand, sores which have been making no progress for a long time often heal rapidly after an attack of cutaneous erysipelas. The disease is most dangerous at the extremes of life.

TREATMENT.—Preventive Measures.—The occurrence of erysipelas is best guarded against by attention to hygienic measures, more particularly proper ventilation with pure air, and the avoidance of overcrowding of patients. With every care, however, erysipelas can never be completely eradicated from surgical wards, as it is often epidemic, and brought into the hospital from without. It often happens that erysipelas is unusually frequent in certain wards and even in certain beds. Its persistence in these respects will be found to be owing to some local cause, such as the emanations from a drain or dust-

bin, on the removal of which the disease will cease. Scrupulous attention to cleanliness on the part of nurses and dressers should also be enforced, and the latter should not be allowed to go straight from the dead-house to the ward without previously washing their hands in some disinfectant or antiseptic solution. When erysipelas has already occurred, its further spread may be prevented by isolating the affected patients, and at once taking active measures to purify the ward from which they have been removed.

The **Curative Treatment** of cutaneous erysipelas must always be conducted with reference to the depressing character of the disease. The apparent intensity of the local inflammation in some cases must not lead the Surgeon into the fatal error of employing any so-called antiphlogistic treatment. The treatment required is essentially of a tonic and stimulating character. The principal medicinal remedies consist of bark, quinine, iron, and ammonia. If there be much thirst, these remedies may be given in an effervescent form; but in any case they should be administered in frequent doses. If medicines are not well borne, the stomach rejecting them, I have seen the best possible results follow the free administration of the brandy-and-egg mixture. During the progress of the disease, simple purgatives must be given from time to time. Tincture of the perchloride of iron, originally recommended by Hamilton Bell in small and repeated doses, is now often given in large doses, forty minims every four hours, as recommended by Russell Reynolds and others. It is supposed to exert a specific influence on the disease, and is certainly useful.

The *Local Treatment* is of equal importance with the constitutional. Innumerable modes of treatment have been recommended by different Surgeons, but all are agreed that the first essential is to keep the inflamed part warm. Cold lotions should never under any circumstances be employed; they lessen the vitality of the tissues, and may thus cause local sloughing. In slight cases the part should be covered with flour or starch powder dusted over it, and wrapped in cotton-wool. In the more severe forms, warm applications assiduously continued, especially hot boric acid fomentations applied by means of flannels or spongio-piline, afford the greatest possible relief. The surface may at the same time be covered with a paint composed of equal parts of glycerine and extract of belladonna. I have seen astringent applications, such as a strong solution of nitrate of silver, extensively employed in former years, but not with any very marked success. At University College Hospital the treatment recommended by Valette of Lyons has been tried with very good results. A 30 per cent. solution of perchloride of iron is prepared; forty minims of this solution may be given internally with a little syrup or glycerine and water every two or three hours, and externally the pure solution is applied to the inflamed area. This must be done thoroughly, the solution being rubbed in with a piece of lint or cotton-wool. If necessary the grease must be removed from the surface of the skin by washing with soap and warm water before the lotion is applied. The application is repeated twice a day as long as it is necessary. Wollner has recommended a mechanical treatment, which consists in applying firm pressure with strapping around the edge of the eruption. This is supposed to prevent its spread by the compression of the lymph spaces. Koch found the following salve useful in ten cases: Creolin one part, iodoform 4 parts, lanolin 10 parts.

The local abstraction of blood and serum from the inflamed part, by the

plan introduced by Dobson, of rapidly making a large number of small punctures, from a quarter to half an inch deep, with the point of a lancet, is of great value when the tension and swelling are extreme: a hot fomentation should be laid over the punctures. Kraske has recently employed scarification of the spreading edge. If the disease have attacked one of the limbs, the application of a bandage is occasionally necessary after the disappearance of the erysipelas, in order to remove the *oedema* that remains.

2. *CELLULO-CUTANEOUS OR PHLEGMONOUS ERYSIPELAS* differs from cutaneous erysipelas in so many respects, that it is best regarded as an entirely distinct affection. It was described by Dupuytren under the name of "diffuse phlegmon." It has been said to occur occasionally in an epidemic form. It rarely occurs in its worst form, except in persons who have been addicted to excessive drinking, or who are suffering from chronic renal disease. Locally, it differs from cutaneous erysipelas in the intensity of the inflammation, which is such that it invariably terminates, if left to itself, in diffuse suppuration and sloughing. In depth it always extends to the subcutaneous areolar tissue, and, though generally bounded by the underlying fasciæ, it not unfrequently implicates these, and extends to the intermuscular areolar planes, the sheaths of the tendons, and other deep structures. There is no defined margin to the superficial redness, and the lymphatic glands are frequently unaffected.

Symptoms.—The inflammation may start from a wound or abrasion at an early period after its infliction, but frequently no such cause can be recognized. It is ushered in by the ordinary symptoms of inflammatory fever, accompanied or followed by the signs of severe inflammation in the part affected. The redness is uniform, of a deep scarlet hue, and although somewhat distinctly bounded, is not limited by a sharply defined line: the pain is at first burning, though it may quickly assume a throbbing character. The swelling, at first soft, diffused, and putting distinctly, soon increases, and becomes tense and brawny, the skin being evidently stretched to its full extent, and the part appearing to be perhaps twice its natural size. Large vesications or blebs containing sero-purulent fluid, sometimes blood-stained, appear in many cases. This condition usually continues up to the sixth or eighth day after the invasion of the disease, during the whole of which time the constitutional symptoms have presented the ordinary type of sthenic inflammatory fever; about this time, however, a change commonly takes place, either for the better or for the worse. If, under the influence of proper treatment, and in a tolerably healthy constitution, the inflammation subsides, resolution takes place, with a gradual abatement of all the symptoms. It, however, as usually happens, the disease runs on to more or less sloughing or suppuration of the part, no increase of the swelling, pain, or redness takes place, but on the contrary, some diminution of these signs may occur, and thus give rise to a deceptive appearance of amendment. The skin becomes darkly congested, and the part, instead of being tense and brawny, has a somewhat loose, soft, and boggy feel, communicating a semi-fluctuating, doughy sensation to the fingers. This change from a tense brawny state to a semi-pulpy condition indicates the formation of pus and slough beneath the integument. The pus can be detected only by careful palpation; hence the Surgeon must daily examine the state of the part, and neither trust to the reports of others, nor to the general appearance of the diseased structures, for a knowledge of the probable condition of the subjacent tissues. If an

incision be now made, the areolar tissue will be found loaded with an opalescent semi-fluid exudation, distending its lymph-spaces but not flowing from the wound: the retention of this fluid gives a gelatinous appearance to the sides of the incision. If the alteration in structure have advanced to a stage beyond this, the areolar tissue will be found to have been converted into dense masses of slough, bathed in thin ichorous pus; these sloughs have not inaptly been compared in appearance to masses of decomposed tow, or wet chamois leather. Whilst these changes are going on below the surface, the skin becomes dusky, and assumes a marbled appearance, rapidly changing into black sloughs, and being undermined by large quantities of broken-up areolar tissue and of ill-conditioned pus, without any appearance of pointing, however extensive the subcutaneous mischief may be. These destructive changes expose muscles, fasciæ, and blood-vessels, and may induce necrosis of the bone, or suppuration of the joints. They occur most readily in those parts of the body that possess the lowest degree of vitality, and hence are more common in the legs than in the scalp. As soon as the skin gives way, unless some means be taken to prevent it, the sloughs undergo ordinary offensive putrefaction, and the products of this process cause local aggravation of the inflammation and the constitutional symptoms of septic poisoning. If the patient recover, there will be a tedious cicatrization of the deep cavities that are left; or considerable œdema, often of a solid character—a kind of false hypertrophy of the part—which may continue for some considerable time. In other cases, there may be such extensive local destruction of the soft tissues, with exposure and death of the bones or suppuration of the joints, that amputation of the limb may be required to save the patient's life. No operation of this kind, however, should ever be practised for phlegmonous erysipelas, unless the disease be strictly localized, and show no further tendency to spread; nor until the fever has subsided, except such as is of a hectic character and dependent on the septic suppuration.

During the progress of these local changes, the *Constitutional Symptoms* undergo corresponding modifications. At first of an active inflammatory character, the fever, when suppuration and sloughing have set in, often suddenly becomes asthenic. Although in some cases there is at first no diminution in the severity of the symptoms, the constitution gradually gives way after the patient has struggled for a few days against the exhausting influences of the disease, and death speedily supervenes. If the patient survive the stage of sloughing, pyæmia, septicæmia or hectic from profuse discharge may carry him off. If recovery eventually take place, it may be with a constitution impaired and shattered for years. The immediate danger is always greatest when the head is affected. The remote danger from the effects of suppuration of areolar tissue, necrosis of bones, and inflammation of the joints, is greatest when the lower extremities are the seat of the disease.

A variety of the cellululo-cutaneous erysipelas has been described as **œdematous Erysipelas**. By this is meant not merely the effusion into the areolar tissue which occurs in all the varieties of the disease, but a peculiar form, specially marked by œdema of the areolar tissue, with less inflammation of the skin than usual. There is great swelling, which pits deeply on pressure, with little pain or tension, and but moderate redness of the skin; the constitutional symptoms are less marked than in the other varieties of the disease; it

is principally met with in old people, or in persons of a dropsical tendency, in whom it occurs especially about the legs, scrotum, or labia, sometimes giving rise to permanent and solid enlargement.

Diagnosis.—Phlegmonous erysipelas is easily recognized by the characteristic symptoms just described, when arising from some slight superficial injury or spontaneously; but if it should happen to complicate a deep wound or compound fracture, it is easily confounded with *simple septic inflammation* consequent upon pent-up decomposing discharges or blood. In all probability a very large proportion of the cases formerly described under the name of erysipelas were in reality simple septic inflammations not of a specific character. The so-called phlegmonous erysipelas of the scalp following a wound is, for example, almost invariably the result of the burrowing of putrid discharges beneath the pericranial aponeurosis.

From *spreading gangrene* it is distinguished by its slower progress and the absence of fetid gases in the sloughs before the skin gives way.

Prognosis.—The prognosis in phlegmonous erysipelas is always grave. Of twenty-four cases admitted into University College Hospital seven died. It is especially dangerous if it affect the head or parts in which the areolar tissue is abundant and lax, as the scrotum or orbit. Much also will depend upon the promptness with which efficient treatment is begun and the means adopted to prevent septic poisoning from putrefaction of the sloughs. The disease is most dangerous at either of the *extremes of life*. If the *constitution* be sound, very extensive mischief may be recovered from; if, on the other hand, it be depressed or broken by want of the necessities of life, by fatigue, over-exertion, or indulgence in stimulants, a very slight amount of disease may prove fatal. The most dangerous complication, and one which when it exists almost precludes the hope of recovery, is *chronic disease of the kidneys*, either in the form of the granular contracted, or of the large white, kidney. I have never seen any patient labouring under these diseases, and attacked with phlegmonous erysipelas, escape with life; the sloughing and suppuration running on unchecked by any treatment that could be adopted.

Pathology.—The disease is a local infective process caused by the presence of the streptococcus pyogenes (p. 241), which is found in the whole affected area and not merely at the advancing margin. The first effect is an abundant coagulable exudation which distends the lymph-spaces to the greatest possible extent. Unless relieved by treatment, the exudation softens, migration continues and the spaces become filled with pus; then partly as the result of the pressure of the exudation, and partly from the direct irritation of the acrid chemical products of the process, the whole affected connective tissue perishes. The inflammation is believed to be caused by the irritating products to which the micro-organisms give rise in the fluids of the part by a process analogous to fermentation. These products soak into the surrounding lymph-spaces and excite further exudation in which the organisms spread. By incisions into the part the exudation is drained away instead of soaking into the surrounding parts, and thus the spread of the organisms is checked, while at the same time tension being relieved one great source of irritation is removed, and the tissues may thus escape death. The viscera present nothing special. There will be the signs of septicæmia (see Septicæmia), or pyæmia (see Pyæmia), should either of these affections have been the immediate cause of death.

Treatment.—In the early stage, our object is to prevent the inflammation from running into gangrene of the affected tissue. The fever being at this period commonly sthenic, the administration of purgatives, or effervescent salines may give relief, but blood-letting is never required: and depressing remedies, such as salines, must be given with great caution. Tonics and stimulants require to be given early and late. As the disease advances, and symptoms of depression come on, a more stimulating plan of treatment must be adopted. As the pulse becomes feebler, and the tongue browner, ammonia, bark, and especially port wine, and the brandy-and-egg mixture, must be administered. In the more advanced stages of the disease our sole object must be by nourishing diet, and the use of stimulants and tonics, to carry the patient through the depression.

Local Treatment.—The part affected must be kept at rest, and elevated, if it be a limb; it must be well painted with equal parts of glycerine and extract of belladonna, and have hot fomentations assiduously applied, cold being even more prejudicial here than in cutaneous erysipelas; in this way, the swelling and tension may perhaps be removed, and sloughing of the areolar tissue prevented. In the majority of cases, however, incisions must be made into the part for the relief of tension. This mode of practice is the most effectual means we possess for the *prevention* of sloughing; hence the incisions should be made early, before there has been time for the tissues to lose their vitality. As soon, indeed, as the skin becomes brawny, indurated, and tense, incisions will afford the greatest possible relief, reducing the tension by the gaping, and the swelling by the exit they afford to the inflammatory exudation. Some Surgeons have recommended that one long cut should be made through the inflamed structures: so considerable a wound, however, not only inflicts a serious shock on the system, but the loss of blood from it may be so great as to be fatal; moreover, a single long incision does not relieve tension so effectually as a number of smaller ones. These preventive incisions should therefore be from two to three inches in length: at most they should not extend deeper than into the gelatinous-looking subcutaneous areolar tissue, unless it happen that the disease has extended beneath the fascia, when they may be carried through it also. The incisions should be so arranged in fours, as
 to enclose a diamond-shaped space, as in this way the greatest relief is given to the tension of the part. As it is desirable that as little blood as possible be lost, hæmorrhage may be prevented by elevating the limb and applying a tourniquet before using the knife, but it is better not to employ Esmarch's bandage, for fear of driving the unhealthy inflammatory products into the circulation. In those cases in which the disease is not already complicated with an open wound and decomposing discharges, great advantage will be derived from the employment of antiseptic precautions, thus preventing putrefaction of the effused inflammatory fluids which fill up the spaces of the areolar tissue exposed by the incisions. Before making the incisions, the limb should be well fomented for a quarter of an hour with cloths wetted with a hot solution of carbolic acid (1 in 20). The tourniquet is then applied, and the incisions made with antiseptic precautions. To arrest excessive bleeding, the wounds must be plugged with iodoform or salicylic wool or some other antiseptic material. The treatment may then be carried out with the carbolic gauze or some other efficient antiseptic dressing, such as hot salicylic wool poultices, iodoform wool or

fomentations of borie lint. If suppuration and sloughing have taken place, as indicated by a boggy feel of the parts, free incisions should immediately be made in order to let out pus and sloughs. After this, the skin will often be found to be greatly undermined, blue, and thin, with matter bagging in the more dependent parts: if so, egress must be made for it by free counter-openings, and drainage-tubes inserted if required. During the after-treatment, frequent dressing is necessary to prevent an accumulation of pus, and the sloughs must be removed as they separate. Care should be taken not to destroy any of the vascular connections of the skin with adjacent parts: but, in order to get proper cicatrization, it will often be found necessary to lay open sinuses, or to divide bridges of unhealthy and blue integument stretching across chasms left by the removal of the gangrenous areolar tissue. If the loss of substance be great, the cicatrix that forms may be weak, imperfect, or so contracted as to occasion great deformity of the limb. In other cases, again, the diseased state of the bones and joints may be such as ultimately to call for amputation, either in consequence of the local deformity and annoyance, or in order to free the constitution from a source of hectic and irritation. In all circumstances, the patient's health will usually continue in a feeble and shattered state for a considerable time after recovery, requiring change of air, great attention to habits of life and a nourishing diet.

3. **CELLULAR ERYSIPELAS**, or as it is more often termed **Diffuse Inflammation of the Cellular Tissue** or **Cellulitis**, is an acute local infective process originating in the inoculation of a virus either in a wound or by a small puncture or scratch. Diffuse cellulitis may arise as a consequence of ordinary injuries, but it is especially apt to follow those in which there has been any inoculation of animal poisons, as from dissection-wounds, the stings of insects, and the bites of venomous reptiles. The diversity of its origin, however, and the different course assumed by different cases would lead us to suppose that the virus in cellulitis is not always necessarily the same. The disease resembles erysipelas in the diffuse character of the inflammation, and it arises under circumstances similar to those in which erysipelas is observed to originate. In some cases the constitutional symptoms present nothing peculiar, being merely those of acute inflammatory fever; in others, especially those arising from the inoculation of the poison of a dead body, the phenomena may be those of acute septicæmia. The term "cellular erysipelas" or "diffuse cellulitis" must, therefore, be regarded as a clinical expression for an acute infective inflammation, spreading by the lymphatics and lymph-spaces of the areolar tissue, and not as implying a definite specific disease, such as simple cutaneous erysipelas undoubtedly is.

Local Signs.—The local signs will vary with the part affected. If it is the subcutaneous tissue of a limb, great swelling, tension and pain are present, and the part feels brawny in some parts, œdematous in others. The skin is slightly reddened in patches, has a mottled appearance, and may in extreme cases follow the same course as phlegmonous erysipelas, running into blackish sloughs. This form in fact differs from phlegmonous erysipelas only in the affection of the skin being entirely secondary to that of the subcutaneous tissue. The extent to which the disease may spread varies greatly; when once it has set in, it frequently runs rapidly up the whole limb, extending also to the sides of the trunk.

In other cases, especially in the form that follows dissection-wounds, the

inflammation at the seat of inoculation may be slight, the mischief being chiefly at a distance; thus in a punctured wound of the finger, the diffuse inflammation may take place principally in the planes of areolar tissue in the axilla and sides of the chest. Diffuse cellulitis also affects the internal planes of areolar tissue. This may happen, for instance, in the fasciæ of the pelvis after lithotomy, or in the anterior mediastinum after operations at the root of the neck. In these cases there is deep-seated pain and tenderness, and the skin may be slightly reddened and cedematous. The superficial veins are often full and clearly indicated on the surface. Sloughing frequently occurs with remarkable rapidity, the areolar tissue being broken down into pus and shredly sloughs in the course of thirty-six or forty-eight hours, more especially when the disease has resulted from the inoculation of decomposing animal matter.

The **constitutional symptoms** vary in different cases. In some they are those of acute inflammatory fever; in others the affection is accompanied by signs of the gravest blood-poisoning. In these latter there is probably a general infection of the system. After the sloughs become exposed to the air decomposition rapidly sets in, and the symptoms then assume the type of acute septic poisoning from the absorption of the chemical products of putrefaction.

Pathological Anatomy.—The state of the areolar tissue is the same as in phlegmonous erysipelas. The streptococcus pyogenes is usually found in the inflammatory exudations. Should the patient die, the viscera present the ordinary appearances of acute blood-poisoning (see Septicæmia).

Prognosis.—If the subcutaneous tissue of a limb only is affected many cases can be saved by proper treatment. Amongst twenty-four cases registered as cellulitis in the reports of University College Hospital there were six deaths. When the deeper planes of areolar tissue are affected, and when the process is very acute, death commonly occurs early, often in two or three days; in other instances life may be prolonged for some weeks, the patient ultimately dying of exhaustion or of some secondary complication, as pyæmia.

Diagnosis.—Superficial cellulitis closely resembles cellulocutaneous erysipelas, and in the later stages it may be indistinguishable when the skin becomes affected. In any case the diagnosis is of little importance as the treatment is the same. Deep-seated cellulitis is often very difficult to recognize; the swelling, with some œdema and slight redness, the fulness of the superficial veins, and the deep-seated pain and tenderness, with the history of a cause likely to induce the disease, such as a *post-mortem* wound, combined with the characteristic constitutional condition, will, however, usually enable the Surgeon to recognize the condition.

Treatment.—In the treatment of diffuse cellulitis it is usually necessary to administer stimulants early; ammonia, wine, or brandy may be required from the very first. The Surgeon must judge of this by the constitutional condition of the patient, and more particularly by the state of his pulse and tongue. The *Local Treatment* is precisely of the same kind as that adopted in phlegmonous erysipelas, except that the incisions require to be made earlier and perhaps more freely; in all other respects, there is no difference between the general management of these two forms of disease.

SPECIAL FORMS OF EXTERNAL ERYSIPELATOUS INFLAMMATION.—**Erysi-**

pelas of Newly-born Infants, Erysipelas Neonatorum, is occasionally met with, more particularly in lying-in hospitals, or in situations where the mother and child are exposed to depressing causes of disease. It usually appears a few days after the birth, at first about the abdomen and genitals, and soon spreads widely over the body, being characterised by a dusky redness which rapidly runs into gangrene of the affected tissues. It starts in many cases from the raw surface left by the separation of the umbilical cord. It is extremely fatal, owing to the feeble vitality of the child, and presents but few points for treatment; change of air and of nursing, with the administration of a few drops of spirits of ammonia or brandy from time to time, being all that can be done.

Idiopathic Erysipelas of the Head is always of the cutaneous form having no tendency to end in suppuration or gangrene. The only peculiarity it presents is the excessive oedema of the subcutaneous tissue usually accompanying it, which completely obliterates the features. As the result of the tension caused by this, a little pus may occasionally form in the eyelids. Large blebs on the skin are very common. It is always accompanied by some redness and soreness of the throat. The inflammation as a rule starts from the junction of the mucous membrane and skin, as at the angle of the eye, spreading quickly to the bridge of the nose; at the orifice of the meatus auditorius externus, or the angle of the mouth. Its origin without a small abrasion or wound has frequently been denied. The course, symptoms, prognosis and treatment are those of simple cutaneous erysipelas (pp. 944 *et seq.*).

Cellulitis of the Orbit may occur primarily, or as the result of extension of the disease from the neighbouring structures. It is dangerous, and often fatal from thrombosis of the cavernous sinus and meningitis. It commences with a violent deep-seated pain in the orbit; the conjunctiva becomes injected and ecchymosed, the eyelids are greatly swollen, red, and oedematous; the eyeball protrudes, and vision is impaired or altogether lost. Symptoms of cerebral inflammation may now set in, the patient becoming delirious and finally comatose.

The *Treatment* consists in fomentations, with early and free incisions into the orbit, made by pushing a lancet flat-wise between the eye-ball and the orbital walls, through the inflamed conjunctiva, the eyelids having previously been everted. In this way inflammatory effusions and pus may be evacuated, and the eye saved. Destructive abscesses of the orbit occasionally occur in the puerperal state, requiring, when practicable, the free evacuation of pus, in the way just mentioned.

Diffuse Cellulitis of the Scalp following a wound has already been described (pp. 717, 720).

Diffuse Cellulitis of the Submaxillary Region was first accurately recognized by Ludwig, of Stuttgart, in 1836; hence the affection has sometimes received the name of Ludwig's Angina. It has also been specially described by Bickersteth, of Liverpool, and by Croly, of Dublin, and in an exhaustive paper by R. W. Parker (*Lancet*, Vol. II., 1879). Submaxillary cellulitis is an acute diffuse inflammation of the areolar tissue beneath the deep cervical fascia, attended with the ordinary severe constitutional symptoms of diffuse cellulitis, and terminating rapidly in suppuration, with sloughing of the affected tissues unless relieved by prompt and efficient treatment. The peculiar danger of the affection depends on the importance of the parts affected.

and on the density of the cervical fascia, beneath which the inflammatory products are pent up at a high degree of tension. The disease may commence without evident cause after exposure to cold, and is said occasionally to have appeared in an epidemic form; it may arise also from extension from the lymphatic glands in scarlet fever, or may follow wounds or other injuries. In other cases it is connected with a diseased tooth, most commonly with a necrosed fang. It may occur at any age; in adults, according to Furneaux Jordan, it most frequently occurs in those addicted to excessive drinking. It commences as a brawny inflammatory swelling at the fore part of the neck, or near the angle of the jaw, surrounding the submaxillary gland, or more rarely the parotid. It rapidly spreads towards the chin, extending to the opposite side, and afterwards down the neck over the larynx. The tongue is pushed upwards, and the hardened tissue can be felt in the floor of the mouth on each side of it; the movements of the jaw are interfered with, and deglutition becomes difficult. Sometimes there is great swelling of the tongue from pressure on the lingual veins. When gangrene of the areolar tissue sets in, the swelling softens and becomes boggy; the mucous membrane may give way, and a foul discharge may come from the mouth. If unrelieved by treatment it is extremely fatal; death may occur from blood-poisoning or from suffocation, the disease spreading to the root of the epiglottis, and producing oedema glottidis.

The *Treatment* consists in making a free incision in the mesial line, from the chin to the os hyoides, through the infiltrated parts, from which, if it be made sufficiently early, a thin dark serum, but no pus will be seen to exude. The incision must be carried to a depth of two inches or more towards the base of the tongue, keeping carefully to the middle line, until the whole of the brawny infiltration has been divided. If the swelling has commenced at one side and has not reached the middle line, whenever it is possible the incision should still be kept in the same situation, as lateral incisions are accompanied by great danger of hæmorrhage which it would be very difficult to arrest. If the condition be connected with a diseased tooth, a small cavity will often be found at a considerable depth, containing horribly fetid matter, and at the bottom of this, bare bone may be felt on the inner aspect of the jaw. In spite of this, recovery usually occurs without the separation of dead bone.

Erysipelas of the Scrotum—the "inflammatory oedema" so well described by Liston—is of frequent occurrence, as the result of wounds, ulcers, and other sources of irritation in this neighbourhood. The scrotum swells to a large size, being uniformly red, but with a semi-transparent glossy appearance, putting readily on pressure, and feeling somewhat soft and doughy between the fingers: the integuments of the penis are also greatly swollen and oedematous, and sometimes the inflammation extends to the areolar tissue of the cord. The chief characteristic of this form of erysipelas is its tendency to run into slough without any previous brawny or tense condition of the parts; the dartos becoming so distended with the inflammatory exudation that the circulation through it is arrested. When an incision is made into it in this state it scarcely bleeds, and the sides of the wound present a yellowish-white gelatinous appearance.

The *Treatment* consists in making a free incision about four inches in length on each side of the septum, taking care not to go so deeply as to wound the testes: the part must then be supported on a pillow, and well fomented. If this incision be not made at once, a great part or even the

whole of the scrotum may slough away, leaving the testes and cords bare; in these unpleasant circumstances, however, the parts will often with great rapidity become covered with new integument. The oedema of the penis usually subsides of itself, or after making a few punctures in it; should its integuments, however, threaten to slough, a free incision must be made into it, or the prepuce must be slit up.

Erysipelas of the Pudenda is occasionally met with in ill-fed unhealthy children in whom cleanliness is neglected. The parts become dusky red, swell considerably, and quickly run into gangrene, which spreads up the abdomen or down the nates. It may prove fatal by inducing peritonitis or exhaustion. In the *Treatment*, ammonia, bark, and chlorate of potash, with good nourishment, and a little wine, are the principal means, at the same time that the parts are bathed in a warm antiseptic solution and well fomented.

Diffuse Cellulitis of the Ischio-Rectal Fossa is not uncommon in old and feeble subjects, as the result of exposure to cold. The symptoms are those of cellulitis in general, a brawny hard swelling by the side of the rectum, with redness of the skin, and great pain and tenderness. The fat of the ischio-rectal fossa rapidly sloughs, and a foul, fetid abscess, the pus of which is mixed with shreds of gangrenous tissue, rapidly forms. The *Treatment* consists of free and early incisions. At a later stage it may be necessary to divide the sphincter before the cavity will heal.

INTERNAL ERYSIPELATOUS INFLAMMATIONS

By **Internal Erysipelas** we mean those forms of diffuse inflammation which affect the Mucous or Serous Surfaces.

ERYSIPELAS OF MUCOUS SURFACES.—The mucous tract that is chiefly affected by this disease is that covering the fauces, the pharynx, and the larynx.

Erysipelas of the Fauces may be due to extension of the disease from the head and face to these parts; or it may commence as a primary affection, occurring perhaps at the same time that the rash appears on the cutaneous surface of some distant part of the body. When the fauces are erysipelatous, they present a bright crimson or scarlet colour, with some swelling and thickening of the soft palate and uvula; the patient also most commonly has huskiness or complete loss of voice, and occasionally some croupy symptoms. The glands at the angle of the jaw are always swollen and tender. At the same time there is a good deal of febrile disturbance, with a pungent hot skin and quick pulse. This form of erysipelas is peculiarly contagious, and occurs not unfrequently in the attendants of those who are labouring under some of the other varieties of the disease; of this I have seen numerous instances. In many cases, also, it is epidemic, spreading through a house and affecting almost every inmate.

Treatment.—The best results are obtained by sponging the inflamed parts freely with a strong solution of the nitrate of silver; and, if there be much constitutional depression, by administering full doses of ammonia, with camphor or bark. Should the disease go on to sloughing (which not unfrequently happens), constituting one of the forms of "putrid sore throat," the mineral acids and bark, with chlorinated gargles, and the brandy-and-egg mixture for support, will be found most useful. In many cases, this disease is limited to the palate and fauces; but in others it extends upwards

or downwards. It may extend upwards through the nares, out through the nostrils, and thus spread over the face and head, or downwards, implicating the larynx.

Erysipelatous Laryngitis is extremely dangerous. The inflammation, commencing in the fauces, rapidly spreads to the mucous membrane and loose submucous areolar tissue external to and within the larynx, giving rise to extensive cedematous infiltration, which, by obstructing the rima glottidis, may readily suffocate the patient. In consequence of this special tendency to cedema, the disease has by many writers been termed "*cedematous laryngitis*." After death, the submucous areolar tissue of the fauces, that about the base of the epiglottis, and especially that which enters into the arytaeno-epiglottidean folds and that covering the posterior part of the larynx, will be found to be distended with serum or a sero-puriform fluid. This infiltration reaches to the rima of the glottis, and, extending into the interior of the larynx, gives rise to such swelling that its cavity is nearly obliterated. Great as the swelling may be in all these parts, however, it never spreads below the true vocal cords. This fact, which is very important, is explained by the mucous membrane being adherent to the fibrous tissue of which these structures are composed, without the intervention of any submucous areolar tissue. The progress of this cedematous inflammation of the mucous membrane and loose submucous tissue in these situations, is often amazingly rapid, the swelling being sufficient to induce suffocation at the end of thirty-six or forty-eight hours or even sooner. If the patient be not carried off in this way, there will be a great tendency to suppuration and sloughing of the affected tissues, leading perhaps eventually to death from septicæmia or pyæmia.

The *Symptoms* of this affection are strongly marked. Difficulty and pain in deglutition, and huskiness of the voice, are followed by more or less difficulty in breathing, hoarse croupy cough and tenderness under the angles of the jaw and about the larynx. The difficulty in breathing increases, and may speedily threaten the life of the patient, giving rise to fits of intense dyspnoea, in one of which he may probably suddenly die. The difficulty is greater in inspiration than in expiration, as the swollen parts above the opening of the larynx fall together like a valve in the former act, while they are easily separated by air coming from below in the latter. On examining the throat the fauces will be found much reddened and dusky in tint, and by depressing the tongue the epiglottis can be felt, and perhaps seen, to be rigid and erect. Examination with the laryngoscope readily shows the condition of the parts to be as above described. Enlarged lymphatic glands can usually be felt early in the case behind the angle of the lower jaw.

In the *Treatment*, local means are of the first importance. The tongue having been well depressed, the posterior part of the larynx, the epiglottis, and the arytaeno-epiglottidean folds must be well scarified by means of a probe-pointed bistoury, protected nearly to its extremity by strapping or lint wrapped round it. If no better instrument be at hand in case of emergency, a very useful amount of scarification may be done by the nail of the Surgeon's index-finger, notched with a knife to make it tear the mucous membrane more readily. The patient should then be directed to inhale the steam of hot water, to which a few drops of creosote or carbolic acid may be added, and several leeches may be applied under each angle of the jaw, to be followed by large and hot poultices. The bowels must be kept well opened: most frequently, I have found antimonials of great service in the early stages, followed later by support and

stimulants. A few hours after the engorged tissues have been unloaded by scarification, the fauces, pharynx and upper part of the larynx should be well sponged out with a strong solution of the nitrate of silver (sixty grains to an ounce), which must be applied freely. If, notwithstanding the employment of these measures, the dyspnoea increase, the face becoming pale, livid, and bedewed with a clammy perspiration, it will be necessary to open the windpipe to save the patient from suffocation. In doing this I prefer laryngotomy, for reasons that will be mentioned when I come to speak of the Diseases of and Operations on the Air-passages. In order, however, that this operation may be successful, it must not be too long delayed, and should not be looked upon as a last resource. If it be done in time (and time in these cases is most precious, owing to the rapid progress of the disease), the patient's life may probably be saved; but if it be deferred too long, congestion of the lungs will come on, and the patient will sink from slow asphyxia, even though air be at last freely admitted. If the patient survive to the stage of sloughing we must rely upon general support, with gargles of chlorate of potash, and bark.

ERYSIPELAS OF THE SEROUS MEMBRANES was formerly supposed to be of common occurrence, all those cases of diffuse inflammation which are now regarded as of septic origin being at one time classed as erysipelatous. It is highly probable that some cases of diffuse meningitis and peritonitis following injuries of the head and abdomen are truly erysipelatous and dependent upon a specific virus; but in by far the greater proportion of these cases the inflammation is due to the diffusion of decomposing discharges over the surface of the serous membrane.

WHITLOW. PARONYCHIA OR PANARITIUM

Whitlow or **Paronychia** is a diffuse inflammation of the finger which is, perhaps, most conveniently described in this place as in many cases of essentially the same character as cellulitis. It occasionally occurs in epidemics; the constitutional disturbance attending it is often very severe for an affection apparently so slight, and assumes the same character of speedy depression that we observe in the erysipelatous group of diseases. In many cases, as the inflammation spreads beyond the finger in which it commenced to the back of the hand, it assumes a distinctly erysipelatous character. In others, however, it is evidently not specific, and results from the inoculation of ordinary septic matter, the subsequent effects being dependent on the anatomical structure of the parts affected.

Four forms of whitlow are commonly described:—

1. In **paronychia unguialis** or **Sub-epithelial Whitlow**, the affection is limited to the unguis phalanx of the finger. It commences as the result of a prick or some other slight injury, or from the inoculation of septic matter into a fissure or edge of the nail. At first there is redness, most commonly at one side of the nail, with some swelling and the most acute tenderness. The inflammation soon reaches the stage of suppuration, and a drop of pus is formed raising the epithelium. The thick epithelium of the finger confines the pus which, not being able to escape superficially, burrows more deeply. If it be in close contact with the matrix of the nail it may extend into this. The nail then becomes partly raised by pus from the matrix, and may separate after

long and tedious suppuration. In other cases the pus burrows into the pulp of the finger, and the condition then merges into the second variety to be described immediately.

Treatment.—As soon as the patient complains of acute pain and tenderness, and redness and swelling are evident in the finger, an attempt should be made to find the exact locality of the pus by pressing on the finger with some blunt instrument such as the point of a pencil. If an acutely tender spot be found the finger must be soaked in hot water to soften the cuticle, which must then be carefully shaved away with a very sharp knife. In this way a small drop of pus may often be let out from between the epidermis and the cutis, and the whole trouble nipped in the bud. A little wet boric acid lint may then be applied and the finger soon heals. If it have extended beneath the nail the loosened portion must be cut away with scissors to give a free exit to the pus, or in extreme cases the whole nail must be removed. A little iodoform may be dusted on the surface, and a boric lint dressing applied. The strong lead lotion (p. 216) is often very useful in these cases.

2. **Paronychia Cellulosa** or **Subcutaneous Whitlow** may arise, as above stated, from an extension of the variety just described. In other cases it is caused by punctured wounds of the finger, especially when made with dirty instruments, and occasionally it arises without evident cause. In it the pus is diffused through the fat and areolar tissue forming the pulp of the finger. It runs the ordinary course of cellulitis elsewhere. The ungual phalanx becomes swollen, tense, red, and most acutely tender. The redness may soon extend to the whole finger, red lines of inflamed lymphatics may be seen running up the arm, and the axillary glands may become swollen and tender. If unrelieved by treatment, the pus, being unable to point through the thick cuticle of the finger, especially in the horny hands of working men, becomes diffused through the whole pulp. The areolar tissue sloughs, and as in this situation it is intimately connected with the periosteum of the ungual phalanx, this also perishes and the bone necroses. If still left unrelieved it most commonly raises the cuticle, and finally this gives way and exposes a sloughing opening in the cutis, through which, if a probe be passed, the bare ungual phalanx may be felt. In some cases, before the pus finds exit externally, it may have extended into the sheath of the flexor tendons or the distal joint of the finger.

Treatment.—In this form also an attempt must be made to find the pus early by shaving away the cuticle, as at first it is often very limited in amount and superficial. If this fails and the symptoms are not very acute, the finger must be thickly coated with glycerine and belladonna, and wrapped in a few layers of hot wet lint, over which must be placed some gutta-percha tissue made into a cot by sealing its edges with chloroform. The finger must then be wrapped in cotton-wool and the hand elevated. Under this treatment the inflammation may subside without suppuration. Soaking the hand at intervals in hot water gives great relief. If, in spite of this, the symptoms become more marked, a longitudinal incision must be made in the middle line of the pulp of the finger. It must be remembered that the tense swollen pulp gives a sensation exactly resembling fluctuation, for which it may readily be mistaken. After the pus is evacuated the wound should be treated by some antiseptic dressing, and usually heals quickly.

3. **Paronychia Osseosa** or **Periosteal Whitlow** is a rare form in which the inflammation commences deeply in the pulp in immediate contact with

the periosteum of the phalanx. It is said most commonly to follow severe pinches or contusions of the finger. It is characterised by intense throbbing pain shooting up the arm. The symptoms develop rapidly, with a good deal of constitutional disturbance. The pulp of the finger is very tense, and the redness extends to the other phalanges. The *treatment* consists of a free incision to the bone in the middle line of the pulp. The phalanx will be found bare and already separated from its periosteum.

The *treatment of a necrosed unequal phalanx*, either arising from this form of whitlow or the preceding, consists in removal of the dead bone through the incision in the pulp. The phalanx should never be amputated, as a useful extremity to the finger is always left after removal of the bone.

4. **Paronychia Tendinosa, Thecal Abscess, or Suppuration in the Sheaths of the Flexor Tendons**, is a more serious condition than the preceding, and is fraught with danger to the finger or hand. It may arise as the consequence of a punctured wound penetrating the sheath, or by extension from one of the other varieties of whitlow. The whole finger, both back and front, swells considerably, becomes red and tense, with much throbbing and shooting pain. The affected finger is semi-flexed, and any attempt to extend it causes intense pain. The swelling soon extends into the palm at the root of the finger and to the corresponding knuckle on the back of the hand. The swollen palm usually preserves nearly its natural colour, or if soaked in water or poulticed becomes dull white, owing to the great thickness of its cuticle. The most marked redness is usually on the knuckle and at the back of the finger, which may give a false idea as to the situation of the pus. The constitutional disturbance is severe and the temperature considerably elevated.

In this condition, unless prevented by treatment, the pus will extend to the limits of the sheath in which it is contained. The sheaths of the index, middle and ring fingers do not communicate with the common sheath which passes under the annular ligament, but are closed below opposite the heads of the metacarpal bones, and, therefore, in suppuration in these fingers the pus does not extend beyond that point. The sheath of the little finger, on the other hand, always communicates with the general sheath. (Fig. 344.) The sheath of the tendon of the thumb is uncertain: in some cases a special synovial membrane covers the tendon passing under the annular ligament without communicating with the general sheath, in others it joins the common sheath. Thecal abscess in the thumb or little finger is, therefore, far more serious than the same condition in the three middle digits. When the suppuration extends to the common sheath the most prominent symptom which attracts the attention of the patient is the red puffy swelling at the back of the hand. The Surgeon on seeing this will always turn the hand over and examine the palm. This will be found to be tense and tender on pressure. There will be fulness in front of the wrist above the annular ligament, and often some redness. If much pus is present, fluctuation may be felt from the palm to the swelling in the wrist. The fingers are semi-flexed, and any attempt to extend them causes pain, but this is most marked in the thumb and little finger. If an opening exists already in the digital part of the sheath of the thumb or little finger, pressure on the palm will cause pus to flow from it. If an exit be not provided for the pus it may burst through the upper limit of the flexor sheath, and extend between the deep and superficial muscles

of the forearm nearly to the elbow. Owing to the close proximity of the synovial membrane to the interphalangeal articulations and the wrist-joint, it not uncommonly happens that these are opened and destroyed by acute septic arthritis; and thus this condition may necessitate amputation of a finger, or if the common sheath is affected, of the whole hand. Sloughing of the flexor tendons is a very common occurrence in thecal abscess, some inches of the tendon coming away after prolonged suppuration, leaving the finger stiff and useless.

Treatment.—It is most important in all cases of thecal abscess that the pus should be let out early and by free incisions, in order to avert the complications above mentioned. To do this the patient should be put under an anæsthetic, and the limb rendered bloodless by elevation and the application of a tourniquet. A median incision on the finger, not opposite one of the interphalangeal articulations, is then carefully made towards the affected sheath. It may be that the pus is in close contact with the sheath and not in it; if the limb be bloodless this can usually be recognized, and the complication of opening the synovial membrane avoided. If the swelling extends from the finger to the palm the thecal abscess may be opened, without danger of wounding the palmar arches or any important nerves, by cutting towards the head of a metacarpal bone upon the bone itself and parallel to its axis, so as to avoid the interdigital spaces. Heath and Murrant Baker have especially insisted upon the advantages of this method of opening a thecal abscess and thus avoiding the median incision on the finger. They recommend that incisions on the finger in cases of whitlow should be placed laterally so that a healthy sheath may not be accidentally opened.

If the common sheath is affected it must be opened above the annular ligament at the wrist.

If the little finger has been the starting point of the mischief the incision

FIG. 344. — Preparation showing the arrangement of the sheaths of the Flexor Tendons at the Wrist. *m.* Sheath of flexors of fingers; the part which has in contact with the annular ligament and the upper limit of the part behind the flexor profundus are represented by dotted lines. *f.* Sheath of flexor longus pollicis; the part which lies in contact with the annular ligament is represented by a dotted line. *m.* Median nerve; *fp.* flexor profundus digitorum; *f.u.* flexor carpi ulnaris; *st.*, styloid process of ulna.

whole of the scrotum may slough away, leaving the testes and cords bare ; in these unpleasant circumstances, however, the parts will often with great rapidity become covered with new integument. The oedema of the penis usually subsides of itself, or after making a few punctures in it ; should its integuments, however, threaten to slough, a free incision must be made into it, or the prepuce must be slit up.

Erysipelas of the Pudenda is occasionally met with in ill-fed unhealthy children in whom cleanliness is neglected. The parts become dusky red, swell considerably, and quickly run into gangrene, which spreads up the abdomen or down the nates. It may prove fatal by inducing peritonitis or exhaustion. In the *Treatment*, ammonia, bark, and chlorate of potash, with good nourishment, and a little wine, are the principal means, at the same time that the parts are bathed in a warm antiseptic solution and well fomented.

Diffuse Cellulitis of the Ischio-Rectal Fossa is not uncommon in old and feeble subjects, as the result of exposure to cold. The symptoms are those of cellulitis in general, a brawny hard swelling by the side of the rectum, with redness of the skin, and great pain and tenderness. The fat of the ischio-rectal fossa rapidly sloughs, and a foul, fetid abscess, the pus of which is mixed with shreds of gangrenous tissue, rapidly forms. The *Treatment* consists of free and early incisions. At a later stage it may be necessary to divide the sphincter before the cavity will heal.

INTERNAL ERYSIPELATOUS INFLAMMATIONS.

By **Internal Erysipelas** we mean those forms of diffuse inflammation which affect the Mucous or Serous Surfaces.

ERYSIPELAS OF MUCOUS SURFACES.—The mucous tract that is chiefly affected by this disease is that covering the fauces, the pharynx, and the larynx.

Erysipelas of the Fauces may be due to extension of the disease from the head and face to these parts ; or it may commence as a primary affection, occurring perhaps at the same time that the rash appears on the cutaneous surface of some distant part of the body. When the fauces are erysipelatous, they present a bright crimson or scarlet colour, with some swelling and thickening of the soft palate and uvula ; the patient also most commonly has huskiness or complete loss of voice, and occasionally some croupy symptoms. The glands at the angle of the jaw are always swollen and tender. At the same time there is a good deal of febrile disturbance, with a pungent hot skin and quick pulse. This form of erysipelas is peculiarly contagious, and occurs not unfrequently in the attendants of those who are labouring under some of the other varieties of the disease ; of this I have seen numerous instances. In many cases, also, it is epidemic, spreading through a house and affecting almost every inmate.

Treatment.—The best results are obtained by sponging the inflamed parts freely with a strong solution of the nitrate of silver : and, if there be much constitutional depression, by administering full doses of ammonia, with camphor or bark. Should the disease go on to sloughing (which not unfrequently happens), constituting one of the forms of "putrid sore throat," the mineral acids and bark, with chlorinated gargles, and the brandy-and-egg mixture for support, will be found most useful. In many cases, this disease continues limited to the palate and fauces ; but in others it extends upwards

or downwards. It may extend upwards through the nares, out through the nostrils, and thus spread over the face and head, or downwards, implicating the larynx.

Erysipelatous Laryngitis is extremely dangerous. The inflammation, commencing in the fauces, rapidly spreads to the mucous membrane and loose submucous areolar tissue external to and within the larynx, giving rise to extensive oedematous infiltration, which, by obstructing the rima glottidis, may readily suffocate the patient. In consequence of this special tendency to oedema, the disease has by many writers been termed "*adenatous laryngitis*." After death, the submucous areolar tissue of the fauces, that about the base of the epiglottis, and especially that which enters into the arytaeno-epiglottidean folds and that covering the posterior part of the larynx, will be found to be distended with serum or a sero-puriform fluid. This infiltration reaches to the rima of the glottis, and, extending into the interior of the larynx, gives rise to such swelling that its cavity is nearly obliterated. Great as the swelling may be in all these parts, however, it never spreads below the true vocal cords. This fact, which is very important, is explained by the mucous membrane being adherent to the fibrous tissue of which these structures are composed, without the intervention of any submucous areolar tissue. The progress of this oedematous inflammation of the mucous membrane and loose submucous tissue in these situations, is often amazingly rapid, the swelling being sufficient to induce suffocation at the end of thirty-six or forty-eight hours or even sooner. If the patient be not carried off in this way, there will be a great tendency to suppuration and sloughing of the affected tissues, leading perhaps eventually to death from septicæmia or pyæmia.

The *Symptoms* of this affection are strongly marked. Difficulty and pain in deglutition, and huskiness of the voice, are followed by more or less difficulty in breathing, hoarse croupy cough and tenderness under the angles of the jaw and about the larynx. The difficulty in breathing increases, and may speedily threaten the life of the patient, giving rise to fits of intense dyspnoea, in one of which he may probably suddenly die. The difficulty is greater in inspiration than in expiration, as the swollen parts above the opening of the larynx fall together like a valve in the former act, while they are easily separated by air coming from below in the latter. On examining the throat the fauces will be found much reddened and dusky in tint, and by depressing the tongue the epiglottis can be felt, and perhaps seen, to be rigid and erect. Examination with the laryngoscope readily shows the condition of the parts to be as above described. Enlarged lymphatic glands can usually be felt early in the case behind the angle of the lower jaw.

In the *Treatment*, local means are of the first importance. The tongue having been well depressed, the posterior part of the larynx, the epiglottis, and the arytaeno-epiglottidean folds must be well scarified by means of a probe-pointed bistoury, protected nearly to its extremity by strapping or lint wrapped round it. If no better instrument be at hand in case of emergency, a very useful amount of scarification may be done by the nail of the Surgeon's index-finger, notched with a knife to make it tear the mucous membrane more readily. The patient should then be directed to inhale the steam of hot water, to which a few drops of creosote or carbolic acid may be added, and several leeches may be applied under each angle of the jaw, to be followed by large and hot poultices. The bowels must be kept well opened: most frequently, I have found antimonials of great service in the early stages, followed later by support and

stimulants. A few hours after the engorged tissues have been unloaded by scarification, the fauces, pharynx and upper part of the larynx should be well sponged out with a strong solution of the nitrate of silver (sixty grains to an ounce), which must be applied freely. If, notwithstanding the employment of these measures, the dyspnoea increase, the face becoming pale, livid, and bedewed with a clammy perspiration, it will be necessary to open the windpipe to save the patient from suffocation. In doing this I prefer laryngotomy, for reasons that will be mentioned when I come to speak of the Diseases of and Operations on the Air-passages. In order, however, that this operation may be successful, it must not be too long delayed, and should not be looked upon as a last resource. If it be done in time (and time in these cases is most precious, owing to the rapid progress of the disease), the patient's life may probably be saved; but if it be deferred too long, congestion of the lungs will come on, and the patient will sink from slow asphyxia, even though air be at last freely admitted. If the patient survive to the stage of sloughing we must rely upon general support, with gargles of chlorate of potash, and bark.

ERYSIPELAS OF THE SEROUS MEMBRANES was formerly supposed to be of common occurrence, all those cases of diffuse inflammation which are now regarded as of septic origin being at one time classed as erysipelatous. It is highly probable that some cases of diffuse meningitis and peritonitis following injuries of the head and abdomen are truly erysipelatous and dependent upon a specific virus; but in by far the greater proportion of these cases the inflammation is due to the diffusion of decomposing discharges over the surface of the serous membrane.

WHITLOW, PARONYCHIA OR PANARITIUM.

Whitlow or **Paronychia** is a diffuse inflammation of the finger which is, perhaps, most conveniently described in this place as in many cases of essentially the same character as cellulitis. It occasionally occurs in epidemics, the constitutional disturbance attending it is often very severe for an affection apparently so slight, and assumes the same character of speedy depression that we observe in the erysipelatous group of diseases. In many cases, as the inflammation spreads beyond the finger in which it commenced to the back of the hand, it assumes a distinctly erysipelatous character. In others, however, it is evidently not specific, and results from the inoculation of ordinary septic matter, the subsequent effects being dependent on the anatomical structure of the parts affected.

Four forms of whitlow are commonly described:—

1. In **paronychia ungualis** or **Sub-epithelial Whitlow**, the affection is limited to the unguis phalanx of the finger. It commences as the result of a prick or some other slight injury, or from the inoculation of septic matter into a fissure or edge of the nail. At first there is redness, most commonly at one side of the nail, with some swelling and the most acute tenderness. The inflammation soon reaches the stage of suppuration, and a drop of pus is formed raising the epithelium. The thick epithelium of the finger confines the pus which, not being able to escape superficially, burrows more deeply. If it be in close contact with the matrix of the nail it may extend into this. The nail then becomes partly raised by pus from the matrix, and may separate after

long and tedious suppuration. In other cases the pus burrows into the pulp of the finger, and the condition then merges into the second variety to be described immediately.

Treatment.—As soon as the patient complains of acute pain and tenderness, and redness and swelling are evident in the finger, an attempt should be made to find the exact locality of the pus by pressing on the finger with some blunt instrument such as the point of a pencil. If an acutely tender spot be found the finger must be soaked in hot water to soften the cuticle, which must then be carefully shaved away with a very sharp knife. In this way a small drop of pus may often be let out from between the epidermis and the cutis, and the whole trouble nipped in the bud. A little wet boric acid lint may then be applied and the finger soon heals. If it have extended beneath the nail the loosened portion must be cut away with scissors to give a free exit to the pus, or in extreme cases the whole nail must be removed. A little iodoform may be dusted on the surface, and a boric lint dressing applied. The strong lead lotion (p. 216) is often very useful in these cases.

2. **Paronychia Cellulosa** or **Subcutaneous Whitlow** may arise, as above stated, from an extension of the variety just described. In other cases it is caused by punctured wounds of the finger, especially when made with dirty instruments, and occasionally it arises without evident cause. In it the pus is diffused through the fat and areolar tissue forming the pulp of the finger. It runs the ordinary course of cellulitis elsewhere. The ungual phalanx becomes swollen, tense, red, and most acutely tender. The redness may soon extend to the whole finger, red lines of inflamed lymphatics may be seen running up the arm, and the axillary glands may become swollen and tender. If unrelieved by treatment, the pus, being unable to point through the thick cuticle of the finger, especially in the horny hands of working men, becomes diffused through the whole pulp. The areolar tissue sloughs, and as in this situation it is intimately connected with the periosteum of the ungual phalanx, this also perishes and the bone necroses. If still left unrelieved it most commonly raises the cuticle, and finally this gives way and exposes a sloughing opening in the cutis, through which, if a probe be passed, the bare ungual phalanx may be felt. In some cases, before the pus finds exit externally, it may have extended into the sheath of the flexor tendons or the distal joint of the finger.

Treatment.—In this form also an attempt must be made to find the pus early by shaving away the cuticle, as at first it is often very limited in amount and superficial. If this fails and the symptoms are not very acute, the finger must be thickly coated with glycerine and belladonna, and wrapped in a few layers of hot wet lint, over which must be placed some gutta-percha tissue made into a cot by sealing its edges with chloroform. The finger must then be wrapped in cotton-wool and the hand elevated. Under this treatment the inflammation may subside without suppuration. Soaking the hand at intervals in hot water gives great relief. If, in spite of this, the symptoms become more marked, a longitudinal incision must be made in the middle line of the pulp of the finger. It must be remembered that the tense swollen pulp gives a sensation exactly resembling fluctuation, for which it may readily be mistaken. After the pus is evacuated the wound should be treated by some antiseptic dressing, and usually heals quickly.

3. **Paronychia Osseosa** or **Periosteal Whitlow** is a rare form in which the inflammation commences deeply in the pulp in immediate contact with

the periosteum of the phalanx. It is said most commonly to follow seven punches or contusions of the finger. It is characterised by intense throbbing pain shooting up the arm. The symptoms develop rapidly, with a good deal of constitutional disturbance. The pulp of the finger is very tense, and the redness extends to the other phalanges. The *treatment* consists of a free incision to the bone in the middle line of the pulp. The phalanx will be found bare and already separated from its periosteum.

The *treatment of a necrosed ungual phalanx*, either arising from this form of whitlow or the preceding, consists in removal of the dead bone through the incision in the pulp. The phalanx should never be amputated, as a useful extremity to the finger is always left after removal of the bone.

4. **Paronychia Tendinosa, Thecal Abscess, or Suppuration in the Sheaths of the Flexor Tendons**, is a more serious condition than the preceding, and is fraught with danger to the finger or hand. It may arise as the consequence of a punctured wound penetrating the sheath, or by extension from one of the other varieties of whitlow. The whole finger, both back and front, swells considerably, becomes red and tense, with much throbbing and shooting pain. The affected finger is semi-flexed, and any attempt to extend it causes intense pain. The swelling soon extends into the palm at the root of the finger and to the corresponding knuckle on the back of the hand. The swollen palm usually preserves nearly its natural colour, or if soaked in water or poulticed becomes dull white, owing to the great thickness of its cuticle. The most marked redness is usually on the knuckle and at the back of the finger, which may give a false idea as to the situation of the pus. The constitutional disturbance is severe and the temperature considerably elevated.

In this condition, unless prevented by treatment, the pus will extend to the limits of the sheath in which it is contained. The sheaths of the index, middle and ring fingers do not communicate with the common sheath which passes under the annular ligament, but are closed below opposite the heads of the metacarpal bones, and, therefore, in suppuration in these fingers the pus does not extend beyond that point. The sheath of the little finger, on the other hand, always communicates with the general sheath. (Fig. 844.) The sheath of the tendon of the thumb is uncertain: in some cases a special synovial membrane covers the tendon passing under the annular ligament without communicating with the general sheath, in others it joins the common sheath. Thecal abscess in the thumb or little finger is, therefore, far more serious than the same condition in the three middle digits. When the suppuration extends to the common sheath the most prominent symptom which attracts the attention of the patient is the red puffy swelling at the back of the hand. The Surgeon on seeing this will always turn the hand over and examine the palm. This will be found to be tense and tender on pressure. There will be fulness in front of the wrist above the annular ligament, and often some redness. If much pus is present, fluctuation may be felt from the palm to the swelling in the wrist. The fingers are semi-flexed, and any attempt to extend them causes pain, but this is most marked in the thumb and little finger. If an opening exists already in the digital part of the sheath of the thumb or little finger, pressure on the palm will cause pus to flow from it. If an exit be not provided for the pus it may burst through the upper limit of the flexor sheath, and extend between the deep and superficial muscles

of the forearm nearly to the elbow. Owing to the close proximity of the synovial membrane to the interphalangeal articulations and the wrist-joint, it not uncommonly happens that these are opened and destroyed by acute septic arthritis; and thus this condition may necessitate amputation of a finger, or if the common sheath is affected, of the whole hand. Sloughing of the flexor tendons is a very common occurrence in thecal abscess, some inches of the tendon coming away after prolonged suppuration, leaving the finger stiff and useless.

Treatment.—It is most important in all cases of thecal abscess that the pus should be let out early and by free incisions, in order to avert the complications above mentioned. To do this the patient should be put under an anæsthetic, and the limb rendered bloodless by elevation and the application of a tourniquet. A median incision on the finger, not opposite one of the interphalangeal articulations, is then carefully made towards the affected sheath. It may be that the pus is in close contact with the sheath and not in it; if the limb be bloodless this can usually be recognized, and the complication of opening the synovial membrane avoided. If the swelling extends from the finger to the palm the thecal abscess may be opened, without danger of wounding the palmar arches or any important nerves, by cutting towards the head of a metacarpal bone upon the bone itself and parallel to its axis, so as to avoid the interdigital spaces. Heath and Marrant Baker have especially insisted upon the advantages of this method of opening a thecal abscess and thus avoiding the median incision on the finger. They recommend that incisions on the finger in cases of whitlow should be placed laterally so that a healthy sheath may not be accidentally opened.

If the common sheath is affected it must be opened above the annular ligament at the wrist.

If the little finger has been the starting point of the mischief the incision

Fig. 144. — Preparation showing the arrangement of the Sheaths of the Flexor Tendons at the Wrist. *a*, Sheath of flexors of fingers; the part which lies in contact with the annular ligament and the upper limit of the part behind the flexor profundus are represented by dotted lines. *b*, Sheath of flexor longus pollicis; the part which lies in contact with the annular ligament is represented by a dotted line. *c*, median nerve; *d*, *p*, flexor profundus digitorum; *f*, *u*, flexor superficialis; *s*, *h*, styloid process of ulna.

may be made to the ulnar side of the middle line. It must be carried carefully down to the tendons of the superficial flexor, which here have some fleshy fibres attached to them. The tendons and bellies of the muscles must then be separated with blunt hooks and the handle of the scalpel, and the pus will be found in the space between them and the deep flexor, or between the latter and the pronator quadratus. In Fig. 344 it is seen how the common sheath sends a prolongation inwards between the front of the styloid process of the ulna and the tendon of the flexor carpi ulnaris. Here also the sheath may easily be opened by an incision carried vertically upwards from a point midway between the pisiform bone and the styloid process of the ulna. If the thumb has been the starting point, the pus may be in a separate sheath to the outer side; the incision must therefore be made, if possible, along the inner side of the flexor carpi radialis. This has the disadvantage of being close to the median nerve, which may be irritated by the drainage-tube, but if the incision be made on the outer side of the tendon, the radial artery is endangered. After these openings have been made the sheaths should be syringed out with perchloride of mercury (1 in 1,000) and drainage-tubes inserted. If the pus bursts beyond the limits of the synovial membrane and burrows upwards between the deep and superficial muscles, it can be reached only from the inner side of the arm by a free incision along the outer border of the flexor carpi ulnaris, as the radial origin of the flexor sublimis comes in the way on the other side. (See ligature of Ulnar Artery in the middle of the arm. Chap. XLIV., Vol. II.) In the after-treatment of these cases some efficient antiseptic dressing should be applied, and much relief is afforded by boracic acid baths. A contracted and useless hand may be left; or in spite of all that can be done, the wrist-joint may be destroyed and amputation become necessary. The only hope of saving a useful hand lies in very free and early incisions, and the use of drainage-tubes and antiseptics in the subsequent treatment. If the hand is put upon a splint, the fingers must be slightly flexed, so that if adhesions form, it may be possible to break them down by forced extension.

Senile Teno-Synovitis.—There is a form of acute suppurative inflammation of the fingers and hand sometimes extending to the wrist-joint, which occurs in old people of feeble constitution. It usually arises from some trivial irritation or infection, and runs its course of disorganization with rapidity. It appears to be a disease of the hand due mainly to senile degeneration, in this respect resembling the gangrena senilis of the foot, but differing in its more acute character and suppurative tendency. The joints of the fingers, metacarpus and carpus, become disorganized and the bones necrose. The disease requires an active tonic and nutritive treatment. The affected parts should not be too much soddened by wet applications. Amputation, partial or complete, may at last be required.

CHAPTER XXXIII.

SEPTICÆMIA AND PYÆMIA. TETANUS.

DEFINITIONS.—The terms “septicæmia” and “pyæmia” have been used with different meanings by different authors, and before proceeding to discuss the affections to which they are applied, it is necessary to define the sense in which they will be used here.

The term **Septicæmia** is applied to a constitutional disorder produced by the entrance into the blood-stream of a poison generated in a wound the discharges of which are undergoing putrefaction or fermentative changes. The resulting process is not accompanied by the formation of secondary centres of inflammation or suppuration. Experiments on animals have shown that two distinct forms of disease may arise from the entrance of putrid matter into the blood-stream. First, an acute general affection, not infective in character, resulting from the admixture of the chemical products of putrefaction with the blood: the poison does not increase in the system, and its effects are proportional to the dose. Secondly, a true infective process, dependent on a specific virus, which multiplies in the body like that of an acute specific fever, so that its effects are not proportional to the original dose. The former of these conditions has received the name of **septic poisoning** or **septic intoxication**, the latter that of **septic infection**. By some authors the infective form of septicæmia has been described under the name of pyæmia simplex.

Pyæmia is a general infective process consequent upon the dissemination throughout the body, by the blood-stream, of a pyogenic virus derived from a local focus of suppuration. It is accompanied by the formation of secondary centres of suppuration disseminated throughout the body. The name “pyæmia” was originally derived from the theory that the condition was due to the entrance of pus into the blood-stream, and, although this theory is no longer regarded as true, the word has come to have so definite a clinical significance that it would be inconvenient to change it. Pyæmia almost invariably arises in connexion with wounds the discharges of which are in a putrid condition, and consequently it is frequently complicated with septic poisoning. It may arise also from wounds or sores which have previously been attacked by cutaneous erysipelas, diffuse cellulitis, or hospital gangrene. It is evident, therefore, that in actual practice these various secondary diseases often become more or less confused together, giving rise to forms apparently intermediate between the different affections, which have led to much confusion with regard to them.

EXPERIMENTAL INVESTIGATIONS INTO THE NATURE OF SEPTICÆMIA AND PYÆMIA.—The first experiments on this subject were made by Gaspard in the early part of this century and first published in 1822, since which time investigations have been almost continuously carried on up to the present time by Virchow, Panum, O. Weber, Billroth, v. Bergmann, Burdon Sanderson, Chauveau, Koch, Hueter, Klebs, and many others. The literature of the

subject is now so vast that it is impossible here to give more than the briefest possible summary of the results that have been obtained.

If a septic liquid, such as putrid blood or serum, or water in which animal tissues have been macerated, be carefully filtered and injected either into the subcutaneous tissue or directly into a vein of an animal, certain definite symptoms are produced. If the dose injected be in sufficient quantity to prove fatal, the first symptom is a slight shudder, followed by some muscular twitchings and restlessness; but muscular power soon begins to fail and the animal falls on its side. In the meantime vomiting and profuse diarrhoea with tenesmus set in; the ejecta being at first feculent, but rapidly becoming serous and tinged with blood. Dyspnoea comes on, power over the voluntary muscles is still further lost, and death ensues apparently from failure of the heart's action. The temperature rises at first from three to four degrees and then gradually subsides, rapidly falling at last to one or two degrees below the normal as the animal dies. The fatal effect is produced in from two to three hours, or even less, to twenty-four hours, or more, according to the dose. If the quantity injected be insufficient to cause death the animal quickly recovers its normal health, even though severe gastro-intestinal symptoms may have been induced. When smaller doses are used a febrile disturbance of limited duration is the only result.

If an animal killed in this way be examined after death, tolerably uniform appearances are met with: the blood is dark-coloured, and sometimes imperfectly coagulated, the inner coat of the vessels and the endocardium are darkly stained, and the serum is reddened by the colouring matter of the red corpuscles, which have become, to a certain extent, disintegrated in the blood even before the death of the animal. Small extravasations of blood (petechiæ) are found beneath the pericardium and pleura, and occasionally in other parts; the lungs are congested, the glandular viscera swollen, and the spleen enlarged, soft, and pulpy. The mucous membrane of the intestines is intensely injected, and its epithelium is found to have been separated.

Further experiments have shown that the blood in an animal thus killed is not infective, and contains no recognizable microscopic organisms. The process is, therefore, assumed to be one of simple poisoning by a chemical poison, and no more an infective process than if arsenic or any similar substance were injected into the blood-stream. The investigations of Brieger, Selmi, Gautier, and others have shown that the so-called "*ptomaines*" derived from decomposing animal fluids are alkaloidal in nature. In chemical composition they are extremely complicated, but can be obtained in a pure crystalline form. The first substance of this kind was obtained by Panum in 1856, and to it the name of "*Sepsin*" was given by Bergmann. It was made by adding strong boiling alcohol to a filtered meat-infusion which had become putrid; the precipitate thus obtained was dissolved in water, and the clear solution gave rise, when injected, to the characteristic symptoms of septic poisoning. The clear solution of the septic poison was perfectly free from microscopic organisms. The relation of micro-organisms to the process of putrefaction has already been discussed (p. 177 *et seq.*); and assuming the germ theory of decomposition to be true, bacteria, although not themselves concerned directly in the production of the symptoms of septic poisoning, are essential to the production of the poison. That they are not the actual poison was shown by Hiller, who collected a mass of the ordinary bacteria of putre-

faction on a filter, washed them in distilled water, and then injected them into animals, and also into his own body, without producing any evil effect. That the bacteria had not been injured was shown by control experiments in which their power of growing and causing putrefaction in organic solutions was demonstrated.

Those experiments may, therefore, be said to show that in the process of putrefaction a complex substance is formed which possesses intensely toxic properties, in small doses giving rise to severe febrile disturbance, in large doses causing a fatal illness accompanied by definite symptoms. The affection thus produced in its most intense form is spoken of as septicæmia, but to avoid confusion is better termed *septic poisoning*. The effect produced by a smaller dose forms, as has already been pointed out, one form of so-called traumatic fever.

The injection of putrid animal fluids into the subcutaneous tissue or blood-stream is not, however, in all cases followed merely by poisoning from the chemical products of putrefaction. Under certain conditions a true infective process ensues, as was first pointed out by Davaine. Perhaps the best example of this process is furnished by the experiments of Robert Koch, in which putrid fluids, such as blood or meat-infusion, were injected into house mice beneath the skin of the back. If the quantity used was sufficient the animals died with all the symptoms of septic poisoning in four or five hours. When one drop only was injected about two-thirds of the mice recovered without any serious symptoms, but in the remaining third, after twenty-four hours of apparent health, a definite illness set in which invariably terminated fatally in from forty to sixty hours after inoculation. The first symptom was a dulness of the eye, with increased secretion from the conjunctiva; the animal became languid, ceased to eat, and finally sat still with its back bent and its legs drawn under it. Its respirations gradually became slower and death came on almost imperceptibly. On examining it after death some local inflammation, with serous exudation, was found at the seat of inoculation, but the internal organs showed no marked change beyond some swelling of the spleen. If the point of a knife was dipped in the blood, or in the exudation at the seat of inoculation, and a mere scratch was then made with it on the ear or tail of another mouse, death invariably followed with the same symptoms and in about the same time, and thus the disease might be transmitted indefinitely from animal to animal. A drop of the blood from an infected mouse placed on a glass slide, dried, stained with methyl-violet, and mounted in Canada balsam, was found to contain vast numbers of very delicate bacilli, about $\frac{1}{1000}$ of an inch long, and one-eighth of their length in breadth. Many of these were seen to have penetrated into the substance of the white corpuscles, and apparently to have multiplied within them.

An attempt was made to transmit the disease to animals of other species, but without success. Even the field mouse, though apparently so nearly allied to the house mouse, was found to be incapable of receiving the poison.

A general infective process was induced by Davaine in a similar way in rabbits by the inoculation of putrid fluids; but the organism found in the blood in that case was a micrococcus not a bacillus. Both Davaine and Koch found that the infective process was more certainly induced by fluids in an early stage of decomposition.

The infective processes arising in this way have been described as "septicæmia" by both Davaine and Koch, but as that term is also applied to the simple chemical poisoning from putrid matter, it is better to speak of the infective disease as *septic infection*, and of the non-infective as *septic poisoning*.

The foregoing experiments have shown, therefore, that an acute infective process, unaccompanied by the formation of secondary centres of inflammation, can be induced both in mice and in rabbits by the injection of putrid animal fluids beneath the skin.

Koch succeeded in further experiments in producing an infective disease in which the development of secondary centres of inflammation formed a part of the process. A fluid, prepared by macerating a piece of the skin of a mouse, was injected beneath the skin of a rabbit. After two days the animal became ill and gradually growing weaker died 105 hours after the injection. The *post-mortem* examination showed a diffuse purulent inflammation at the seat of inoculation, which had extended to the peritoneum; the spleen was swollen and the liver contained grey wedge-shaped patches, and dark red airless spots the size of a pea were found in the lungs. Micrococci were found in great numbers throughout the body, especially in the parts that had undergone changes visible to the naked eye. In the vessels in many parts, dense masses of micrococci mixed with red corpuscles were found adherent to the walls, and Koch felt justified in coming to the conclusion that capillary thrombi were thus produced, and that the patches in the lungs and liver were caused in this way. In the metastatic deposits, not only were the vessels plugged with mixed red corpuscles and micrococci, but the organisms had penetrated the walls of the vessels and were invading the surrounding tissues. Some blood from the affected animal injected beneath the skin of another rabbit produced essentially the same condition which terminated fatally in forty hours. The disease thus induced was, therefore, a general infective process accompanied by secondary or metastatic deposits closely resembling those met with in pyæmia in man.

Lastly, numerous experiments have been made by Cruveilhier, Sedlitz, Virchow, O. Weber, Henry Lee, Savory, and many others with the view of ascertaining the part played by embolism in the production of the secondary abscesses in pyæmia. The result of these has been to show, that if a fluid holding in suspension solid particles of sufficient size to lodge in the smaller arteries of the lung be injected into the blood-stream, the effect produced will depend upon whether the solid matter is irritating or not. Non-irritating emboli lodging in the terminal arteries of the lung cause the part cut off from the direct blood-supply to be intensely injected with blood. The walls of the capillaries soften and give way, and hæmorrhage takes place into the tissue of the lung. A wedge-shaped airless patch is thus formed of dark purple colour on the surface, or as it is called a *hæmorrhagic infarct*. The whole infarct is gradually absorbed without suppuration, leaving a cicatrix on the surface. O. Weber also states that very fine solid particles may pass through the capillaries of the lung and give rise to embolism in the course of the systemic circulation. Should the embolus, however, possess irritating properties, the infarct softens and breaks down, inflammation and suppuration following in the surrounding tissues, and thus an abscess is formed. If the irritating embolus be so small as to lodge in the capillaries only, it will directly excite inflammation and suppuration at the point at which it lodges. The

experiments have shown that similar results follow whether the embolus owes its irritating properties to its mechanical condition, its chemical composition, or to its containing a specific virus. Thus abscesses in the lung have occasionally followed the injection of charcoal, and mercury. Decomposing fibrin or blood-clot or putrid fat never fails to produce them. If the emboli enter the general circulation, abscesses may form in other viscera or tissues. These observations show that the existence of secondary or metastatic abscesses does not necessarily indicate a true general infective process, as the causes of the disseminated local inflammations may be carried by the blood without developing or multiplying in that fluid.

Experimental pathology has thus thrown great light upon the nature and causes of septicæmia and pyæmia, but much still remains to be explained. It will be noticed that the genuine infective diseases are associated with the presence of definite microscopic organisms which, there is every reason to believe, stand in a direct causal relation to the process, yet they all arise from the injection of apparently similar putrid fluids. Microscopic examination shows that in the early stages of putrefaction numerous different organisms—bacilli, bacteria, and micrococci—are found in the putrid fluid; but it has not been clearly shown that each of the forms subsequently found in the blood of the affected animals is present. As putrefaction advances, the ordinary septic bacteria which, as shown by Hiller, cannot develop in a living animal, become more abundant, choking the other forms, and this fact has been suggested as an explanation of the diminished virulence of the fluid after the second day.

Septic poisoning by the chemical products of putrefaction can be produced with certainty in any animal by the injection of a sufficient dose of the putrid fluid. The symptoms produced are nearly identical in all species, though some animals, as the rodents, suffer more severely than the carnivora. (On the other hand true septic infection cannot always be produced at will. The same dose of the same fluid injected into different animals of the same species may induce the disease in some and fail in others: and different species are differently affected. It is evident therefore that there are other causes dependent upon the animal itself, which are essential to the development of the infective disease, and of the nature of these we are still ignorant. When once, however, the disease is developed, it can be communicated from one animal to another of the same species with perfect certainty; but frequently it is incapable of being transmitted to animals of a different species.

Our knowledge may be briefly summarised thus: All putrid animal fluids contain a chemical poison which, if absorbed, will cause a constitutional disturbance proportional to the dose, and they frequently, and perhaps always, contain also a virus capable under favourable conditions of setting up a true general infective disease; lastly, should solid particles, as from a softening thrombus, enter the blood-stream, they will, if impregnated either with the simple chemical poison or the specific virus, set up disseminated centres of inflammation and suppuration wherever they lodge. The importance, therefore, in regard to the prevention of pyæmia and septicæmia, of avoiding putrefaction in the discharges of wounds cannot possibly be over-rated.

Although the conditions in a wound in the human subject are somewhat different from those present in experimenting on animals, yet the analogy is close enough to justify us in applying the results obtained to surgical practice.

A recent wound with decomposing discharges, or a deep cavity with pent-up putrid pus in it, are conditions essentially similar to those obtained by injecting a syringe-ful of a putrid fluid beneath the skin of an animal.

CAUSES OF SEPTICÆMIA AND PYÆMIA.—Simple septic poisoning may occur whenever a sufficient quantity of decomposing blood, serum or pus is collected in a wound or cavity of the body. Putrefaction, as before pointed out, will occur in such collections of fluid under all ordinary conditions to which a patient is exposed either in hospital or private practice. Septic poisoning affects a patient debilitated by want of proper food and bad hygienic conditions more severely than one placed in better circumstances: beyond this however, the surroundings of the patient exercise but little influence on its occurrence. The causes of the process are to be looked for in the wound itself, and septic poisoning may always be prevented by efficient drainage and antiseptic treatment.

The genuine infective processes will on the other hand rarely develop in spite of the presence of decomposing matter in the wound except when the patient is placed under unfavourable hygienic conditions. The experiments already described, in which septic infection and pyæmia have been induced artificially by the injection of putrid fluids beneath the skin of an animal, show that the presence of decomposing matter is an important element in the causation of these diseases. Clinical experience has fully confirmed this fact. Pyæmia has been practically banished from many hospitals in which it was formerly a frequent cause of death merely by the adoption of antiseptic methods of treating wounds—ventilation, cubic space, and other conditions surrounding the patient being unchanged. On the other hand, a strict attention to the laws of hygiene has been almost equally successful in preventing these diseases even when the Surgeons have not adopted any special mode of antiseptic treatment.

These diseases are predisposed to by all conditions, either before or after operations or injuries, that tend to impair the health, and to lower the strength, such as constant want of fresh air, overcrowding, abuse of alcohol, and insufficient or improper food. Of all these causes, overcrowding is undoubtedly the most frequent and the most fatal; more particularly is this injurious, if many patients are suffering from suppurating wounds. That pyæmia is the result of the faulty hygienic conditions just alluded to, viz., want of pure air, overcrowding, and insufficient and unwholesome diet, is evident from the fact of its being most destructive where these causes of disease prevail, as amongst the poorer classes of all large and densely peopled towns; while in the pure air of country districts, or in private practice amongst the wealthier classes, it is rarely met with. It is one of those causes of death after operations that might and ought to be prevented; and wherever it is frequent, we may be sure not only that proper attention is not being paid to cleanliness and the prevention of decomposition in the treatment of the wounds, but that either the constitutions of the patients are peculiarly deteriorated, or else that the hygienic conditions to which they are exposed after the injury or operation are more than usually faulty. That it may be prevented has been abundantly proved by the experience gained in the Franco-German war of 1870. The fact, which had previously been well known to all scientific Surgeons, was then established beyond all possibility of cavil, that the danger of pyæmia increased, *ceteris paribus*, in proportion as the hygiene was faulty.

and as wounded patients were closely crowded, so that the atmosphere surrounding them became contaminated by fetid exhalations from the decomposing discharges of suppurating wounds. It was found that, in the great mass of the wounded, pyæmia was developed among those who were aggregated within the walls of hospitals or regular buildings, such as churches, barns, school-houses, and conservatories, which, though clean and airy, did not admit of thorough ventilation: while it was far less common among wounded soldiers of exactly the same class who were treated in hastily constructed open and draughty huts.

SEPTICÆMIA.

The two forms of disease known as septicæmia, septic poisoning, and septic infection, are not always to be clearly distinguished from each other in surgical practice, partly because the symptoms of the two affections closely resemble each other and partly because the true infective process is frequently complicated or preceded by the non-infective. They are sufficiently distinct, however, to justify a separate description.

SEPTIC POISONING, SEPTIC INTOXICATION, or, as it has sometimes been called, **Sapremia**, is the general affection produced by the absorption of a sufficient dose of the chemical products of putrefaction to endanger life. The milder effects of the same poison are classed as septic traumatic fever. Such a division as this is unscientific, and will no doubt before long be done away with, but at the present time to speak of the milder forms of septic wound-fever as septicæmia would only increase the confusion already existing.

For septic poisoning to take place it is necessary that there should be a considerable quantity of decomposing matter so situated that absorption of the poison can readily take place. The conditions under which it is most likely to occur, therefore, are large and irregular wounds, such as those resulting from compound fractures of the bones of a limb; hollow wounds, such as those left by the removal of tumours; wounds of joints; wounds involving the pleura and peritoneum, and large abscesses opening externally by an insufficient aperture. Perfect drainage of injuries of this kind so far limits the quantity of septic matter as to render acute septic poisoning almost impossible. Absorption takes place most readily from recent wounds, and serous or synovial cavities. When suppuration has set in absorption takes place much less readily, as healthy granulations take up the poison with difficulty, unless the septic matter is pent up in contact with them at some degree of pressure.

The **symptoms of acute septic poisoning** are the following. On the second day after the injury or operation the temperature rises considerably, reaching from 103° F. to 104° F., or even higher. The skin is dry, and feels hot to the hand. There may be a chill or even a severe rigor, but this is by no means constant. The patient feels very ill, there is complete loss of appetite, with headache, a quick pulse, and a dry furred tongue. Delirium usually sets in at night, and occasionally is violent. By the third day after the injury some disturbance of the alimentary tract sets in. Vomiting is common, but diarrhœa is not frequent. In very acute cases the symptoms of collapse quickly come on. The pulse is rapid, feeble, and irregular, the tongue brown and dry, and the lips covered with sordes; the temperature

falls, and may sink even below normal, consciousness is lost, and the patient may become comatose before death. Dyspnoea is a common symptom during the last days. The skin may assume a yellowish tint before death. The urine frequently contains albumen.

In cases in which the septic matter which is causing the mischief is in the cavity of the pleura or peritoneum the symptoms may set in and prove fatal before the end of the third day. When the primary mischief is a large wound of the soft parts, or a compound fracture, the symptoms may be less severe and the duration of the case may extend to a week or more before death takes place. In these less acute cases the temperature is lower; vomiting and diarrhoea are common; there is rapid emaciation with loss of strength, death finally occurring rather from exhaustion than collapse.

In contrasting these symptoms with those produced in animals by the injection of putrid fluids beneath the skin, it will be seen that there is a general resemblance, which is quite as close as could be expected when the differences in the conditions are considered. In experimental septic poisoning the full dose is injected once for all under the skin, or into the blood; if in sufficient quantity it is speedily fatal, if not the animal recovers. In septic poisoning, as it occurs in man, the process of putrefaction gradually develops in the putrescible matter in the wound, and the symptoms consequently are more slowly manifested. The local inflammation caused by the putrid septic discharges is necessarily accompanied by exudation, which maintains a constant supply of fresh decomposable matter, and consequently a continuous development of the poison takes place. The symptoms are in fact as a rule the result of the prolonged administration of a moderate dose of the septic poison rather than of the sudden entrance of a fatal quantity into the blood-stream.

The **Post-mortem Appearances** are almost identical with those observed when the disease is produced artificially in animals. In extremely acute cases the signs of decomposition set in early, and the surface in a few hours after death becomes marked by lines corresponding to the superficial veins. Rigor mortis is often feebly marked. On opening the body the blood may be found imperfectly coagulated and dark in colour, but this is by no means common. A slight excess of serum, often darkly stained with the colouring matter of the blood, may be found both in the pericardium and the peritoneum. The heart is flabby, and marked in many cases by small extravasations of blood (petechiæ) beneath the pericardium, usually most abundant at the back of the organ. Similar petechiæ may also be found beneath the pleura and peritoneum. On opening the heart the endocardium is found darkly stained, even at an early period after death. The lungs always show marked hypostatic congestion, their posterior part being dark purple, swollen and oedematous. The liver and kidneys are swollen and often full of blood, and the spleen is swollen and soft, sometimes almost diffuent. The mucous membrane of the alimentary canal is often congested, but with nothing approaching to the intensity met with in animals.

The *post-mortem* appearances are due, first to the changes in the blood, the most marked of which is the rapid disintegration of the red corpuscles, causing the staining of vessels and tissues. This disintegration takes place in extreme cases before death. The corpuscles are found not to run together in rouleaux but to form irregular clumps. This has also been observed during

life, and the blocking of the vessels by these masses of corpuscles is probably the cause of the capillary hæmorrhages found throughout the body. Secondly there is a marked tendency to passive congestion of the viscera consequent on the feeble action of the heart before death; and, lastly, there is cloudy swelling of the epithelium of the glandular viscera.

In more chronic cases of septic poisoning similar changes are found, but less marked in proportion to the chronicity of the case.

Diagnosis.—Septic poisoning can be confounded only with some malignant specific fever, but the connexion of the symptoms with their cause is in most cases so evident that an error is scarcely likely to be made. In former times many cases of septic poisoning after operations were classed as collapse, or exhaustion.

Prognosis.—The prognosis depends upon the severity of the symptoms and the possibility of removing the cause. If the accumulation of septic matter can be cleared away and its re-accumulation prevented, cases apparently hopeless may sometimes recover.

Treatment.—The treatment consists in removing the cause, as by laying a joint freely open, enlarging the aperture in an imperfectly opened abscess, or establishing good drainage in a cavity, as the peritoneum or pleura, or in a wound. The occurrence of septic poisoning can always be prevented by antiseptic treatment, and efficient drainage. The patient's strength must be kept up by stimulants and liquid food.

SEPTIC INFECTION.—An acute general disease accompanied by symptoms closely resembling those just described as resulting from septic poisoning is occasionally met with in circumstances which preclude the possibility of its being due merely to the absorption of a chemical poison. The conditions which would lead us to believe that a given case is the result of a true infective process are, first, its arising from a wound of such size as to render it impossible for the necessary dose of septic matter to be formed in it; secondly, evidence of infection from one patient to another; and, thirdly, the presence of active living organisms in the blood. The first condition is met with in those cases of septicaemia that follow the inoculation of the poison of dead bodies, by a scratch or puncture during a *post-mortem* examination. In these the local inflammation may be very slight, the patient dying rapidly from blood-poisoning. Similar cases are sometimes met with after operations in which the wound is too small to furnish a fatal dose of the chemical products of putrefaction. The second condition, infection from another patient, is seldom observed in surgical practice. It is, however, very marked in the septicaemia which forms one of the varieties of puerperal fever, the intense infectiousness of which is but too well known. The last condition, the presence of specific organisms in the blood, has been observed in many cases of septicaemia, but our knowledge on this subject is at present very imperfect when compared with that which we possess with regard to septic infection in animals. It must be remembered, however, that until recently the non-infective and infective forms of septicaemia were confounded together, and the methods of observation have only lately been brought to any degree of perfection.

Those cases of septic infection which arise as a consequence of large wounds, the discharges of which are in a state of decomposition, are necessarily complicated to a greater or less degree by septic poisoning, and the recognition of the infective process then becomes correspondingly difficult.

Although at present, therefore, we are unable always to separate septic poisoning and septic infection in actual practice, it is to be hoped that further observation will enable us to do so, for the importance of the distinction is very great. Septic poisoning is not infectious, and can be relieved by removing the local source of the septic poison; septic infection, on the other hand, is supposed to be intensely contagious, and may be readily communicated from one patient to another, and as it is a general or blood-disease no relief can be hoped for from treatment applied to the local source of infection.

Symptoms of Septic Infection.—The disease is usually ushered in by a distinct rigor, often severe, and sometimes repeated more than once. The temperature rapidly rises, reaching 104° F. or 105° F., or even a higher point during the rigor. The subsequent symptoms closely resemble those already described as occurring during septic poisoning. There is delirium, ending in insensibility, and even in profound coma. The pulse is extremely rapid and quickly becomes feeble. The tongue soon becomes dry and brown, and the lips and teeth are covered with sordes. Diarrhœa or vomiting may occur. The skin assumes a yellowish tint, and purpuric spots may appear in it. The temperature may fall and become subnormal before death, or may remain high to the end. Dyspnoea is often a marked symptom before death.

In very acute cases death takes place on the second or third day after the commencement of the disease, but life may be prolonged even for a week.

The **post-mortem appearances** are the same as in septic poisoning—visceral congestion, subserous petechiæ, early and intense *post-mortem* staining, and usually a swollen and softened spleen. In some cases there is pneumonic consolidation of the lung, and there may be pleurisy with blood-stained effusion. It is probable that different forms of micro-organisms may by infecting the blood cause the symptoms of true septicæmia in man. It is known that the pyogenic organisms may under certain circumstances be present in the body without causing suppuration. According to Von Eiselsberg, quoted by Watson Cheyne, staphylococci or streptococci were found in almost all the cases of septic fever which he examined; whilst Monod and Macaigne have recorded five cases of septicæmia in which streptococci were present in the blood.

Diagnosis.—In the present state of our knowledge it is frequently impossible to distinguish septic infection from septic poisoning except in the definite absence of the cause of the latter condition, as in some poisoned wounds. Septic infection is also identical in its symptoms and *post-mortem* appearances with the malignant forms of the acute specific fevers in which the patient dies before the characteristic eruption appears, and unless the source of infection is evident the diagnosis may be very doubtful.

Prognosis.—The uncertainty of the diagnosis necessarily interferes with an accurate prognosis; but when the evidence is strong that the affection is a genuine infective process the case is almost hopeless.

Treatment.—If the case is complicated by a septic wound, means must be taken to remove the septic matter and clean out the cavity with some strong antiseptic solution, as of chloride of zinc (40 gr. to 3j), or carbolic acid (1 in 20), or perchloride of mercury (1 in 500). The patient's strength must be supported by fluid nourishment, and stimulants and quinine may be given in large doses.

PYÆMIA.

Pyæmia is merely a clinical expression for a pathological process dependent upon the dissemination by the blood-stream of the causes of suppuration derived from a local source of infection. It most commonly, in fact almost invariably, arises as the secondary result of a primary inflammation which has reached the stage of suppuration, and the name was derived from the theory that the disease was due to the entrance of the pus into the blood-stream, or "purulent absorption." Although in the great majority of cases in which pyæmia comes under the observation of the Surgeon it occurs as a complication of wounds or injuries in which the discharges are in a state of putrefaction, this is not invariably the case. Thus, in the disease known as acute necrosis of bone, pyæmia often sets in before the subperiosteal abscess has been opened, and when the pus is perfectly free from any signs of decomposition. The primary disease in this case is, however, itself an infective process, and not a simple inflammation. Pyæmia is frequently met with as a consequence of other specific suppurative inflammations: thus, we see boils, carbuncles, diffuse cellulitis, and phlegmonous erysipelas often precede and lead to its occurrence.

Pyæmia was formerly a very common cause of death after operations and injuries, especially those implicating the veins, bones, or joints. The improved hygienic condition of most hospitals, and the introduction of antiseptics and drainage in the treatment of wounds have almost banished it from surgical practice. In properly constructed and well regulated hospitals and in private practice it is rarely met with except as a complication of cases in which efficient antiseptic treatment is impossible, as in operations on the urinary organs, or as a sequence of some specific inflammation, as carbuncle, acute necrosis, or scarlatinal inflammation of the fauces.

In some rare cases the symptoms and *post-mortem* appearances of pyæmia are observed without any primary inflammation being found. These cases have been described as idiopathic or spontaneous pyæmia.

The nature of the poison and its mode of entrance into the system will be discussed with the pathology of the disease.

Pyæmia is characterized especially by two series of phenomena: 1. A peculiar train of Constitutional Symptoms attended with a state of great depression of the powers of the system; 2. the formation of Abscesses, and the occurrence of diffuse inflammations in various parts of the body. The disease may be acute, subacute, or chronic. Usually it is subacute, and often chronic. Whatever form it may assume, the symptoms are essentially the same, differing only in degree.

Symptoms.—The invasion is as follows: During the period of apparently ordinary febrile disturbance, the patient is seized with a rigor, usually very severe and prolonged. The rigor presents no difference from that met with in the invasion of many other specific febrile affections (p. 197) except in its severity. In some cases of pyæmia the rigor is not repeated, but more frequently it recurs at irregular intervals of from twenty-four to forty-eight hours; and, as the disease becomes established, even twice or oftener in the day. A single rigor, although a very alarming symptom, may pass off without the development of the disease. The subsequent sweating is very profuse, the

bedclothes being soaked with the perspiration. The rigors are very exhausting to the patient.

The *temperature* in pyæmia presents remarkable and characteristic fluctuations. It is uniformly higher than normal, but rises above and falls in its general level in exact accordance with the development of the rigors. The

accompanying Diagrams (Figs. 345, 346), for which I am indebted to Ringer, who took them from patients of mine, will indicate this more clearly than any description. Wunderlich observes that the rise of temperature in the onset of pyæmia is greater in a shorter time than in any other disease, and that the fall is equally rapid with the rise, and sometime

more so. But it does not, as a rule, reach the normal point, and usually ascends again before this is reached. In some cases, however, the temperature falls slightly below normal during the profuse sweating following a rigor, as shown in the accompanying temperature charts. The rise in the temperature precedes the occurrence of the rigors; and the approach of a rigor may be predicted by noting a commencing rise in the thermometer.

Fig. 346.
Temperature Chart in a rapidly fatal case of Pyæmia following a Compound and Comminuted Fracture of the Bones of the Leg.

There are sometimes actually two rigors during one continuous rise of temperature.

Should the rigors recur with some degree of regularity the pyæmia may closely resemble an attack of ague. As a rule, however, the regular periodicity so characteristic of ague is wanting in pyæmia. After the occurrence of rigors other changes begin to manifest themselves.

Any open wound that may exist is usually in an unhealthy state at the time of the invasion of the disease. It is either foul, or sloughy, or inflamed, and discharging decomposing pus, which perhaps does not find a ready exit. Even when the wound appears healthy superficially, it is probable that some pus is deeply pent up within it, or possibly, if the bone is injured, inflammation and suppuration are taking place in the medulla. Pyæmia never arises from

a healthy superficial granulating sore. When pyæmia has set in, the wound usually becomes dry and ceases to discharge pus. Even if the superficial parts remain tolerably healthy, the granulations become pale and healing ceases. In very chronic cases, however, healing may go on while the patient is still suffering from secondary abscesses in different parts of the body. The skin is continuously hot, and has often a burning pungent feel. The breath has that peculiar sweetish, or fermentative smell that is commonly noticed in all febrile diseases of a low type; this odour of the breath, and indeed of the body generally, is often noticed early in the disease, and must then be taken almost as a diagnostic, and certainly as a most unfavourable, sign. The secretions are arrested; the pulse is quick and soft; the face is usually pale, with a very anxious drawn look, but sometimes flushed and the eyes bright; there is hebetude of mind, with slight nocturnal delirium, but perfect consciousness on being spoken to. Rapid wasting of the body sets in about this period; patches of erratic erythema frequently make their appearance on the surface; and the skin assumes a dull sallow and earthy, or a bright yellow icteric tint, which may extend to the conjunctivæ. The symptoms now indicate an extreme depression of the vital powers; the pulse becoming small and fluttering, the tongue, which has been dry, becoming brown, sordes being deposited about the teeth, and low delirium supervening. Usually from the sixth to the tenth day, but sometimes earlier, suppuration commences in different tissues, joints, and organs.

The **Formation of numerous centres of inflammation and suppuration**, "secondary" or "metastatic" abscesses as they are termed, is the most marked feature of pyæmia. The pus in these abscesses is often thin and oily-looking; sometimes, however, it is thick and creamy. In the oily-looking pus the cells are extremely granular, and sometimes so far degenerated that no nucleus can be recognized even after the addition of acetic acid; the liquor puris contains large quantities of granular debris. In some cases the pus has been observed to form a firm coagulum, and occasionally it is fatal. These purulent collections vary greatly in size and in situation. They are found in the viscera, in the intermuscular and subcutaneous areolar tissue, in the serous cavities, in the joints, and occasionally in the muscles, or at the seat of subcutaneous injuries received at the same time as the wound from which the infection has taken place.

Pyæmic abscesses differ from ordinary purulent collections, not only in the peculiar character of the pus that they contain, but more particularly in the rapidity with which they form, a few days commonly sufficing for them to attain a large size. This, with their very widespread character, and the insidious manner in which they occur, often with few if any local signs, constitute the distinguishing features of these collections.

The visceral abscesses vary in size from a pin's head to a walnut; in many cases the organs affected are studded with them. These collections are most frequently met with in the lungs, being seated at the posterior part and on the surface of these organs, or in the interlobular fissures. They form often without cough or pain, and the area of consolidation is rarely sufficient to be recognized by percussion. They are usually rapidly followed by pleurisy with effusion, which conceals any physical signs of the mischief in the lung tissue. The organ that is most frequently affected next to the lung is the liver. Here also the abscesses are usually small and numerous. They can occasionally be

recognized by irregularity of the surface of the liver in the superficial part in the epigastrium and by tenderness on pressure. Jaundice often forms a marked symptom. In some cases, especially when the disease is secondary to dysenteric ulceration of the intestine, the abscess is single and of considerable size. Secondary abscesses are not uncommon in the spleen, where they can only occasionally be recognized by tenderness and pain in the splenic region. They are also met with in the kidney, less commonly in the brain, and, in rare cases, in the parotid gland, the prostate, and testes.

Inflammations of the serous membranes in pyæmia are usually secondary to abscesses of the viscera, but they are occasionally met with independently. There is usually abundant effusion, which rapidly becomes purulent. The pleura is most commonly affected, the peritoneum least frequently. The symptoms of these serous inflammations as a rule present nothing peculiar except in the rapidity with which effusion takes place.

The joints are frequently affected, especially the knees and shoulders; whilst not unfrequently the sterno-clavicular joints are involved. They become rapidly filled with a thin yellowish purulent liquid. This is usually indicated by intense pain, often cutaneous or superficial, with fluctuation and swelling in the joint. Often, however, large accumulations of pus form suddenly in joints, without having been preceded by pain or any other sign of mischief; in these cases the interior of the joint, though filled with pus, remains tolerably healthy, there being no erosion of cartilage or destruction of ligament, but merely some inflammatory injection of the synovial membrane.

When the pus is infiltrated into the areolar tissues and muscles of the limbs and trunk, it forms diffuse collections of a thin serous matter commonly mixed with shreds of the areolar membrane of the part, having no boundary. These collections are met with in the axilla, down the flank and about the back, in the ilio fossa, thigh or calf, and may either be confined to the subcutaneous, or extend to the deep intermuscular, areolar planes in these regions; or they may form even in the muscular substance itself, being diffused between the fasciæ, which are softened and disintegrated. Most commonly the presence of these collections is indicated by patches of cutaneous redness, and by a doughy, œdematous, and boggy state of the superjacent integuments. Sometimes superficial patches of redness with some œdema appear in different parts of the body, afterwards subsiding without the formation of pus, giving rise to one form of the condition known as "erratic erysipelas."

Amongst the rarer complications of pyæmia is acute suppuration of the eye-ball, or *metastatic panophthalmitis*. All the structures of the globe are affected. Virchow has shown that it is due to the lodgment of infective emboli in the vessels of the eye. Litten and Leube have observed retinal hæmorrhage in many cases of puerperal pyæmia. In some cases they appeared to be the result of embolism, but in others this seemed doubtful. Plugs of micrococci have been observed in the retinal vessels after death. These conditions are met with only in very grave cases, and usually indicate the approach of death. The ophthalmoscope may therefore sometimes furnish valuable evidence both of the nature of the disease and of its probable termination.

The progress of the disease is usually from bad to worse, sometimes rapidly, but at other times not uninterruptedly so, there being remissions and apparent, though not real, improvement. The patient rapidly wastes, the body becoming shrunken, the muscles soft, and the skin grey or sallow, loose and pendulous;

great debility also sets in. The abdomen becomes tympanitic, diarrhoea or profuse sweats come on; pneumonia or pleuritic effusions declare themselves; delirium, from which the patient is easily roused, alternates with stupor; and at last he sinks from exhaustion. Death takes place usually about the tenth or twelfth day; though it may occur as early as the fourth, or the patient may linger on for six or seven weeks.

POST-MORTEM APPEARANCES.—The body is usually emaciated and rigor mortis is feebly marked. The skin is generally yellowish in tint, sometimes intensely jaundiced. Purpuric spots are occasionally noticed on the surface, especially in the lower extremities. Decomposition as a rule sets in early.

Appearances at the Seat of Infection.—Any external wound is usually grey, sloughy, or dry, and the parts round it may be œdematous. If the wound be one implicating the bones, as an amputation, or an excision of a joint, it very frequently presents the appearances of septic or gangrenous osteomyelitis. The exposed end of the bone is bare, and the periosteum is loosened. If the shaft of a long bone has been implicated, the medullary canal contains gangrenous fat mixed with offensive pus; if the cancellous tissue has been opened up, the spaces are filled with a similar material. (See Osteomyelitis, Vol. II.) In the bones of the skull the diploë may be found infiltrated with pus.

The **Veins** leading from the wound are in some cases perfectly healthy; far more commonly, however, they are found to present marked evidences of disease. While exposing the vein by dissection it will usually be noticed that the areolar tissue in its neighbourhood is infiltrated with inflammatory products for a considerable distance from the wound, and occasionally the vessel may be surrounded here and there by pus. When the vein is exposed, it is seen to be distended, being in parts dark purple, and in parts yellowish, as if filled with pus. On opening the vein its coats are found to be swollen and thickened, and its lumen filled with a thrombus in various stages of softening and disintegration. This thrombus may extend for a great distance, as from the leg to the groin, its extremity sometimes projecting into the main trunk into which the affected vein enters. The fragments of the softened thrombus may thus be carried on into the circulation as emboli, lodging in the lungs and giving rise to secondary abscesses. In some cases the source of the secondary mischief may be recognized by the state of the veins. Thus in cases of osteomyelitis, the thrombosis of the main trunk may commence at the point at which the veins from the bone enter it. In a case in which a patient died of pyæmia after an amputation of the thigh in University College Hospital, the veins leading from the stump were perfectly healthy, while those leading from a foul bed-sore were full of disintegrated clot.

General Post-Mortem Appearances.—The blood may be dark in colour and imperfectly coagulated, as in septicæmia, but in the vast majority of cases it presents no naked-eye abnormal appearance.

The veins of distant parts are occasionally found to contain softening thrombi similar to those observed at the seat of infection. In the 110 cases of pyæmia collected by the Committee of the Pathological Society this condition was observed in six. These cases are of great interest as indicating that the general infection of the blood may, in some cases at least, be an important factor in causing thrombosis at the original seat of infection.

Secondary Centres of Inflammation occurred in the following order of frequency, in the 110 cases reported in the Transactions of the Pathological

Society of London, 1879. The table is divided into two columns, A and B, A showing the frequency with which the secondary inflammation was limited to one organ or tissue, and B the number of cases in which the special part was affected in combination with others.

	A	B	Total
Joints	12	8	20
Subcutaneous and intermuscular areolar tissue	4	8	12
Muscles	0	1	1
Bruises and other subcutaneous injuries	1	1	2
Serous membranes	6	4	10
Lung	33	24	57
Liver	1	11	12
Spleen	1	10	11
Kidneys	0	6	6
Brain	1	5	6
Heart, substance of	1	4	5
Endocardium	0	1	1
Parotid Gland	0	1	1

The cases of inflammation of serous membranes do not include those in which the mischief was merely secondary to abscesses in the organs they cover. The relative frequency of the affection of the different membranes was as follows: pleurisy, 4; meningitis, 3; pericarditis, 2; peritonitis, 1.

The **Heart** is frequently the seat of small extravasations, which may be found either beneath the pericardial or endocardial lining, or in the muscular substance itself. Sometimes, though not very often, abscesses are found situated either in the wall or in the papillary muscles: these are usually small collections of puriform matter, rarely much larger than a pea, and often surrounded by a zone of congestion or hæmorrhage. The muscular substance is flabby, and the lining membrane of both the heart and the aorta is usually more or less deeply stained by imbibition of the colouring matter of the blood. Pericarditis may occur independently or in connection with metastatic abscesses in the heart, or may be secondary to the inflammation of the pleura. Occasionally diffuse acute inflammation of the muscular structure of the heart is found, without any distinct abscess having been formed.

The **Lungs** are much congested, especially at the posterior bases, where the tissue is friable; sometimes this congestion passes into true pneumonia. The most important condition present in pyæmia is the existence of *metastatic abscesses*, which may vary much in number and size. These are usually found scattered over the surface, and are most common in the upper part of the lower lobes, and the interlobular fissure. Their position is indicated by induration and a slight elevation, to be felt on passing the hand over the surface of the lung. It occasionally happens that all stages of development of the "secondary abscesses" may be observed in the same lung. The earliest stage is merely the effect of embolism. A small terminal artery having been obliterated by an embolus, the wedge-shaped portion of lung it supplies becomes intensely engorged with blood by regurgitation from the surrounding parts, or from the vessels of the pleura; the walls of the vessels soften and hæmorrhage into the lung tissue and air-vesicles takes place. The portion of the lung tissue then presents the ordinary appearance of so-called pulmonary apoplexy: it is dark red on section, like damson-cheese, airless and solid, but breaking down readily on pressure. The consolidated portion is spoken of as a "hæmor-

rhagic infarct." If this were due to the lodgment of an unirritating embolus, the extravasated blood and the tissues which have been deprived of their blood-supply would gradually be absorbed, leaving a depressed cicatrix in the lung tissue. In pyæmia, however, the embolus is infective and intensely irritating; consequently the vessel in which it is lodged sloughs, and the mischief extending to the surrounding tissues, the whole infarct softens and breaks down. The products of this process soaking away into the surrounding lung tissue cause inflammation, with exudation into the air-vesicles identical in its pathological appearances with ordinary croupous pneumonia. Occasionally all these conditions may be recognized in one infarct. On making a section through it a grey or yellowish fluid may be seen in the centre; it is not pus, being produced by gangrenous softening of the central parts of the infarct. Round this is a zone of pulmonary apoplexy; then follows a paler solid area, having the ordinary appearances of pneumonic consolidation, and round this again a zone of hyperæmia, in which the vesicles still contain air. As the area of softening extends, the cavity becomes a true abscess, containing pus mixed with the *debris* of the tissues of the lung, and the wedge-shaped form is then lost. The size of these abscesses varies greatly, from less than that of a pea to two or three inches in diameter. The pleurisy which accompanies, and in most cases results from, the formation of the abscesses is often very severe. The pleural surface is thickly covered with patches of inflammatory lymph, whilst quantities of deeply coloured turbid fluid are usually collected into the pleural sac. Sometimes, though rarely, small collections of pus are found scattered through the substance of the organ without affecting its pleural surface, or giving rise to any of the wedge-shaped masses above described.

The **Liver** frequently presents no abnormal appearances, even in severe cases, where the lungs have suffered most markedly; in others, again, it is the seat of many abscesses, which often attain a very large size. These have more the same character, both as to form and position, as those in the lungs, and are usually surrounded by a zone of hæmorrhage and congestion. When, however, they occur without any deposits in the lungs preceding them, they may appear as simple collections of pus, having a more or less branched arrangement. The form of pyæmic abscess does not appear to be the result of arterial embolism. In cases in which the general blood poisoning is more marked than the local effects, the liver is found to be swollen, its structure is soft and more friable than usual, and its colour uniform and muddy. The epithelium is found on microscopic examination to be excessively granular.

The **Spleen** is usually large, soft, very friable, and often of an almost pulpy consistence. Infarcts unconnected with the pyæmic state are frequently met with in this organ; metastatic abscesses are not, however, very common.

The **Kidneys** are almost invariably swollen and soft; the epithelium cloudy, excessively granular, and often choking the tubules in irregular masses. They are very frequently congested, and sometimes the seat of abscesses presenting the same varieties as those found in other parts.

The **Intestines** rarely suffer, but abscesses may be found in the submucous or subserous areolar tissue. Local peritonitis not unfrequently follows the formation of hepatic abscesses, and may become very severe.

Of the other organs the **Brain** is most commonly affected. Diffuse suppura-

is occasionally met with in the **parotid gland**, and in rare cases abscesses have been observed in the **prostate**.

One or more **Joints** are frequently found to be swollen, and on opening them a large quantity of pale yellow or thick, flaky, and puriform fluid escapes. There is congestion of the synovial fringes, with softening or destruction of the cartilage.

MICROSCOPIC APPEARANCES OF TISSUES AND ORGANS IN PYEMIA.—The blood in almost all cases contains a considerable excess of white, with deficiency of red corpuscles, but this condition is by no means peculiar to pyæmia. The red corpuscles are usually unchanged; but, occasionally, they have been observed to run together into irregular masses instead of forming rouleaux. Microscopic organisms have frequently been observed in the blood, and these will be more fully referred to afterwards.

The yellowish fluid found in the veins as the result of softening of the thrombi closely resembles pus in appearance, but on microscopic examination is found in many cases to be composed merely of granular debris containing true pus-cells. In other cases, as I have frequently observed, cells having the ordinary appearance of pus-cells are more or less abundantly present.

The so-called "secondary deposits" may in an early stage in like manner be found not to contain pus, being composed merely of gangrenous tissue. In the later stages pus is always present.

The epithelium of the liver and kidney is usually granular and swollen.

Microscopic Organisms.—In almost all cases of pyæmia, micrococci can without difficulty be recognized in various situations. Of these, the *staphylococcus pyogenes aureus* and the *streptococcus pyogenes* seem to be the most important.

At the seat of infection they are frequently found in large quantities in the discharges, and in the slough that so frequently covers the surface of the wound. They are always present in the fluid resulting from the softening of the thrombi in the veins. In the blood they are recognized with greater difficulty, and the evidence as to their presence has been very conflicting. Throughout all other parts of the body they have been observed in the purulent fluids in the secondary abscesses, but their most characteristic appearance is as colonies or zooglaeal masses blocking the smaller arterioles or capillaries. In this form they are readily recognized in sections prepared in the ordinary way, and stained with logwood or methyl violet. They form rounded granular masses, in which it is often difficult to recognize the individual organisms except at the edge of the mass. The vessel is slightly distended at the part in which they are lodging, and a coagulum is occasionally seen above and below the obstruction. Sometimes the wall of the vessel appears to have given way, and the organisms are found outside it. In most specimens no change is observed in the tissues around the vessel, but occasionally inflammatory exudation has taken place, and the group of micrococci seems to form the centre of a commencing abscess. These colonies of micrococci are found in the lymphatic glands nearest to the seat of infection, in the liver, heart, thyroid body, and with especial frequency in the tufts of vessels in the Malpighian bodies of the kidney. The accompanying drawings (Figs. 347, 348, 349) copied from the Transactions of the Pathological Society of London, 1879, and from Koch's work on Infective Processes in Wounds, show very clearly the appearances presented by the micrococci in pyæmia.

General Pathology.—On contrasting the symptoms and the *post-mortem* appearances just described with those observed in the diseases experimentally produced in animals (see p. 968), it will be seen that they closely resemble, if they are not identical, with them. In those cases in which a softening thrombus is found in a vein, and the secondary abscesses in the lungs only, the conditions are identical with those obtained by injecting putrid matter containing coarse solid particles in suspension into the veins of an animal. In other cases the disseminated abscesses, with capillary thrombosis and the distribution of colonies of microscopic organisms throughout the system, closely resemble the results obtained by Koch from the injection of putrid fluids beneath the skin

Fig. 347. — A colony of micrococci living amongst the muscular fibres of the heart. (From Path. Soc. Trans. 1879.)

of a rabbit. In the human subject the conditions under which the disease arises also closely resemble those obtained experimentally in animals.

The thrombosis which is so frequent a precursor of pyæmia is predisposed to by all those conditions which favour thrombosis in general (see Diseases of Veins), but it is usually determined in one of two ways. In many cases an unhealthy diffuse inflammation spreads upwards from the wound in the areolar tissue surrounding the vein. This periphlebitis leads to the inflammation of the coats of the vessel followed by coagulation of the contained blood. The clot becoming impregnated with the products of the unhealthy inflammation,

Fig. 348. — Colony of micrococci, from a lymphatic gland. (Path. Soc. Trans. 1879.)

softens and becomes disintegrated. In other cases, the thrombus forms in the vein either in consequence of its having been divided and ligatured, or from death of the tissues from which it derives its blood, as in necrosis of bone. If under these circumstances the distal end of the thrombus becomes exposed to septic matter, as in a foul wound, the clot decomposes and disintegrates. The presence of the decomposing clot causes inflammation of the vein, and an extension of the thrombus; the new clot in its turn decomposes, and thus the process extends up the vein almost indefinitely. In whichever way the spreading thrombosis takes place, it may continue to extend till it reaches a

point at which the affected vessel joins another large trunk, when the softened fragments may be washed on into the circulation, and cause the effects already described wherever they lodge.

In some rare cases the cavity of a foul abscess may open directly into a large vein by ulceration of the wall.

In those cases in which decomposing discharges are pent up in a deep wound, the conditions are essentially analogous to those which exist when putrid fluids are injected beneath the skin, as in Koch's experiments.

The explanation of the pathology of pyæmia may therefore be fairly sought in the experimental investigations which have already been described. That in all cases a true infective process is developed in which a specific poison enters the blood and multiplies in it is not proved. In some cases, in which the secondary abscesses are limited to the lungs, it is possible to explain all the phenomena by supposing that the fragments of a putrid clot enter the blood-stream, and lodging in the lung, cause a number of embolic abscesses which may prove fatal without any general infection of the blood.

VARIETIES OF PYÆMIA.—In the preceding pages a description has been given of the general symptoms and *post-mortem* appearances of pyæmia. The

Fig. 349. Microscopical, plugging a small branching arteriole in the muscular fibre of the heart. The tissues around are infiltrated with inflammatory exudation. (Koch.)

disease, however, does not always run the same course, and a few definite varieties may be mentioned.

Acute Pyæmia.—In this form the rigors are well marked, the fever is high, secondary abscesses form early, and almost invariably affect the viscera; death takes place usually before the tenth day. Acute pyæmia is found after death to be almost constantly associated with softening thrombi in the veins, and embolic abscesses. It is most common after operations or injuries involving the bones, as amputations or compound fractures, and is frequently preceded by septic osteomyelitis. It is invariably fatal. The part taken by embolism in the production of the secondary abscesses is often so evident in this form that it has been described as *embolic pyæmia*.

Chronic Pyæmia.—In this form of the disease the fever is less intense; there may be but a single rigor, but occasionally it may be repeated frequently throughout the case. The secondary inflammations affect chiefly the subcutaneous cellular tissue and the joints, and occasionally the pleura, the viscera not being affected. Sometimes the secondary abscesses appear at points ex-

posed to pressure, as the shoulders, the elbows, or the back; in other cases suppuration takes place in subcutaneous injuries, as bruises or simple fractures. The patient may linger on for weeks, and finally die of exhaustion; or recovery may take place, leaving him in shattered health, with perhaps one or more joints firmly ankylosed. Chronic pyæmia is most frequently met with after injuries of the soft parts, especially the genito-urinary organs, and it constitutes a not uncommon form of puerperal fever. It has been known to follow gonorrhœa, and is allied to some forms of "gonorrhœal rheumatism." Should the patient die, as a rule no softening thrombi are found in the veins.

Umbilical Pyæmia is a name which has sometimes been given to a form of the disease occurring in infants from thrombosis of the umbilical vein, with subsequent softening of the clot.

Pyæmia without an Open Wound.—This may occur as the result of ulcerations of the alimentary canal, as in typhoid fever or dysentery, or as a consequence of some infective inflammation of a deep part. A general febrile disease with rigors and the formation of metastatic abscesses has also been observed as a complication of gonorrhœa. Perhaps the most common example of pyæmia from a subcutaneous inflammation is the form that so frequently follows acute necrosis of bones in children. This is an acute infective inflammation terminating rapidly in the formation of pus beneath the periosteum. It is very frequently complicated by thrombosis of the veins leading from the bone, and subsequent softening of the thrombi and embolism. The emboli are impregnated with the infective products of the local inflammation, and wherever they lodge they give rise to abscesses. The *staphylococcus aureus* (p. 243), is always found in these cases, and its presence has been demonstrated in the secondary abscesses as well as in the primary.

Idiopathic Pyæmia is a term applied to those rare cases in which the symptoms during life and the *post-mortem* appearances are those of pyæmia, and yet no local source of infection can be found.

Mixed forms of Pyæmia and Septicæmia.—Although these diseases have been described separately, it must not be supposed that they are always met with in actual practice distinct from each other. In most cases of pyæmia the patient suffers at the same time more or less severely from septic poisoning; the early blood-staining, the soft and swollen spleen, the subcutaneous petechiæ, and the other characteristic signs of that condition form prominent features at the *post-mortem* examination. In other cases, with the exception of an unhealthy wound, a softening thrombus in the vein, and some softened infarcts in the lungs, the *post-mortem* appearances may be those of a healthy body. Between these extremes every variety may be met with. It is this that has led some Surgeons to the conclusion that septicæmia and pyæmia are mere modifications of a single process.

Prognosis.—The prognosis in pyæmia is always bad. When active acute pyæmia has fairly set in, recovery rarely, if ever, takes place, the patient usually dying between the fourth and the twelfth days. One or two rigors may occur, and yet the patient may recover. Each repetition of the attack adds to the gravity of the case. In fact, the rapidity of the fatal termination in any given case will generally correspond to the frequency of the rigors and their severity.

When the pyæmic attack is from the first subacute or chronic, it may be recovered from, after prolonged illness, the formation of numerous or large abscesses, and great and continued disturbance of the general health. In

these less active and acute forms of pyæmia, the joints are specially liable to implication, more particularly the knee, and elbow. Destructive suppuration may be set up in the joint, and loss or permanent impairment of utility of the limb will be the inevitable result.

DIAGNOSIS.—The diagnosis of pyæmia requires to be made :—1, from ordinary Surgical Fever, the Inflammatory Fever which accompanies wounds and Injuries, and Typhoid Fever ; 2, from Ague ; 3, from Rheumatism ; 4, from Septicæmia.

1. The **Diagnosis from ordinary Surgical Inflammatory Fever and Typhoid Fever** is usually sufficiently easy, the course of these fevers being unbroken by severe rigors, by sudden fluctuations of temperature, or by sweats. An ordinary fever may be ushered in by a rigor ; but this is seldom so intense as that which marks pyæmia, and certainly does not recur during the attack. The temperature also in ordinary fevers is more uniform. It is not marked by those sudden exacerbations, followed by equally rapid declines, that are so characteristic of pyæmia.

2. From **Ague** the diagnosis would not be easy in the earlier stages, if the patient had been exposed to malarial influences, and was at the same time suffering from surgical fever resulting from a wound, as then the characteristic feature of intermittent fever, the prolonged period of normal temperature between the rigors, will be wanting. Thus in a person injured whilst living in a swampy country, there may be much doubt as to the nature of the attack ; but in large towns, the general absence of ague and the obvious surgical cause of the pyæmia will render the diagnosis more easy. In the later stages, the signs of articular inflammation and suppuration, the secondary visceral and areolar abscesses, will all tend to clear up the diagnosis. In any doubtful case a chart should be made of the temperature, when the regular periodicity of the attacks in ague will be very apparent if that disease is present.

3. From **Rheumatism** it is easy to make the diagnosis of pyæmia, provided the recurrent rigor and other early symptoms have been well marked. But if these have been somewhat obscure, and if the secondary articular implication be early developed, there may be some difficulty in determining the nature of the disease. But, independently of the recurrent rigor, the great prostration, the early supervention of atonic symptoms, and the local centres of suppuration, will establish the true nature of the disease. Moreover, the temperature of rheumatic fever does not show the extraordinary variations seen in pyæmia ; and the sweating in rheumatism is continuous, and not merely the sequence of a rigor. In pyæmia the tongue is usually dry, and perhaps brown, and never presents the creamy white fur characteristic of rheumatism. The smell of the patient is sweet or "saccharine" in pyæmia, while in rheumatism it is sour, and quite distinctive.

4. From **Septic Poisoning** and **Septic Infection** it is not always possible to make the diagnosis. In fact, as before stated, pyæmia is in the majority of cases more or less complicated by septic poisoning. In septic infection the acute symptoms, the single rigor, the marked signs of blood change, such as the icteric tint, the dyspnea, and the early insensibility together with the absence of secondary inflammations, may serve to determine the nature of the case ; but in many cases the diagnosis is almost impossible during life.

TREATMENT.—The *Preventive Treatment* is *Local* and *General*.

The **Local Preventive Treatment** consists in preventing the accumula-

tion of decomposing discharges in the cavities of wounds or abscesses. This is carried out, first by properly draining the cavity in such a way that an accumulation of decomposable matter is impossible, and secondly by employing antiseptic agents in the dressing in such a way as to prevent even the slightest trace of putrefactive change in the discharges. It is evident that in many operations about the throat, rectum, and genito-urinary organs these principles cannot be fully carried out. In certain specific inflammations, as in infective endocarditis, or acute necrosis of bone, the inflammatory products possess infective properties independently of any contamination from the external air; and if they enter the blood-stream they may give rise to embolism of distant parts with softening of the infarcts and suppuration around them. Pyæmia cannot, therefore, be entirely banished from surgical practice, but it can be limited to a few exceptional cases. The experience of Lister, and of all Surgeons who have adopted the antiseptic treatment of wounds, has shown beyond a doubt that in all such cases as amputations, excisions of joints, recent compound fractures, removal of tumours, and the like, pyæmia can and should be entirely excluded, even in hospital practice.

The **General Means for the Prevention of Pyæmia** consist in a scrupulous attention to those hygienic measures which have been described in the earlier chapters of this work; and above all to a careful avoidance of *overcrowding*. Overcrowding is, however, a relative term. If, as must often happen in military practice, efficient antiseptic treatment is impossible, pyæmia is certain to break out if but a small number of patients are accumulated in a limited area: on the other hand if decomposition of the discharges can be prevented, a larger number may be treated in the same space without danger. No wise Surgeon would, however, on this account neglect the well-known laws as to cubic space, free ventilation, and general cleanliness, relying solely on antiseptics to prevent contamination of the air. It has already been pointed out in the early chapters of this work, that although putrid discharges are the most dangerous and most powerful source of contamination of the atmosphere of a surgical ward, the products of respiration and the accumulation of excreta will of themselves so vitiate the air as to impair the health and lower the vitality of those that breathe it; and thus delay the healing of wounds and favour the development of infective diseases.

A **Curative Treatment** of pyæmia can scarcely be said to exist. It doubtless happens that patients occasionally recover from this disease, even after the formation of diffuse abscesses; but such a result must be looked upon as a happy exception to its commonly fatal termination, rather than as the result of any special mode of treatment. The only treatment that holds out any hope of success appears to me to be the stimulating and tonic one, consisting of alcoholic stimulants, tonics, and liquid nourishment. I have certainly seen recovery follow, in some cases, the administration of large doses of quinine, five grains being given every third or fourth hour. Among many others, I may mention a very serious case of pyæmia following amputation of the arm, and accompanied not only by all the symptoms of that disease in a very marked degree but by pleuritic effusion, swelling and tenderness over one hip, and secondary hæmorrhage from the stump, which recovered under the tonic and stimulating plan of treatment. The quinine appears to check the rigor and to reduce the temperature. In some cases I have administered chlorate of potash largely (3 ij. to 3 iv. in the day), in addition to the quinine and

wine, with apparent benefit. If the depression be very great, carbonate of ammonia in five or even ten grain doses may be given; such fluid nourishment as the patient will take, with a liberal allowance of alcohol, wine or porter, being also administered. In addition to this medicinal treatment, hygienic measures must be put in force. The patient should throughout be placed in an airy and well-ventilated apartment, and all hygienic rules carefully attended to.

As abscesses form, they must be freely opened. This should be done with antiseptic precautions, as the pus in the secondary abscesses is not in a state of putrefaction, and the patient's condition will be greatly aggravated if it be allowed to decompose. In cases arising as the consequence of septic osteomyelitis following amputations or compound fractures, removal of the limb at the next joint above the affected bone has been recommended and successfully practised by Joseph Fayrer, even after one or more well marked rigors.

If convalescence take place, the patient will recover slowly. The rigors and sweats will gradually become less frequent; the appetite will improve; the countenance will lose its anxious expression, and the skin its unhealthy hue. But strength returns slowly. The disease may assume a relapsing character. Great caution, therefore, is necessary before a patient can be pronounced safe. Even after recovery he will continue pale and wasted; energy is lost; nutrition is impaired; and at a more remote period some low form of disease, as phthisis or albuminuria, may prove fatal. These evils are best prevented by a course of sulphurous mineral water, followed by a long sea-voyage.

TETANUS.

Tetanus is an infective disease due to the presence of a specific virus in the body. It is characterized by painful and continued spasms of the voluntary muscles, alternating with incomplete relaxation, and it usually terminates fatally.

Causes of Tetanus.—The causes of tetanus are: first, the *essential cause*, the virus or contagium; and secondly, the *predisposing causes*, including such local and general conditions as predispose the patient to receive the virus.

The Essential Cause of tetanus is a small rod-shaped organism—the *Bacillus tetani*. This is rather longer than the bacillus of mouse septicæmia; spore formation takes place at one extremity of the rod and thus the organism assumes a characteristic "drum-stick" shape. The bacillus is anaerobic and its spores are very resistant to high temperatures.

The first evidence of the infective nature of tetanus was obtained in 1884 by Carle and Rattone from a patient who died of that disease originating from a suppurating acne pustule. They removed the inflamed area immediately after death, and having squeezed the fluid from it and diluted it with sterilized water injected the emulsion so prepared beneath the skin in twelve rabbits. Eleven of these died of undoubted tetanus. The blood of the dead animals failed to induce the disease when injected into others, but pieces of the sciatic nerve, into the sheath of which the emulsion had been introduced in four instances, were found, when crushed up in water and injected, to give rise to tetanus. In the same year Nicolaïer, while making observations on the bacilli of earth, accidentally found that in a considerable

number of cases the subcutaneous injection of earth in rabbits, mice and guinea-pigs was followed by a fatal disease exactly resembling tetanus. Whenever this occurred there was present in the tissues, with other organisms, a fine and very small bacillus. Further observations showed that pus from the seat of inoculation produced the same disease in other animals, and contained the organism. It was subsequently cultivated on coagulated serum and inoculated with positive results. Dogs were not affected by the virus. In 1886 Rosenbach communicated a disease exactly resembling tetanus to rabbits by inoculating them with matter taken from the edge of the sore in a case of frost-bite, which terminated fatally from acute tetanus. In the diseased tissues he found, amongst other organisms, a very fine bacillus exactly resembling that described by Nicolaier. He obtained cultivations of this almost pure, being contaminated only by a septic bacillus which could not be separated, and with this cultivation he uniformly obtained positive results on inoculating rabbits.

Kitasato first obtained the bacillus in a pure state. Cultivations from the pus of a tetanic patient were made in an atmosphere of hydrogen, in which only anaerobic organisms could grow. By then exposing the mixed culture to a temperature of 80° C. the bacillus tetani which had already formed spores survived, whilst the other organisms with which the cultivation was contaminated were destroyed.

Predisposing Causes.—Tetanus is in the great majority of cases **Traumatic** in origin, and undoubtedly the most important local cause is the *presence of a wound*, by which the specific virus enters the body. From what has been said above it is clear that a wound contaminated with soil is especially liable to be infected, and thus the truth of the popular belief that tetanus is more likely to follow wounds of the hands and feet, and more especially of the ball of the thumb and of the great toe, can readily be understood. Although this may be true of the wounds common in civil life, the statistics of the American war show that wounds of the hands and feet are not more important in this respect than similarly contaminated wounds in other parts of the body. Of 505 cases, 21 followed wounds of the head or neck, 55 of the trunk, 137 of the upper extremity, and 292 of the lower. Of the 137 wounds of the upper limb which were followed by tetanus, 36 were above the wrist, and of the 292 of the lower extremity, only 57 were of the foot.

In the majority of cases the wound is punctured, contused or lacerated, more rarely incised. In one recorded case a man playing in a bowling-alley ran a splinter of wood under his finger nail; he died of tetanus, and fragments of wood from the floor gave fatal tetanus to mice when introduced beneath the skin. In another instance a boy wounded his foot in a playground and died of tetanus; earth from the playground produced tetanus in rabbits. The poisoned arrows of some savage tribes undoubtedly contain the virus of tetanus and cause death preceded by convulsions.

Tetanus in rare cases follows the clean-cut wounds made in surgical operations: thus, it has been known to follow removal of the breast, ovariotomy, amputation, ligation of the larger arteries, and the operation for hernia. The minor surgical operations also are not free from the possibility of this dangerous complication. It has been observed after the operation for fissure in ano, the ligation of piles and varicocele, and the removal of nasal polypus. I have seen a fatal case resulting even from the establishment of an issue; and burns are occasionally followed by tetanus. It has also been known to follow the

ligature of the umbilical cord in infants, and even the uterine irritation following abortion.

Tetanus may be occasioned by injuries that do not give rise to breach of surface: thus I have known it occur in a child which was suddenly thrown down upon its back by another at play, in a girl from a boy jumping on to her back, and in a lad by another striking him on the back by running a wheelbarrow at him; and Reid mentions a case produced by the stroke of a whip; but in the great majority of cases, it is directly occasioned by a wound of some kind.

It is also stated that the disease may arise from other causes besides injuries occasioning the **Idiopathic** form of tetanus: thus, for instance, it has been said to have been due to exposure to cold and wet.

Tetanus may occur at all ages, from the earliest infancy to an advanced period of life. In hot climates it is common amongst newly-born infants, in the form of *Trismus Neonatorum*. In this country it rarely occurs at this very early period of life, but is most common in young adults. I have most frequently observed it between the ages of 16 and 25, and after that in old people; but it may occur at any period of life. It is far more common amongst males than females—in the proportion of about four to one. *Season of the year* seems to exercise little influence over it. It occurs in all states of the atmosphere, and at all periods of the year; but is certainly most common when the weather is suddenly changeable—alternating from heat to cold. Indeed, long exposure to cold and wet, more particularly after the body has been heated, is said to be the most common cause of tetanus when it occurs independently of surgical injury, and is a frequent predisposing cause in persons who have been wounded.

Tetanus may occur in all *constitutions*; it is especially apt, however, to occur in feeble and debilitated individuals, and, indeed, may be looked upon as a disease of debility. When it occurs in persons who are otherwise strong and in the prime of life, it will usually be found that they have been exposed to causes of depression affecting the nervous system. In *tropical climates*, as in some of the West India Islands, and amongst the marshes of Cayenne, it occurs with peculiar frequency, and after the most trifling scratches or punctures. Poland states that the mortality from it is in London 0.25 per cent., whereas in Bombay it causes 2.5 per cent. of the total deaths. It is interesting to observe, that the natives of hot climates are far more liable to this disease than Europeans resident there. In the American Civil War, 8.1 per cent. of the cases occurred amongst the negro troops, who furnished only 2.7 per cent. of the total number of wounds.

In *military practice* tetanus is of common occurrence. Its frequency varies much in different campaigns and under different circumstances, especially of season and climate. In the Peninsular War, it was estimated to occur in the proportion of about one case in every 200 wounded; in the Schleswig-Holstein War of 1849, according to Stromeyer, once in about 350 cases. In the Crimea it appears to have been of rare occurrence. In the American War it occurred in 0.2 per cent. of the wounded. After naval engagements, however, the mortality has often been high, more particularly in tropical climates. Gilbert Blane states that, after Rodney's action in the West Indies, out of 810 wounded 20 were attacked with tetanus, being one in 40. All European Army Surgeons are agreed that sudden changes from heat to

General Pathology.—On contrasting the symptoms and the *post-mortem* appearances just described with those observed in the diseases experimentally produced in animals (see p. 968), it will be seen that they closely resemble if they are not identical, with them. In those cases in which a softening thrombus is found in a vein, and the secondary abscesses in the lungs only, the conditions are identical with those obtained by injecting putrid matter containing coarse solid particles in suspension into the veins of an animal. In other cases the disseminated abscesses, with capillary thrombosis and the distribution of colonies of microscopic organisms throughout the system, closely resemble the results obtained by Koch from the injection of putrid fluids beneath the skin

Fig. 347. A colony of micrococci lying amongst the muscular fibres of the heart. (From Path. Soc. Trans. 1870.)

of a rabbit. In the human subject the conditions under which the disease arises also closely resemble those obtained experimentally in animals.

The thrombosis which is so frequent a precursor of pyæmia is predisposed to by all those conditions which favour thrombosis in general (see Diseases of Veins), but it is usually determined in one of two ways. In many cases an unhealthy diffuse inflammation spreads upwards from the wound in the areolar tissue surrounding the vein. This periphlebitis leads to the inflammation of the coats of the vessel followed by coagulation of the contained blood. The clot becoming impregnated with the products of the unhealthy inflammation,

Fig. 348. Colony of micrococci, from a lymphatic gland. (Path. Soc. Trans. 1870.)

softens and becomes disintegrated. In other cases, the thrombus forms in the vein either in consequence of its having been divided and ligatured, or from death of the tissues from which it derives its blood, as in necrosis of bone. If under these circumstances the distal end of the thrombus becomes exposed to septic matter, as in a foul wound, the clot decomposes and disintegrates. The presence of the decomposing clot causes inflammation of the vein, and an extension of the thrombus: the new clot in its turn decomposes, and thus the process extends up the vein almost indefinitely. In whichever way the spreading thrombosis takes place, it may continue to extend till it reaches a

point at which the affected vessel joins another large trunk, when the softened fragments may be washed on into the circulation, and cause the effects already described wherever they lodge.

In some rare cases the cavity of a foul abscess may open directly into a large vein by ulceration of the wall.

In those cases in which decomposing discharges are pent up in a deep wound, the conditions are essentially analogous to those which exist when putrid fluids are injected beneath the skin, as in Koch's experiments.

The explanation of the pathology of pyæmia may therefore be fairly sought in the experimental investigations which have already been described. That in all cases a true infective process is developed in which a specific poison enters the blood and multiplies in it is not proved. In some cases, in which the secondary abscesses are limited to the lungs, it is possible to explain all the phenomena by supposing that the fragments of a putrid clot enter the blood-stream, and lodging in the lung, cause a number of embolic abscesses which may prove fatal without any general infection of the blood.

VARIETIES OF PYÆMIA.—In the preceding pages a description has been given of the general symptoms and *post-mortem* appearances of pyæmia. The

Fig. 340.—Microscopist, plugging a small branching arteriole in the muscular fibre of the heart. The tissues around are infiltrated with inflammatory exudation. (Koch.)

disease, however, does not always run the same course, and a few definite varieties may be mentioned.

Acute Pyæmia.—In this form the rigors are well marked, the fever is high, secondary abscesses form early, and almost invariably affect the viscera; death takes place usually before the tenth day. Acute pyæmia is found after death to be almost constantly associated with softening thrombi in the veins, and embolic abscesses. It is most common after operations or injuries involving the bones, as amputations or compound fractures, and is frequently preceded by septic osteomyelitis. It is invariably fatal. The part taken by embolism in the production of the secondary abscesses is often so evident in this form that it has been described as *embolic pyæmia*.

Chronic Pyæmia.—In this form of the disease the fever is less intense; there may be but a single rigor, but occasionally it may be repeated frequently throughout the case. The secondary inflammations affect chiefly the subcutaneous cellular tissue and the joints, and occasionally the pleura, the viscera not being affected. Sometimes the secondary abscesses appear at points ex-

covered and 69 died during the first day; 1 recovered and 83 died on the second day; 49 died on the third; 31 on the fourth; 22 on the fifth; 19 on the sixth; 14 on the seventh; and 7 on the eighth day. Thus of the acute cases 2, evidently slight in character, recovered; 294 died before the end of the eighth day; and in 203, or more than half, the disease did not exceed three days in duration. From the ninth to the nineteenth day inclusive, 36 died and 6 recovered; from the twentieth to the twenty-seventh inclusive, 7 died and 7 recovered; and 6 survived beyond the twenty-seventh day and finally recovered. The longest period during which the disease lasted was forty-nine days. These interesting statistics confirm the view that the more chronic the disease becomes the better is the chance of recovery; indeed, if the patient survive the tenth day, the prospect of a favourable issue to the case is materially increased. As a general rule, the danger is in the ratio of the acuteness of the attack, both as to severity and also as to rapidity of invasion after injury.

Rose has described a variety, which he called *Cephalic Tetanus*, resulting from wounds of the head, but more especially of the face. The most marked features of this form of the disease are facial paralysis on the same side as the injury, and marked pharyngeal and laryngeal spasm. On account of the latter symptoms the disease bears some resemblance to rabies, and it has therefore been called "hydrophobic tetanus."

Pathology.—Reference has already been made (p. 989) to the evidence that tetanus is produced by the action of a specific virus—the bacillus tetani. It is a fact of much importance that in cases following a wound the bacillus is not found in the blood, and further that it increases only to a very limited extent in the tissues of the damaged part.

It thus seemed probable that the symptoms of the disease were produced by a powerful poison absorbed into the blood from the focus of inoculation, and acting like strychnine upon the nervous system, especially the medulla and the upper part of the spinal cord. Vaillard and Vincent shewed that by filtering a pure culture of the bacillus they could obtain a liquid free from the organism itself, but which had the power of producing a typical fatal tetanus if inoculated into rabbits, guinea-pigs or mice. On the other hand, these observers found that inoculation of the bacillus purified from its products did not cause tetanus, and that under these circumstances the organism did not multiply at the seat of inoculation. When, however, earth containing the tetanus bacillus is inoculated, the organism multiplies locally and the absorption of the chemical products causes the typical symptoms. Vaillard and Vincent suggest that the difference is probably to be explained by the fact that in the latter case a mixed infection occurs, and that thus the tissues are in some way prepared for the growth of the specific organism by the other organisms which simultaneously enter them. Brieger has described four separate toxic substances which he obtained from cultures of the bacillus; the most important of these he called tetanin and tetano-toxine. It seems probable that the essential poison may be an albuminous body, allied to the soluble ferments.

Considerable success has attended the endeavours which have recently been made to produce immunity against tetanus in susceptible animals. Tizzoni and Cattani administered gradually increasing doses of a pure culture of tetanus bacillus to dogs and horses until they could resist a large dose of the most virulent poison. The serum of the immunised animal was found

possess the remarkable properties of destroying the tetanus poison outside the body, and in some instances of conferring immunity on other susceptible animals. These properties were supposed to be due to an albuminous body—"tetanus antitoxine"—contained in the serum. Several cases have now been recorded in which injections of such serum appears to have arrested the disease in man after the onset of the first symptoms. In some of these cases, however, the disease was of the more chronic form, and we have already seen that in these the hope of recovery is much greater than in the acute form.

The Post-mortem Appearances to the naked eye are, apart from the local injury, most commonly those of a perfectly healthy body. Should the patient have died of asphyxia during a spasm, the distension of the right side of the heart, the engorgement of the lungs and the general venous congestion characteristic of that condition are present.

The microscope has shown evidences of inflammation in the nerves passing from the wound, and the theory that the disease is the result of an ascending neuritis was at one time suggested. In the majority of cases the changes in the nerve trunks are probably not more marked than those found in the immediate neighbourhood of any suppurating wound. In rare instances however more extensive neuritis has been met with, and Gowers suggests that this may possibly be of some importance in explaining those cases in which the spasms start from the seat of the injury.

The microscopic changes in the spinal cord in cases of tetanus have been studied by Lockhart Clarke, Dickinson, and Clifford Allbutt. Lockhart Clarke, in at least six cases, observed lesions of structure in the spinal cord, consisting of disintegration and softening of a portion of the grey substance of the cord, which appeared in certain parts to be in a state of solution. The fluid thus formed was in some parts granular, holding in suspension the fragments and particles of the disintegrated tissue, but in many places it was perfectly pellucid. He considers this due to hyperemia of the cord, accompanied by exudation and disintegration. Dickinson has described intense hyperemia with a structureless exudation poured out around the vessels in many parts of the grey matter, breaking down the surrounding tissue. He also observed some hæmorrhages in the white columns. These observations have been confirmed by Clifford Allbutt, but the exact significance of the changes observed is still uncertain.

TREATMENT.—The treatment of tetanus is local and constitutional. The **Local Treatment** has for its object to bring the wound into as healthy a state as possible, and to remove every source of irritation from it. In the light of our present knowledge of the nature of the disease the indications would seem to be—first, to lay open the wound to the full extent; secondly, freely to excise the tissues surrounding it; and thirdly, to apply some powerful antiseptic agent such as pure carbolic acid or chloride of zinc (40 grains to the ounce). Amputation has been recommended and has been followed by recovery in some of the more chronic forms of the disease, yet milder local means have sufficed equally well, and in the majority of cases it has had no effect; hence so severe an operation can scarcely be recommended for general adoption. Nerve section and nerve stretching have been practised in the belief that an ascending neuritis played an important part in the causation of the disease. As with every other of the score of remedies, local and constitutional, that have been employed for tetanus, recoveries have taken place after the

employment of these measures. On the other hand, in acute cases they have proved as impotent as the others.

In the **Constitutional Treatment** of the disease it is necessary to bear in mind that tetanus is an affection of debility, the violence of the spasmodic paroxysms giving an appearance of false strength to the patient; and that the principal source of danger and death is the exhaustion induced by the energy of the muscular movements. The means adopted should, therefore, have for their object the removal of irritation and the support of the patient's strength, so as to enable him to hold up against the disease.

Nothing can be more unsatisfactory than the treatment of the *Acute* form of traumatic tetanus. In it, all drugs are useless as curative agents, unless perhaps the antitoxine already mentioned (p. 995) prove an exception. Medicines may however act as palliatives, and afford relief to the patient; and much may be done by the Surgeon to mitigate his sufferings, and to place him in a favourable condition to withstand the exhaustion, and to lessen the torture of the spasms. With this view, the first thing to be done is to clear the bowels out well with an aperient dose; aided, if necessary, by a turpentine enema. The patient should then be kept perfectly quiet in a room by himself, a screen or muslin curtains, as recommended by Marshall Hall, being drawn round the bed, as noise or movement of any kind greatly increases the spasms. In order to allay the spinal irritation the most effectual plan is, perhaps, that recommended by Todd, of applying ice along the whole length of the spine: this is best done by a caoutchouc spine-bag. This is a powerful depressing agent, and care must be taken in its use. It may, however, be applied with safety for six or eight hours, the condition of the patient being carefully watched in the meanwhile. Sedative or antispasmodic agents are of no use whatever in acute traumatic tetanus. I have seen many drugs of this kind employed, without lessening in any degree the violence of the convulsions. In most cases, however, the inhalation of chloroform, or the administration of chloral, materially diminishes their severity, and gives the patient at least temporary ease.

In the *Subacute* or *Chronic* form of the disease, recovery is much more likely to take place; and it is only in these cases that antispasmodics and sedatives have been of use, and in these also chloroform and chloral are far more beneficial than in the acute cases. Almost every drug in the Pharmacopœia of a tonic, sedative, or antispasmodic nature has been employed in tetanus: and the recovery which has occasionally resulted has been perhaps over hastily attributed to the remedy, rather than to the employment of these dietetic and hygienic means which are of the first importance, by enabling the patient to live on until the disease wears itself out. Tonics, especially iron and quinine, have been employed by some. Elliotson was strongly impressed with the value of the carbonate of iron. Sedatives in all forms—conium, belladonna, opium, and their alkaloids—have been largely, and for the most part ineffectually, employed. Miller speaks highly of cannabis indica pushed to narcotism, three grains of the extract, or thirty minims of the tincture, being given every half hour or hour; and Haughton has employed nicotine in one-drop doses administered every second hour, with some apparent success in severe cases of traumatic tetanus.

The Calabar bean (*Physostigma*) is the remedy that perhaps deserves physiologically the most attention; for as it is nearly if not quite antagonistic

to the tetanic spasms of strychnia, it was hoped that it would be found equally useful as a sedative to the spinal cord in those arising from traumatic causes. In E. Watson's hands, very successful results followed its administration. Yet it is far from being a specific. I have tried it in several cases, with no appreciable good effect. It may be given by the mouth, hypodermically, or *per anum*: in the form of a solution or a tincture of the extract in half-grain doses, by the mouth; hypodermically, in doses of one-sixth of a grain: *per anum*, in grain doses. The dose should be given at least every second hour, until complete contraction of the pupil occurs. Stimulants, as brandy, should be administered to counteract the depression that will result from the use of the drug. At the same time that recourse is had to such measures as these, it must not be forgotten that the disease is one of great exhaustion, and that the patient will die worn out, unless he be supplied with plenty of nourishment. Beef-tea and wine should, therefore, be administered by the mouth, as long as the patient can swallow, and nutritious enemata by the rectum; and in this way the powers of life may be supported until the violence of the disease has spent itself. I am, however, disposed to think that even in these chronic cases, much more may be done by simple than by specific treatment. Clearing out the bowels by a turpentine enema, breaking the violence of the spasms and giving the patient rest and ease by chloroform inhalations or by chloral enemata, and keeping up the powers of the system by injections of beef-tea, egg, and brandy into the rectum, till the disease wears itself out, appear most likely to be followed by a satisfactory result, when used in addition to the hygienic measures recommended in the acute form of the disease.

CHAPTER XXXIV.

TUMOURS.

It is extremely difficult to give a short definition of the word Tumour, which shall cover all we mean by it and not extend beyond. According to Hunter, a tumour is "a circumscribed substance produced by disease, and different in its nature and consistence from the surrounding parts." Cornil and Ranvier define a tumour as a "mass composed of a tissue of new formation (a neoplasm) having a tendency to persist and to increase," and Lucke as "an increase in size from the growth of new tissue, which comes to no physiological termination." A tumour increases in size by an inherent force of its own, of the nature of which we are ignorant; and this is irrespective of the growth of the rest of the body, though the new tissue of which it is formed is developed by the same processes as those observed in normal growth. Although a tumour may closely resemble in structure the part in which it is growing, it can always be recognized by the naked eye if a section be carried through it, either by some slight difference in texture, or by its forming a clearly defined mass isolated from the surrounding structures. A tumour is distinguished from simple hypertrophy by the isolation of the growth and by the marked alteration in the form of the part to which it gives rise. In simple hypertrophy the new tissue is continuous with the old, identical with it in structure, and the general form of the part is maintained. Thus, if the great toe be uniformly enlarged in all its parts while maintaining the general form natural to it, the condition is termed hypertrophy, but a small outgrowth of bone from the ungual phalanx is a tumour. Inflammatory new growth is distinguished from a tumour by the fact that it takes place under the influence of some definite cause of irritation, and ceases at once if this be removed; the products of the inflammatory process are then absorbed more or less completely, any residue becoming developed into connective tissue. A tumour grows indefinitely, maintaining its original type of structure whatever size it may attain to, and is not dependent upon any evident source of irritation; in fact, should such arise, the tumour itself becomes inflamed. An inflammatory process is as a rule conservative in character, being concerned in some cases in repair of injury, in others in elimination of a virus, or the extrusion of a foreign body; the growth of a tumour serves no such purpose.

CLASSIFICATION OF TUMOURS.—The only complete classification of tumours adopted at the present time is founded on their anatomical structure, but in addition to this, other less perfect divisions are employed for clinical purposes. Surgeons have long divided tumours into two great classes, the **simple** or **non-malignant** and the **malignant**. As a rule, this division corresponds accurately with that founded on the histological structure, and from microscopic examination of a tumour we can say with certainty whether it is simple or malignant. Thus some tumours, as the cancers, are always malignant, and others uniformly benign, as a fatty tumour. In others there may be some

doubt if the fully developed portion of the growth only be examined. Thus some cartilaginous tumours are as simple as a fatty tumour, and others as malignant as a cancer. These have been termed **semi-malignant**, but the name is not a good one. In the example above mentioned, the malignant cartilaginous tumours and the simple will be found to bear no resemblance to each other if carefully examined at their growing margins.

The **Non-Malignant, Innocent, or Benign Tumours** are strictly local growths, and are rarely connected with any hereditary peculiarity. They resemble more or less completely the normal textures of the part in which they grow. They usually, though not invariably, grow slowly, are more or less distinctly circumscribed, being often enclosed in a loose capsule of connective tissue, and have no tendency to involve neighbouring structures; any change that they induce in contiguous parts consists simply in displacement or atrophy from pressure. They are usually single, but not infrequently multiple, developing either simultaneously or successively; but if in the latter mode, without any connection with preceding growths. If completely removed by operation, they do not return; but if left to the ordinary processes of nature, they slowly attain a great size, and at last the central parts degenerate or necrose, or if the tumour be superficial, the skin covering it ulcerates, and the mass inflames and sloughs. In some cases, after reaching a considerable size, they may remain stationary.

Malignant Tumours differ widely from those just described. The essential feature of malignancy is that the growth is not surrounded by any limiting capsule, but invades the structures amongst which it is growing, destroying them and occupying their place. The effect of the growth may not go beyond this, and the tumour would then be said to be merely *locally malignant*. In most malignant tumours, however, the effects are not merely local. Sooner or later the cell-elements of the tumour are carried through the lymphatics or the blood-vessels to distant parts, and there establish growths of the same nature as the primary tumour. The tumour is then said to possess **general** as well as **local malignancy**. A primary malignant tumour usually more or less closely resembles in structure the tissue in which it commenced. Thus, the essential feature of true cancers is the presence of epithelium in the new growth, and the form met with is always that normal to the part in which the tumour originated, as for instance, squamous in the tongue, columnar in the rectum, and spheroidal in the breast. In no malignant tumour does epithelium arise except from pre-existing epithelium. The malignant connective tissue tumours (sarcomata) show the same tendency. When they contain any fully developed connective tissue it is usually that normal to the part in which they are growing, as bone or cartilage in bone, or fibrous tissue in skin or fasciæ. Although, therefore, the structures composing malignant tumours are not, as was at one time supposed, foreign to the body, they deviate from the normal condition, so to speak, in time and place. The tissue of which the growth is composed is more or less approximated to the embryonic type normal to the part. Thus the malignant connective-tissue tumours are composed of embryonic tissue, sometimes pure, but more commonly showing a tendency towards development into the type normal to the part in which the tumour is growing. This is less marked in the true cancers which are, as a rule, composed of fully developed tissues, but even in these we often see the epithelium showing a tendency to return to the primitive rounded cell with a large nucleus,

and to lose the characteristics of the form in which it originated. Thus, in rapidly growing cancers of the tongue or rectum, the squamous or columnar cells may almost lose their special form. This reversion to the primitive type is not uncommon in the secondary tumours. In place, the deviation is most marked in the true cancers, in which we see epithelium penetrating deeply beneath the surface into parts where no such structure is normally present.

The following may be looked upon as the chief clinical and pathological characteristics of a malignant growth. The tumour, often at first circumscribed with a defined outline, soon invades the surrounding parts, and thus becomes fixed, moving, when manipulated, with the parts in which it lies, not in them. The rate of growth is, as a rule, rapid, but varies considerably. The vitality of the new tissue is usually low, and while its circumference is actively extending its central parts commonly undergo degenerative changes. When it reaches the surface it speedily sloughs, or ulcerates, giving rise to profuse discharge often offensive in character, and not unfrequently to abundant hæmorrhage. As its circumference continues to invade neighbouring parts a progressive destruction of the surrounding tissue takes place. At a variable period secondary growths make their appearance in different parts of the body. In the true cancers these appear first in the lymphatic glands, in some forms never going beyond these, in others subsequently extending to the viscera. In malignant connective-tissue tumours the glands often escape, the dissemination of the elements of the tumour taking place only through the blood-vessels, and the secondary growths appearing first in the viscera. When these have developed they serve as new foci for the dissemination of the disease, and usually assume a more active character than the primary affection. The patient now shows signs of serious modifications of nutrition. The body wastes, the skin becomes sallow, the digestive powers become impaired and anæmia supervenes; in short the patient develops the so-called *cancerous cachexia*. Most malignant tumours cause pain as they invade the surrounding parts, and, as a rule, they are more vascular than simple growths, and thus give rise to serious hæmorrhage when ulceration takes place. After removal they very commonly return locally, having infected the surrounding parts beyond the area removed. In other cases the patient escapes local recurrence, but perishes from the secondary growths. A malignant tumour if left to nature is inevitably fatal, from the exhaustion of the discharges or hæmorrhage, from implication of vital organs, or from the disturbance of health induced by the secondary tumours. Malignant growths are more commonly hereditary than simple tumours. The question of the local or constitutional origin of malignant growths will be discussed with cancers.

The term "*cancerous*" was at one time used as synonymous with *malignant*, but as our knowledge of the structure of tumours has increased, the large group of sarcomata has been separated from true cancers or carcinomata, and thus, though all cancerous tumours are malignant, all malignant tumours are not cancers. It is in this group of sarcomata that we find that less accurate correspondence between histological structure and clinical malignancy which gave rise to the use of the term "*semi-malignant*." Paget, for instance, observed that tumours apparently similar in structure may run a very different course in different individuals, in some being in every way innocent, and in others malignant. Thus a tumour, composed purely of spindle-shaped cells, may in

one case show no tendency to recur after removal, or to affect distant parts; whilst in another it may run a malignant course both locally and generally. The tumour would necessarily in both cases be classed under the same name in an anatomical classification. A careful investigation of the growing edge in the two cases would probably show that in the one case the tumour was growing in a capsule of areolar tissue, and in the other that this was wanting, and the new growth was distinctly invading the surrounding parts. Of the causes of this great difference in apparently similar growths we know nothing. In the cartilaginous tumours, which are sometimes given as typical examples of this uncertainty, the similarity of the malignant and simple forms is more apparent than real. In the malignant forms the cartilage will be found to be developed from a surrounding zone of embryonic tissue infiltrating the neighbouring structures. In the simple form the new cartilage is merely covered with a perichondrium, as in the normal cartilage of a growing bone. The former is a chondrifying sarcoma, the latter a true chondroma.

Even in undoubtedly malignant growths, as in carcinomata, we find the degree of malignancy very various in different cases without our being in any way able to account for it, either by the structure of the growth or by any peculiarity in the patient. Thus one man may die from secondary disease of the glands after a primary cancer in the tongue no bigger than a split pea, and another may show no glandular infection when half the tongue is destroyed. In other cases the malignancy may be from beginning to end local. This is the case in the disease known as rodent cancer. Some sarcomata recur locally, but after repeated removal the tendency may disappear and the patient eventually recover.

Innocent and malignant tumours are occasionally met with in the same person, four or five different kinds of growth even occurring in one individual. I have seen in one patient a carcinoma of the breast, an enchondromatous tumour of the leg, and an atheromatous cyst on the back, with scrofulous glands in the neck. New formations of different types may be found even in the same mass; thus, encephaloid carcinoma and spindle-celled sarcoma have been found together in the testis. This, however, must not be taken as any evidence of the possibility of the conversion of one into the other, but rather as the result of a departure in different directions from the normal mode of growth. There is indeed no proof that a non-malignant can be converted into a malignant tumour of a different type; a fibrous tumour may take on rapid growth and assume the characters of a malignant sarcoma, but there is no evidence that it can ever be changed into a carcinoma. A malignant tumour may, however, appear on the site of a non-malignant growth that has been removed: thus I have seen a scirrhus nodule grow in the cicatrix left after the removal of a cystic sarcoma of the breast. Warts and moles may exist for years without causing trouble, but at last may rapidly grow and develop either into malignant sarcomata or squamous carcinomata.

A classification founded upon an anatomical basis not only enables the observer to comprehend the precise relation which any particular growth under observation bears to others that resemble it, but leads him to trace the origin of the new formation from the pre-existing structures of the part in which it occurs, thus forming the first step towards a knowledge of the etiology of the disease. Tumours are said to be *heterologous* or *homologous*, according as they present a greater or less deviation from the normal condition

of the tissues from which they spring. These terms are essentially relative; and it is only to instances at the extreme ends of the series that either term can be definitely applied. At the same time it must be borne in mind that Virchow's law holds good even for the most heterologous growths: this law states, that "the same types of anatomical structures exist in new formations as are found in the body generally," and he thereby denies the possibility of the occurrence of a true heteroplasia, and the existence in new formations of specific elements differing from any normal cells in the body. The more heterologous the growth—that is, the greater the departure from the normal structure of the part in which it occurs—the more malignant, as a rule, will it be; whilst the reverse, with some exceptions, is true of homologous formations.

In classifying tumours according to their anatomical structure, they are divided primarily into four chief groups. First, those composed of one of the forms of connective tissue; secondly, those composed of tissue resembling one of the higher tissues of the body; thirdly, those composed of embryonic tissue, either pure or developing into connective tissue; and fourthly, those in which epithelium forms the essential part of the growth. Cystic tumours are classed by themselves, forming a fifth group.

General Characters of Typical Tissues.—Before proceeding to consider the individual growths, it will be desirable to describe briefly the essential features presented by the structures upon which the types of some of the classes are founded.

First as to **connective tissue**:—This exists throughout the body, presenting many varieties of form adapted to the special functions of the part in which it appears. It consists essentially of an intercellular substance, homogeneous, hyaline or fibrillated, in which are imbedded cells having an oval, caudate, fusiform, or branched form, and usually presenting a distinct central nucleus and nucleolus. In addition to these, in fibrous or areolar tissue, wandering cells, with amoeboid movements, are normally present. These are regarded as white corpuscles, which have migrated from the vessels. The fixed connective-tissue corpuscle was looked upon by Virchow and his followers as the starting-point from which are derived the various cell-structures, entering into the formation of all tumours. Other pathologists have believed that connective-tissue tumours might arise by the growth and development of leucocytes which have migrated into the affected part. At the present time, whatever part may be ascribed to leucocytes in the formation of new tissue as a consequence of inflammation, they are not supposed to take any share in the growth of tumours of the connective tissue type.

The following are the chief forms of connective tissue: areolar tissue, adipose tissue, white fibrous tissue, yellow elastic tissue, bone, and cartilage. Mucous tissue must also be included under the same type. It is met with as the Whartonian jelly of the umbilical cord, and in the adult only as the vitreous humour of the eye.

The simplest form of **embryonic tissue** is composed of small round cells about the size of white blood corpuscles, connected with each other by a small quantity of homogeneous intercellular substance. The cell consists merely of a small mass of protoplasm with a nucleus in the centre, which may be somewhat difficult to distinguish. The vessels in such tissue are abundant, and extremely thin-walled, like those of granulations. The modifications

in this tissue observable in tumours are seen both in the cells and in the intercellular substance. The cells may be of great size, almost resembling epithelial cells with a large oval vesicular nucleus: they may be spindle-shaped, oval, or stellate. The intercellular substance may be small in quantity and homogeneous, or it may be increased in amount without apparent change in its nature. The most common modification is a development of fibrous tissue between the cells. In other cases it may be developed into bone or cartilage. It must be remembered, however, that in tumours classified under the type of embryonic tissue, with rare exceptions, a recognizable intercellular substance, either homogeneous or fibrous, extends between the individual cells, and this serves as an important point of distinction between some modifications of embryonic tissue and epithelium.

Epithelium is composed of cells united together by a homogeneous material or cement, which is not sufficient in quantity to be recognizable under ordinary circumstances. No vessels ever penetrate amongst the cells, nor do the fibres of the surrounding or subjacent connective tissue extend between the individual elements. Consequently if, on washing a microscopic section so as to remove the cells, a reticulate fibrous stroma is seen forming spaces in which single cells have lain, the tissue is not epithelial. It will be seen hereafter that some forms of tumour, composed of one of the modifications of embryonic tissue, may so closely resemble epithelial growths that it is only by carefully observing a washed specimen that the distinction can be made. Epithelium cells vary much in shape and size, and their outline is sharply defined. They possess usually one nucleus, sometimes two, with one or more highly refracting nucleoli. The nucleus is frequently eccentric. The form of epithelium met with in a primary tumour is always similar to that normal to the part in which the tumour is growing: thus in the skin it is squamous, in the intestines columnar, and in glands it is spheroidal. In secondary tumours, the type of epithelium corresponds to that of the primary growth. Primary tumours containing epithelium never originate except in connection with parts in which epithelial cells are normally present. This fact has led to another classification, according to the origin of the part in which the tumour grows, from one or other of the three layers into which the blastoderm divides in the first stages of development. From the superficial layer or epiblast are developed the central nervous system, the organs of sense and the cuticular covering of the body, and the glands of the skin; from the lower layer or hypoblast arise the epithelial lining of the air-passages, and of the alimentary canal with the epithelial lining of ducts opening into it, and the special epithelium of the glands themselves. The rest of the body arises from the middle layer or mesoblast. It is supposed that, after this early differentiation of the embryonic cells, the tissues which belong to one layer can never be developed from the cells of another. Thus tumours such as carcinomata, in which epithelium forms the active and essential element, can never develop primarily in those parts which arise from the mesoblast. Tumours have, therefore, been classified as epiblastic, mesoblastic, and hypoblastic.

The following classification may be adopted as possessing clinical convenience, and, at the same time, presenting, as far as possible, an anatomical uniformity.

I. Cystic Tumours generally.

II. Tumours composed of one of the modifications of fully developed Connective Tissue.

- a. Fat—Lipoma.
- b. Fibrous Tissue—Fibroma.
- c. Cartilage—Chondroma, Enchondroma.
- d. Bone—Osteoma, Exostosis.
- e. Mucous Tissue of Umbilical Cord or Vitreous Humour—Myxoma.

III. Tumours which resemble in structure more or less perfectly one of the more Complex Tissues of the body.

- a. Muscle—Myoma.
- b. Nerve—True Neuroma.
- c. Blood-vessels—Angioma, Haemangioma, Naevus.
- d. Lymphatic Vessels—Lymphangioma, Lymphatic Naevus.
- e. Lymphatic Glands—Lymphadenoma.
- f. Papillae of Skin or Mucous Membrane—Papilloma.
- g. Secreting Glands—Adenoma.

IV. Tumours composed of Tissue which is either purely Embryonic, or is showing some signs of a tendency to develop into adult tissue of the Connective type.

Sarcomata.—These are subdivided first, according to the shape and size of the cells of which they are composed, into round-celled, oval-celled, spindle-celled, giant-celled sarcoma, &c.; and secondly, according to the development they may undergo, into fibrifying, chondrifying, ossifying sarcoma, &c.

V. Tumours composed of Cells of an Epithelial Type, arranged in spaces in a vascular stroma consisting of more or less perfectly developed fibrous tissue.

Carcinomata or true Cancers.—Spheroidal or Glandular, Squamous and Columnar.

ETIOLOGY OF TUMOURS.—In the great majority of cases we have not the remotest idea of the causes which have led to the growth of the tumour. Hereditary tendency has a marked influence in the growth of many forms, more especially of malignant growths. The cancers are certainly inherited in a large proportion of cases; in simple tumours hereditary tendency is less marked, but is occasionally to be traced. Paget also makes the very interesting practical remark, which agrees entirely with the result of my own observation, that the children of cancerous parents may be the subjects of tumours not carcinomatous in structure, but closely resembling such growths in the rapidity of their progress, their liability to ulcerate and to bleed, and their great disposition to return after removal. Local irritation or mechanical injury is undoubtedly the determining cause of the growth of the tumour in a certain proportion of cases. The effects of this cause are also most marked in malignant growths. The proportion, however, in which such a cause can be traced is very small, varying, according to different authors, from 7 to 14 per cent. Cohnheim has suggested the hypothesis that some tumours may arise from the minute portions of embryonic tissue which have persisted in an undeveloped state amongst the mature tissues; but there is little definite evidence to support this theory.

CYSTIC TUMOURS.

A **Cyst** is defined as a cavity of new formation, or resulting from the abnormal distension of a natural space, surrounded by a more or less distinct

wall, and filled with fluid or semi-solid matter. The wall of a cyst is lined by epithelium or endothelium, or has no definite lining, according to its origin. The accurate classification of cysts is difficult, because conditions which are pathologically similar are clinically spoken of as cysts in some parts of the body and not in others. The method usually adopted is that in which they are divided according to their mode of origin, as follows :—

1. Cysts arising from the distension of pre-existing spaces.
2. Cysts of new formation.
3. Congenital cysts.
4. Parasitic cysts.

1. CYSTS ARISING FROM THE DISTENSION OF PRE-EXISTING SPACES.—These are subdivided into : (a.) Exudation cysts ; and (b.) Retention cysts.

(a.) **Exudation Cysts** arise from chronic exudation into cavities which are not provided with excretory ducts, as, for instance, the bursæ, which often attain a considerable size in these circumstances. Strictly speaking, chronic synovitis, with "dropsy of the joint," hydrocele of the tunica vaginalis, and spina bifida, should be included in this class, but clinically these affections are never spoken of as cysts. A form of exudation cyst is sometimes met with in connection with serous and synovial membranes, which arises from a hernial projection of the membrane with subsequent constriction and obliteration of the neck of the protrusion, so that a separate cyst is formed. Some of the cysts met with in the popliteal space, and some of those formed in connection with the sheaths of tendons, or *ganglia*, are supposed to be formed in this way. Similar cysts are occasionally met with in one of the situations of abdominal hernia, which are evidently formed by the obliteration of the neck of the sac of the peritoneum, with subsequent exudation into the closed cavity.

In cysts formed in connection with synovial membranes or bursæ, opaque, white, or yellowish bodies, resembling melon seeds in size and form, are not unfrequently met with. Sometimes these are attached to the cyst-wall by a narrow pedicle, but more often they are free. They are supposed to arise in three ways : first, as an outgrowth from the cyst-wall ; secondly, by changes taking place in extravasated blood ; and lastly, from a fibrinous exudation from the wall of the cyst. The presence of blood-crystals, which has been recognized in some cases, proves that they occasionally arise in the second way. The symptoms and treatment of these affections are described with diseases of bursæ (see Vol. II.).

One form of *cystic disease of the ovary* may be placed under this head, as it arises from dilatation of the Graafian follicles. The cysts are usually numerous, but do not individually reach any very great size. They contain a serous fluid, and ova have been recognized within them, thus proving their origin.

(b.)—**Retention Cysts** arise from an obstruction to the escape of some natural secretion, in consequence of which the acini, or tubules, of the gland become expanded, or the duct becomes dilated to such an extent as to form a distinct cyst. The process by which the cyst is formed is not one of simple dilatation : it is accompanied by a new growth of fibroid tissue, resulting from the irritation caused by the tension of the retained secretion, so that in almost all cases the wall of the fully developed cyst is many times thicker than the structure from which it originated. If the cyst springs from a duct, the walls of which contain involuntary muscular fibre, this will be found to have disappeared, the new tissue being purely fibrous. The cyst-wall is lined with

epithelium of the same character as that naturally lining the cavity from which it has originated. The contents may still resemble the natural secretion, but more commonly they are altered by degeneration and inspissation, or by exudation from the wall of the cyst.

Retention cysts may be divided into three groups: (*a.*) Atheromatous cysts; (*β.*) Mucous cysts; and (*γ.*) Cysts from the dilatation of large ducts. The first two groups are spoken of as "follicular cysts."

(*a.*) **Atheromatous Cysts** are those arising in connection with the sebaceous glands of the skin. They are usually situated upon the scalp, face, neck, or back; sometimes, however, they occur elsewhere—thus I have removed a very large one from the fore part of a girl's arm, and others from the labia and groin. Their size varies from that of a pin's head to an orange: the smallest occur on the eyelids, the largest on the shoulders and scalp.

Fig. 350.—Contents of Atheromatous Cyst (454 diam.).

- a.* Epithelial cells showing various degrees of fatty degeneration.
- b.* The same with calcareous degeneration.
- c.* Crystals of cholesteroline.
- d.* Oleaginous and fatty particles.

Fig. 351.—Wall of Atheromatous Cyst (500 diam.).

- aa.* Epidermal lining, the superficial cells swollen and fatty.
- a'.* A thick or fatty cells peeling off.
- bb.* Fibrous capsule.
- c.* Surrounding connective tissue.

Atheromatous cysts are often very numerous, especially about the head. Most frequently they form in women about the middle period of life; they are smooth, round, or oval, usually adherent to the skin at one spot but movable over the deeper structures, either semi-fluctuating or elastic, though sometimes solid to the touch. In some parts where the sebaceous follicles are large, as on the back, a small black point can often be detected on the surface of the tumour, through which an aperture may be found leading into its interior, and allowing the expulsion of its contents. A sebaceous tumour consists of a cyst-wall and contents. The cyst-wall is composed of dense white fibrous tissue, having elongated connective-tissue corpuscles scattered through it. It is connected to the surrounding parts by loose areolar tissue, containing yellow elastic fibres in some abundance. The thickness of the wall varies greatly. When the cyst is situated on the hairy scalp it is always tough and thick, while in all other situations it is much thinner. Immediately in contact with the inner surface of the cyst-wall, a layer of actively growing

epithelial cells is found closely resembling the deeper layers of the epidermis : further from the wall these assume a more flattened form ; then they become filled with fat granules, and finally break down into a fatty granular mass (Fig. 351). The atheromatous mass forming the contents of the cyst is composed of this fatty *débris*. If examined when freshly removed from a tumour, it will be found to be soft, creamy, pultaceous, or sometimes cheesy-looking, of a yellowish white colour. Sometimes in old cysts it becomes dry and laminated, looking not unlike Parmesan cheese. In some cysts of old standing and large size, the contents may be semi-fluid, the more liquid parts being of a brown, green, or blackish tint, and having a very offensive sour smell. These various contents are composed of sebaceous matter, mixed in various proportions with epithelial scales, fat granules, and cholesterine (Fig. 350). Sometimes the wall sends fibrous septa towards the centre of the cyst, apparently representing the remains of the tissue between the acini of the follicle ; but true papillæ or hair-follicles are never found in cysts due to obstruction of the excretory ducts of a sebaceous follicle. Occasionally a part of the cyst-wall may undergo calcification, and calcareous particles may be found among its contents (Fig. 350 *b*). Malherbe has described a true ossification of the cyst-wall with calcification of the epithelium cells. This is rare, and the tumours have been described as osteomata of the skin before their true nature was understood. Some forms of cysts of new formation closely resemble those just described in their contents and naked-eye appearances, but differ from them in the structure of their walls, which is that of true skin. These will be referred to again under "dermoid cysts."

Progress.—The growth of these tumours is often very slow ; but not unfrequently, after remaining stationary for years, they increase rather rapidly. The tumour itself, though painless, may give rise to uneasy sensations, by compressing nerves in its vicinity ; it usually continues to grow slowly, until the patient, being annoyed by its presence, has it removed by operation. If left untouched, it occasionally, though rarely, happens that the sebaceous matter, exuding through an aperture on its surface, forms a kind of scab or crust, which by a process of sub-deposition becomes conical ; and, being gradually pushed up from below, at the same time that it assumes by exposure a dark brown colour, forms an excrescence that looks like a horn, and is usually considered to be of that character. These "horns" have been met with on the head, on the buttock, and in other situations. The accompanying drawing (Fig. 352), is taken from a child four years old, brought to me to have its horn removed ; a woman also once applied to me with one about an inch and a half long, growing from the upper lip.

In other cases, these tumours inflame and suppurate ; the skin covering them becomes adherent and reddened, ulceration takes place, and, if the cyst be small and dense, it may be destroyed by suppuration around it. If it be larger, ulceration of the integuments covering it takes place, and the sebaceous matter is exposed ; this may then putrefy, become horribly offensive, and break away in unhealthy suppuration. In other cases, peculiar changes take place in the cyst-wall : large granulations are thrown out in it, and the cyst-wall appears to vascularize, becoming irregular and nodulated, rising up in tuberos growths with everted edges, exuding a foetid discharge, becoming adherent to subjacent parts, and assuming a malignant appearance, forming at last a sore as large as a saucer (Fig. 353). Cysts that have undergone this

change show great local malignancy, rapidly infiltrating and destroying the surrounding parts, but as a rule the lymphatic glands are not implicated. I have seen a case in which the skin was destroyed from a little below the vertex to the root of the neck, and from ear to ear transversely. The surface was covered with fungating granulations, but there was no implication of the glands. Lücke states that in such cases a genuine transformation of the atheromatous cyst into a squamous carcinoma has taken place, the epithelium penetrating the cyst-wall and growing in the tissues beyond. It most commonly occurs after middle life.

Diagnosis. The only diseases with which these tumours can be confounded are abscesses and fatty growths. From an *abscess* a sebaceous cyst may be distinguished by its history, slow growth, situation, elasticity, and mobility, and if there should be present the dilated orifice of the sebaceous duct, through

Fig. 352 — Horn on Nose of a Child.

Fig. 353 — Ulcerated Cystic Tumour of Scalp.

which some of the contents can be squeezed, the microscopical examination of these will serve to confirm the diagnosis. From *fatty tumours* these growths may be diagnosed by their firmer and more regular feel; and in case of doubt, by the evacuation and examination of their contents. Sometimes the cysts may be lobulated so as closely to resemble a fatty tumour (Fig. 354). But even in these cases they may be distinguished by the Surgeon pressing on the edge of the tumour; if cystic it will remain fixed, and the finger can be pressed through it; if a lipoma it will roll away. When this cyst has become cancerous, its origin can be ascertained only from the history.

The *Treatment* of a tumour of this kind consists simply in its removal, after which it is never reproduced, unless a small portion of the cyst-wall has been left behind. So long as these tumours are small, and do not give rise to inconvenience, they may be left without surgical interference. But when large and more particularly when they have become inflamed, they should be removed. The method of operation will vary according to the situation of the cyst and the thickness of its wall. When situated on the scalp, where the cyst is dense and tough, the tumour may very readily be removed by transfixing it and the skin covering it with a scalpel, squeezing out the contents, and then seizing the cyst-wall with forceps and pulling it out. In this little operation

there are two points that require attention : first, the base of the cyst should never be transfixed ; and, secondly, no attempt at dissection should be made. If either of these precautions be neglected, troublesome hæmorrhage may ensue. The hair should be cut away from the immediate neighbourhood of the tumours and the scalp thoroughly washed with soap and hot water and a dilute solution of ammonia. A towel soaked in 1 in 50 carbolic lotion should be applied for half an hour before the operation. The incisions should be sutured, and dressed with an efficient antiseptic dressing firmly applied with a capeline bandage. When situated about the face, back, trunk, or limbs, sebaceous cysts usually require to be dissected out, being thin and more closely incorporated with the skin ; and often, in consequence of former inflammation, adherent to the subjacent parts. In doing this, care should be taken that the whole of the cyst-wall is extirpated. If, however, any portion of the wall be left, it should be freely rubbed with nitrate of silver, lest a troublesome fistula remain. When the tumours are situated between the shoulders or on the back, and the patient is unwilling to submit to an

Fig. 354.—Large Atheromatous Cyst from the Back, simulating Fatty Tumour. (Half the natural size.)

operation, I have sometimes cured them by opening up with a probe the small black orifice, which will always be found leading into them, squeezing out the contents of the cyst, and then pushing in two or three silk threads, which, acting like a seton, have excited the amount of inflammation requisite to bring about a closure of the cyst.

The horns and malignant ulcers that result from these growths require excision. If, however, the ulceration be connected with the cranium by its base, or be very extensive, as in the case depicted (Fig. 353), it may be impossible to remove it, and it will be safer to treat it by the application of the chloride of zinc, or by occasionally touching it with *potassa fusca*.

(B) **Mucous Cysts** arise in mucous membranes in the same way as atheromatous cysts in the skin. Their walls are usually thin, and, as a consequence, they seldom reach any great size. Their contents usually consist of a turbid viscid fluid, and cholesterine is sometimes present. They are most commonly met with in the mouth, and occasionally in the tongue. They form one variety of ranula ; and the so-called dropsy of the antrum, is in most cases a mucous cyst developed within the cavity. They are also met with in the labia, arising from the glands of Bartholini, and Cowper's glands in the male are said occasionally to undergo a similar change. They are best treated by excising a piece of the wall and applying a strong solution of chloride of zinc to the interior of the cavity.

(Y) **Cysts arising from the dilatation of the ducts of glands** are less

common. They are met with in the mamma from obstruction of the lacteal ducts, in the mouth as ranula from obstruction of Wharton's duct, and in the testicle, forming the so-called encysted hydrocele or spermatocele. Cysts of similar origin are also met with in the liver and kidney. The consideration of the symptoms and treatment of these cysts must be deferred to the chapters on the diseases of the organs in which they occur.

II. CYSTS OF NEW FORMATION.—Cysts of new formation may be divided into (a) Simple or serous cysts; (b) Hæmatoma or blood-cyst; (c) Cystic tumours, compound and proliferous cysts; (d) Cysts in tumours.

(a) **Simple or Serous Cysts** may occur in any part of the body. They are composed of a thin wall lined with a flat endothelium, like that of a serous or synovial membrane. Their contents are a slightly viscid serous fluid. They are supposed to arise from effusion of fluid in the spaces of the areolar tissue; by the pressure of the fluid the surrounding fibres are squeezed together and thus form the membranous wall of the cyst, which subsequently becomes thickened by new growth of fibrous tissue.

False or Accidental Bursæ arise in this way over any bony prominence which is exposed to pressure and friction; in fact there is some reason to believe that all bursæ are thus formed. Whether this be the case or not, false bursæ when once formed are liable to the same diseases as those that are usually assumed to be of normal development. The most common and troublesome false bursa is that formed over the projecting head of the first metatarsal bone which gives rise to the condition known as a "*bunion*."

It is probable that many of the tumours classed as "*ganglia*" are formed in the same way, especially those on the back of the hand, as the extensor tendons in that region do not possess a sheath sufficiently definite to allow of a normal protrusion from it.

The serous cysts met with in the neck do not belong to this class. They are either congenital or formed by dilatation of pre-existing spaces, such as the bursæ about the hyoid bone or larynx.

(b.) **Hæmatoma or Blood-Cyst.**—Under this term have been included four entirely different conditions:—

(1.) *The true blood-cyst.* This is a thin-walled cyst containing pure blood; if its contents are withdrawn by puncture it rapidly fills again, and cases have been recorded in which death from hæmorrhage has followed incisions made into such cysts. They are most common about the neck, in close connection with the sheaths of the vessels, or the parotid region; but they have been met with elsewhere. Their origin is very doubtful. Some, from their multilocular form and direct communication with the veins are supposed to have originated in naevi. In others, the cyst is single, and has no connection with any distinct vessel; the blood seems in these to be furnished by an extremely vascular cyst-wall, as in a case recorded by Gay. These sanguineous cysts may sometimes resemble in general appearance a soft vascular sarcoma. A case of this kind was sent to me by Henry Bennet: a tumour about the size of an orange, of nodulated appearance, was situated in the leg of a woman below the knee, where it had been gradually increasing in size for about a couple of years. So close was the resemblance to malignant disease, that amputation had been advised by some Surgeons who had previously seen the case; as, however, the growth, on examination, proved to be a sanguineous cyst, with thin and adherent walls, and as it extended too deeply into the ham to admit of ready removal, I

reduced it by successive tapplings, and then, laying it open, allowed it to granulate from the bottom. When practicable, however, the cyst should always be dissected out.

(2.) Many cases have been described as blood-cysts, which are in reality *serous cysts into which an accidental hæmorrhage has taken place*. In these, unless the hæmorrhage be very recent, the blood has undergone changes in colour from disintegration of the corpuscles. In some cases it is treacly from absorption of a part of the serum.

(3.) The term "hæmatoma" is more commonly applied to *cysts which have their origin in an extravasation of blood*. The changes that occur in extravasated blood have already been described (p. 812). In some cases, as there pointed out, absorption fails to take place. The extravasated blood distends the spaces of the areolar tissue, or fills a cavity formed by subcutaneous laceration. A deposit of fibrin first takes place, and subsequently, in consequence of the irritation caused by the tension of the fluid, an ill-defined capsule of fibrous tissue is formed round the extravasation. The contained blood becomes altered in colour from disintegration of the corpuscles, and finally the contents assume the appearance of more or less darkly-tinged serous fluid. The hæmatoma of the ear so frequently met with as the result of violence during the game of football, when played according to the Rugby rules, is a cyst of this kind. Similar cysts are not uncommonly met with in the ears of lunatics, and in these cases the cause is not so evident. I have seen a large hæmatoma on each ear of a lunatic. The contents consisted of semi-solid coagulum.

Similar cysts are occasionally found as a result of hæmorrhage into the subarachnoid space. The coagulated blood in the course of time becomes completely discoloured, and forms a thin membrane-like layer of tissue which encloses a cavity containing a small quantity of serous fluid.

(4.) In many cases which have lately been recorded, it has been found that tumours which were described clinically as blood-cysts were in reality *soft sarcomata*, the structure of which had been broken down by hæmorrhage. (See Sarcomatous Blood-cysts.)

(c.) **Cystic Tumours.**—These are tumours in which the development of cysts is an essential of their growth, and not merely an accidental complication. To this class belong the *compound* or *multilocular cysts* met with in the ovary, the mamma, and the testicle. In many cystic tumours solid growths project from the walls into the cavities, and from this they have received the name of *proliferous cysts*; the growths are spoken of as *intracystic growths*. Multilocular cysts, as met with in the ovary, form the best example of this form of tumour. These cysts are composed of a fibrous wall and an inner lining of columnar epithelium. Immediately beneath the epithelium is a layer of embryonic tissue, from which spring the intracystic growths. These assume the form of branched papillæ projecting into the cavity of the cyst; they are covered by columnar epithelium. Wilson Fox showed that secondary cysts may be formed by the adhesion of adjoining masses of this papillary growth, thus forming small closed spaces or daughter-cysts, which gradually become distended by secretion. In some cases the reverse process takes place, and instead of the number of cysts increasing by the formation of daughter-cysts, they become diminished by coalescence. Unilocular ovarian cysts are supposed to be often formed in this way. The contents of these cysts vary from a liquid as thin as ordinary blood-serum, to a viscid fluid. It is alkaline in

reaction and sometimes coloured from the admixture of altered blood. Chemically it is found to contain met-albumin and par-albumin, and sometimes mucin, from which it is assumed that the fluid is a true secretion, in the formation of which the epithelial lining is concerned.

In the proliferous cysts of the mamma the intracystic growths assume a lobulated or cauliflower-like form, and in structure are found rudely to resemble the normal structure of the mamma. These growths may, according to Paget, by their increase in size cause the gradual absorption of the more fluid contents, until, at last, their development is arrested by the cyst-wall. The tumour would then resemble an ordinary adenoma of the mamma surrounded by a distinct capsule.

The cystic tumours of the ovary, mamma, and testis, will be more fully described with the diseases of those organs.

(d.) **Cysts in Tumours** form, not as an essential part of the growth, but

Fig. 355. Head and neck of an adult, with diagrammatic lines, representing the situation and direction of the branchial and other clefts: 1, 2, 3, 4, first, second, third, and fourth clefts; 5, intermaxillary cleft; 6, Fronto-orbital fissure; 7, nasomaxillary foramen.

as an accidental complication. They may arise from softening of portions of the growth, or from hæmorrhage into its structure. As a rule they are not surrounded by a distinct wall, but in some simple tumours they seem to increase by transudation of serum into the cavity, and thus the surrounding structure may be compressed so as to resemble a limiting membrane. Cartilaginous tumours occasionally become cystic from mucous softening of the matrix. Cysts in tumours will be more fully described with the growths in which they occur.

III. CONGENITAL CYSTS.—This class includes:—(a.) Cysts lined with skin or mucous membrane and resulting from inclusion of the epiblast within the mesoblast during development or more rarely from imperfect obliteration of some foetal canal. These are Dermoid Cysts. (b.) Cysts arising from imperfectly obliterated temporary foetal structures.

(a.) **Dermoid Cysts.**—The majority of these result from inclusion of a portion of the epiblast. Cysts thus formed are distinguished as "*sequestration dermoids*," by Bland Sutton, who has added much to our knowledge regarding this highly interesting class of cystic formations.

It will be remembered that in the very earliest stages of development the germinal membrane or blastoderm divides into three layers. From the most superficial of these, or epiblast, is developed the cuticular covering of the body, with the hairs and glands of the skin and the central nervous system; from the deepest layer, or hypoblast, arise the epithelial lining of the air-passages and of the alimentary canal and the epithelium of the glands connected with it; while the rest of the body is developed from the middle layer or mesoblast. The blastoderm is at first flat, but in the process of development it becomes folded on itself, and thus encloses the abdominal cavity; the mouth and neck are developed from lateral processes, the branchial arches, which curve downwards till they meet in the middle line, and between these arches are fissures, the branchial clefts. The lateral parts of the face are developed in the same way, while the nose and middle parts above the mouth arise from a descending process proceeding from the frontal region. By the confluence of all these the face and throat are formed. It can easily be understood how in this process a portion of the epiblast may become included and remain imbedded in the tissues belonging to the deeper layer. Should this happen, a closed cyst may be formed lined internally with the structures proper to the skin, and yet entirely unconnected with it. Dermoid cysts are met with most commonly in the

Fig. 355.—Wall of Dermoid cyst (40 diam.).

- a. Epidermis.
- b. Hair-follicle.
- c. Sebaceous gland.
- d. Surrounding connective tissue with small masses of fat.

subcutaneous tissue in situations in which their position can be explained by the process of inclusion above described. The accompanying diagram, (Fig. 355) from a paper by Cusset, well illustrates the lines in the neck which correspond to the branchial clefts, and to the meeting of the various processes from which the face is developed in the fetus. It is in these lines that dermoid cysts are most commonly met with. They are most often found at the upper and outer angle of the orbit. Here there is often an indentation in the bone corresponding to the cyst, and in some cases the bone may be wanting, the tumour being in direct contact with the membranes of the brain, a fact which it is important to remember in attempting their removal. They have occasionally been found within the skull on the meninges.

On the trunk dermoid cysts are occasionally met with along the middle line where the opposite halves of the body wall join each other.

The walls of the superficial dermoid cysts present all the structures of true skin—cuticle, cutis vera, papillæ, sweat-glands, sebaceous follicles, hair-

follicles, and hair (Fig. 356). Their contents are usually rather thinner than those of the ordinary atheromatous cyst, though closely resembling them in appearance. Often a small ball of coiled-up hair is found inside the cavity. The contents are the accumulated secretions of the glands in the cyst-wall mixed with desquamated epithelium.

It is interesting to note that cysts lined with epidermis are occasionally met with on the fingers or elsewhere as the result of punctured wounds. In such cases the epithelium from which the cyst formed has been driven into the subcutaneous tissue by the instrument inflicting the injury.

Those rarer forms of dermoid cysts which develop from an embryonic canal which fails to undergo the normal process of obliteration are distinguished by Bland Sutton as "*tubulo-dermoids*." A well-known example is the dermoid cyst which occasionally forms beneath the tongue in the middle line of the floor of mouth. This cyst, in some cases at least, is developed from the thyreo-lingual duct or canal of His, which passes from the foramen caecum at the back of the tongue downwards behind the hyoid bone to the isthmus of the thyroid body. Normally this duct becomes completely obliterated, but should the closure fail in that part which lies above the hyoid bone a sublingual dermoid cyst may result. To the same class belong those dermoid cysts which occasionally occur in the neck beneath the deep cervical fascia at the anterior border of the sterno-mastoid, and arise in a deep unobliterated portion of one of the branchial clefts. Dermoid cysts of this class may or may not contain sebaceous glands in their wall, and accordingly the contents may consist of the usual sebaceous matter or of clear fluid.

Dermoids of the ovary are remarkable from the complex nature of the structures often present in their walls. Among these may be mentioned bone, teeth, cartilage, &c., whilst in two remarkable specimens a mammary gland projected into the interior of the cyst; one of these recorded by Bland Sutton is preserved in the Museum of the Middlesex Hospital. Ovarian dermoids may gradually contract adhesions to the omentum or mesentery and lose their connection with the ovary itself.

(b) **Congenital Cysts arising in Imperfectly Obliterated Portal Structures.**—Certain dermoid cysts already described arise in this way, but the cysts included in this class differ from them in possessing no lining of skin or mucous membrane. To this variety may be referred the cysts of the spermatic cord which arise from the distension of a portion of the processus vaginalis testis which has remained unobliterated, although cut off from the cavity of the peritoneum above and the tunica vaginalis below.

Some tumours of the testicle and some growths arising in the neighbourhood of the kidney which contain large cysts lined with columnar epithelium are supposed to arise from the unobliterated remains of the Wolffian body; and the parovarian cysts arising in the broad ligament of the uterus have the same origin.

A rare form of congenital tumour known as a **teratoma** may conveniently be mentioned here. It consists of a complicated mass of various tissues and organs, which is adherent to or included within the body of an otherwise perfectly developed fetus. Certain congenital tumours of the sacral region are supposed to be of this nature.

(c.) **Parasitic Cysts.**—Cysts occasionally come under the care of the Surgeon which owe their origin to the presence of a *parasite*. The most

common of these is the **hydatid cyst**, which, although somewhat rare in this country, is extremely common in Australia. The parasite is met with in its fully developed state only in the wolf and dog. It is a small tapeworm about $\frac{1}{2}$ inch in length, the *tænia echinococcus*, consisting of four segments or proglottides, the last of which is the largest, and contains the ova. The latter usually find their way into the human subject in water or in food contaminated by the excrement of the dog. On entering the human intestine, the small embryo contained in the egg is set free, and by means of a boring apparatus with which it is provided, penetrates the wall of the gut. It is then carried by the blood-stream to some distant part, in which it develops into a cyst or hydatid. The hydatid cyst is composed of an outer cuticular layer and an inner granular lining composed of cells, muscular fibres, and a water vascular system. The contents of the cyst consist of a clear fluid of very low specific gravity, usually not over 1007, and containing either no albumen or the faintest possible trace, with a considerable quantity of sodium chloride. The cyst-wall to the naked eye appears as a delicate, semi-transparent, elastic membrane not unlike the white of a hard-boiled plover's egg. It is seldom more than one-eighth of an inch in thickness, and can be seen by the naked eye to be laminated, and a still finer lamination is recognized under the microscope. On the inner surface of this membrane the *tænia* heads or scolices are formed by a development from the living tissue lining the cyst. The head is a small round dot, just recognisable to the naked eye, and about $\frac{1}{100}$ inch in diameter. It is provided with four suckers and a ring of hooklets, which are generally seen retracted into the middle of the head (Fig. 357). If the hydatid perishes, these heads break up, but the hooklets being indestructible, can usually be detected in the fluid. The cyst may be single, but very commonly "daughter cysts" are formed from the wall of the parent cyst, and become free in the cavity or outside it. The parasite is not capable of further development in man, and it is only by a migration in some way again to the dog or wolf that it can reach the stage of the fully developed *tænia*. The size to which the cyst may attain is sometimes enormous, as much as five pints of fluid having often been removed. The irritation set up by the cyst causes a development of fibrous tissue in the structures surrounding it, which usually assumes the form of a tolerably distinct membrane or pseudo-cyst. This is of course continuous with the tissues in which the parasite is lying, and cannot be removed. The cyst belonging to the parasite itself is usually loosely attached, and can be peeled off without difficulty. Hydatid cysts are found in almost all parts of the body. They are most common in the liver, and occur in other organs in the following order of frequency:—lungs, muscles and subcutaneous tissue, kidneys, pelvis, nervous centres, bones and breast. The parasite not uncommonly perishes. When this occurs, the pseudo-cyst surrounding it may become calcified, and the cyst itself seems to break up in the fluid. In this way all danger is removed, but the tumour remains. In other cases suppuration takes place round the hydatid. The migrating cells penetrate the wall of the parasite, and the whole cavity becomes filled with a

Fig. 357.—*Tænia* head from Hydatid Cyst (250 diam.). A single hooklet is shown more highly magnified (840 diam.).

thin purulent fluid. The cyst-wall often becomes loosened and partially disintegrated. Finally the abscess may possibly burst superficially, and the whole cyst be discharged. I once opened a very large abscess in the adductor region of a young woman's thigh, and gave exit to nearly a pint of pus, containing dozens of hydatid cysts about the size of gooseberries. The diagnosis of these cysts when seated in the subcutaneous or muscular tissues cannot be made with certainty, except by withdrawing some of the fluid with the aspirator, and submitting it to microscopic and chemical examination. If it be of low specific gravity and free from albumen, it is almost certain to have come from a true hydatid cyst, and if hooklets are found no doubt remains. The *Treatment* of these cysts when seated in an external part, such as a limb, is complete removal of the parasite by a free incision. In this way I removed a hydatid cyst of the size of a fist from the muscles at the back of the neck of a young man. In internal organs, if enucleation be impossible, aspiration is the best treatment, and is said to cure about half the cases operated on. In spite of antiseptic precautions, aspiration is not uncommonly followed by suppuration. If this occur, or if the aspiration fail to cure, the only efficient treatment is to open the cavity, to attach the walls of the pseudo-cyst to the skin where possible, and to insert a drainage-tube. The parasitic cyst may sometimes be removed from the cavity, but more often this is impossible owing to the softness of its walls, and the small size of the opening that can be made. The operation should be performed with the strictest antiseptic precautions, as the dead parasite and the watery fluid contained in the cyst are highly putrescible, and owing to the size of the cavity septic poisoning is very likely to occur especially if the drainage and asepsis be imperfect.

II.—TUMOURS COMPOSED OF ONE OF THE MODIFICATIONS OF FULLY DEVELOPED CONNECTIVE TISSUE.

The structures included under the term "connective tissue and its modifications," are fat, fibrous and areolar tissue, cartilage, bone, and mucous tissue. The tumours composed of any of these tissues in a state of perfect development are uniformly benign. Occasionally a cartilaginous tumour assumes a malignant form, but it will then be found that, instead of being covered by a firm fibrous membrane at the margin of the growth, there is a zone of embryonic tissue which is infiltrating the surrounding parts on one side and becoming developed into cartilage on the other—in fact, that the tumour is not a chondroma but a chondrifying sarcoma. It is from this tissue, probably, that the system becomes infected, and not from the fully developed cartilage. In the same way, tumours which to the naked eye seemed to be composed of bone may assume all the characters of malignancy; but on microscopic examination it will be found that they do not grow as normal bone does, either from a fibrous membrane (periosteum) or from cartilage, but are in fact ossifying sarcomata. These will be described amongst the sarcomata. Again, there is no absolute boundary between sarcoma and fibroma. Many tumours composed almost entirely of spindle-cells contain a large proportion of fibrous tissue between the cells. If the fibres very much exceed the cells, the growth would be called a fibroma; if the reverse a sarcoma; and one between the two is often spoken of as a fibro-sarcoma. As a broad rule, it may be said that

the benignancy of the growth will be in proportion to the perfection of the development of the tissue of which it is composed.

a. Fatty Tumour or Lipoma.—These tumours occur in any part of the subcutaneous tissue, and at all ages, though they are most commonly met with about the earlier periods of middle life. In the majority of cases they appear to originate without any evident cause; in other instances they can be distinctly traced to pressure or to some local irritation, as to that of braces or shoulder-straps over the back and shoulders. In one case I have known the disease to be hereditarily transmitted to the members of three generations of a family.

Fatty growths occur under two forms, one diffused, the other circumscribed: it is the latter variety only that is termed the **Adipose or Fatty Tumour**. The diffused form of fatty deposition occurs in masses about the chin or nates and may occasion much disfigurement. This form was described by Brodie under the name of "**fatty outgrowth**."

Fatty tumours may form in all parts of the body as soft, painless, inelastic doughy swellings, usually giving rise on manipulation to a feeling closely resembling fluctuation. They grow very slowly, and are commonly oval or round in form, but frequently lobulated to a most extraordinary degree. They occur most frequently in the subcutaneous fat about the neck and shoulders, and are occasionally met with between muscles, in the neighbourhood of joints and of serous membranes and of mucous canals, sometimes in very unusual situations, where such growths would scarcely be looked for. Thus I once removed a lipoma three inches in length, and as thick as the thumb, from under the annular ligament and the palmar fascia of a young woman. A very curious circumstance connected with these tumours is that they occasionally shift their seat, slowly gliding for some distance from the original spot on which they grew; thus, Paget relates cases in which fatty tumours shifted their position from the groin to the perineum or the thigh. I have known one descend from the shoulder to the breast. When growing superficially, they sometimes become pedunculated. They may attain a large size, but occasion inconvenience only by their pressure or bulk; sometimes they appear in great numbers, upwards of 250 tumours of various sizes having been found in the same individual; and C. v. Lutzau records a case in which they reached the extraordinary number of 2,436. They rarely ulcerate, except when, having attained a great size, they become irritated by the friction of the clothes. In these cases the tumour may be much hardened by an overgrowth of its fibrous tissue. Occasionally patches of calcification are met with. The calcareous matter sometimes forms a layer like an egg-shell, enclosing a space in which the fat is softened and apparently saponified.

Fig. 294.—Fatty Tumour (see Janm.).
Some of the cells show crystals of fatty acids.

The typical **lipoma** is simply a mass of fat, usually differing in structure in no way from the ordinary subcutaneous adipose tissue (Fig. 358), but it is not uncommon to find crystalline deposits of the fatty acids in the cells. It is enclosed in a fine thin capsule of areolar tissue, having small vessels running over its surface. This capsule is adherent to the surrounding structures, but loosely connected with the tumour itself; so that, in removing these growths, it is important to open the capsule thoroughly before attempting to enucleate the tumour.

These tumours, which present the least possible deviation from the normal structure of the parts in which they grow, are derived from the connective tissue by an increased development of fat. They present occasionally some minor varieties of structure. Thus the fibrous tissue may be in excess, giving rise to the so-called "fibrous lipoma," or the tumour may be permeated by numerous dilated vessels, as in the "erectile lipoma" or "naevo-lipoma." These conditions are, however, rare. Occasionally mucous tissue may be found intermixed with the adipose, forming the "myxo-lipoma." This will be mentioned again under myxoma.

The **diagnosis** of a fatty tumour is usually easy. It is not adherent to the muscles over which it is lying. This can easily be ascertained by making the patient throw the muscles into contraction, when the mobility of the tumour will be found to remain unaltered. It is more easily confounded with a soft sarcoma or a chronic abscess. The sarcomata usually spring from, or early become adherent to, the deep fasciæ or muscles. On pinching up the skin over a fatty tumour, it will be found to dimple in several places, although it is quite freely movable over the growth. This sign is wanting in a sarcoma. A fatty tumour is distinguished from a cyst or chronic abscess by pressing on its edge, when the solid tumour will be felt to roll away from under the finger. In a collection of fluid, the finger sinks through the edge without the sensation of anything slipping away from beneath it. When the tumour is lobulated there can be little doubt as to its nature. If any doubt should remain, the mass may be punctured with a grooved needle or a fine trochar.

In the *Treatment* of fatty tumours nothing can be done except extirpation with the knife. The tumour, being but loosely adherent to its capsule, readily turns out if the latter be freely opened, so that the smooth shining surface of the tumour is seen in the bottom of the wound. Great care must be taken that none of the lobules frequently found in these tumours are left behind, as they would certainly serve as starting points for new growths.

b. Fibroma: Fibrous or Fibroid Tumours, Desmoid Tumours, Areolar and Fibro-cellular Tumours.—In the healthy body, fibrous tissue is found either dense and firm as in tendons, or loose and filamentous as in areolar tissue, and between these two extremes every variety of density is observed. In healthy areolar tissue two kinds of fibres are almost invariably present, the white fibrous and the yellow elastic tissue. In tumours composed of fibrous tissue, similar variations in density are met with. Thus we have fibrous tumours as dense in structure as ligaments, and others as loose as areolar tissue, but in all it is extremely uncommon to find any yellow elastic fibres. Fibrous tissue enters very largely into the composition of many tumours besides the true fibromata. Thus the stroma of almost all cancers is composed of fibrous tissue, the intercellular substance of a sarcoma may be abundantly fibrous, and in a lipoma the lobules of fat are bound together by areolar tissue.

The term "fibroma" is, however, applied only to those tumours in which fibrous or areolar tissue forms by far the most abundant constituent, and in which all the cells are of the type of connective-tissue corpuscles, and uniformly distributed amongst the fibres. As before stated, no sharp line can be drawn between fibroma and sarcoma, and the term "fibro-sarcoma" is frequently applied to those tumours in the border-land between the two. Fibromata may be divided into two chief classes:—1. Soft fibromata, areolar tumours, and fibro-cellular tumours; 2. Firm fibromata, desmoid tumours, and fibroid tumours.

1. **Soft Fibromata.** These may be diffused or circumscribed: in some cases they are distinctly encapsuled. The diffused variety or *areolar tumours* are little more than a simple hyperplasia of the subcutaneous or submucous areolar tissue. They are represented by pendulous fleshy growths, forming large tumours, commonly called **Wens**, which may occur on any part of the surface. They are smooth, pedunculated, non-elastic, pendulous, and movable, slowly increasing without pain often to a very great size. They are thinly covered with skin, bearing abundant papillæ, and sometimes enlarged sweat-glands and hair-follicles. Large vessels may ramify on the surface, and occasionally the skin is pigmented. They are sometimes congenital. In the disease known as **molluscum fibrosum** these tumours form pedunculated masses or rolls, hanging from the skin of the buttocks, thighs, and other parts of the body, and may attain such a size as seriously to inconvenience the patient by their weight. These masses are composed merely of connective tissue, sometimes dry and tough, sometimes œdematous. They contain large blood-vessels, frequently of such size as to render removal of the growth a most hazardous operation.

In the *Treatment* of these affections, pressure and iodine applications may be tried in the earlier stages, with the view, if possible, of checking their growth; at a later period they must, if large, be removed by operation, though this procedure is at times an extremely severe one, owing to their great size and vascularity.

Tumours of the *circumscribed variety*, described by Paget as fibro-cellular, are not of common occurrence; and when met with they are most frequently found in the scrotum, the labium, the deep muscular interspaces of the thigh or axilla, and on the scalp, in which situation they may form large masses, sometimes weighing many pounds. When seated in the subcutaneous tissue these tumours may become pedunculated, as in Fig. 359, which represents a tumour of this kind which I removed from the side of a woman. I have removed one weighing nearly four pounds from the axilla of a woman, where it lay between the serratus magnus and the ribs. When they occur about the scrotum and labium, these tumours must not be confounded with

Fig. 359.—Pendulous soft Fibroma.

The typical **lipoma** is simply a mass of fat, usually differing in structure in no way from the ordinary subcutaneous adipose tissue (Fig. 358), but it is not uncommon to find crystalline deposits of the fatty acids in the cells. It is enclosed in a fine thin capsule of areolar tissue, having small vessels ramifying over its surface. This capsule is adherent to the surrounding structures, but loosely connected with the tumour itself; so that, in removing these growths it is important to open the capsule thoroughly before attempting to enucleate the tumour.

These tumours, which present the least possible deviation from the normal structure of the parts in which they grow, are derived from the connective tissue by an increased development of fat. They present occasionally some minor varieties of structure. Thus the fibrous tissue may be in excess, giving rise to the so-called "fibrous lipoma," or the tumour may be permeated by numerous dilated vessels, as in the "erectile lipoma" or "naevo-lipoma." These conditions are, however, rare. Occasionally mucous tissue may be found intermixed with the adipose, forming the "myxo-lipoma." This will be mentioned again under myxoma.

The **diagnosis** of a fatty tumour is usually easy. It is not adherent to the muscles over which it is lying. This can easily be ascertained by making the patient throw the muscles into contraction, when the mobility of the tumour will be found to remain unaltered. It is more easily confounded with a soft sarcoma or a chronic abscess. The sarcomata usually spring from, or early become adherent to, the deep fasciæ or muscles. On pinching up the skin over a fatty tumour, it will be found to dimple in several places, although it is quite freely movable over the growth. This sign is wanting in a sarcoma. A fatty tumour is distinguished from a cyst or chronic abscess by pressing on its edge, when the solid tumour will be felt to roll away from under the finger; in a collection of fluid, the finger sinks through the edge without the sensation of anything slipping away from beneath it. When the tumour is lobulated, there can be little doubt as to its nature. If any doubt should remain, the mass may be punctured with a grooved needle or a fine trochar.

In the *Treatment* of fatty tumours nothing can be done except extirpation with the knife. The tumour, being but loosely adherent to its capsule, readily turns out if the latter be freely opened, so that the smooth shining surface of the tumour is seen in the bottom of the wound. Great care must be taken that none of the lobules frequently found in these tumours are left behind, as they would certainly serve as starting points for new growths.

b. Fibroma: Fibrous or Fibroid Tumours, Desmoid Tumours, Areolar and Fibro-cellular Tumours.—In the healthy body, fibrous tissue is found either dense and firm as in tendons, or loose and filamentous as in areolar tissue, and between these two extremes every variety of density is observed. In healthy areolar tissue two kinds of fibres are almost invariably present: the white fibrous and the yellow elastic tissue. In tumours composed of fibrous tissue, similar variations in density are met with. Thus we have fibrous tumours as dense in structure as ligaments, and others as loose as areolar tissue, but in all it is extremely uncommon to find any yellow elastic fibres. Fibrous tissue enters very largely into the composition of many tumours besides the true fibromata. Thus the stroma of almost all cancers is composed of fibrous tissue, the intercellular substance of a sarcoma may be abundantly fibrous, and in a lipoma the lobules of fat are bound together by areolar tissue.

The term "fibroma" is, however, applied only to those tumours in which fibrous or areolar tissue forms by far the most abundant constituent, and in which all the cells are of the type of connective-tissue corpuscles, and uniformly distributed amongst the fibres. As before stated, no sharp line can be drawn between fibroma and sarcoma, and the term "fibro-sarcoma" is frequently applied to those tumours in the border-land between the two. Fibromata may be divided into two chief classes:—1. Soft fibromata, areolar tumours, and fibro-cellular tumours; 2. Firm fibromata, desmoid tumours, and fibroid tumours.

1. **Soft Fibromata.**—These may be diffused or circumscribed; in some cases they are distinctly encapsuled. The diffused variety or *areolar tumours* are little more than a simple hyperplasia of the subcutaneous or submucous areolar tissue. They are represented by pendulous fleshy growths, forming large tumours, commonly called **Wens**, which may occur on any part of the surface. They are smooth, pedunculated, non-elastic, pendulous, and movable, slowly increasing without pain often to a very great size. They are thinly covered with skin, bearing abundant papillæ, and sometimes enlarged sweat-glands and hair-follicles. Large vessels may ramify on the surface, and occasionally the skin is pigmented. They are sometimes congenital. In the disease known as **molluscum fibrosum** these tumours form pedunculated masses or rolls, hanging from the skin of the buttocks, thighs, and other parts of the body, and may attain such a size as seriously to inconvenience the patient by their weight. These masses are composed merely of connective tissue, sometimes dry and tough, sometimes cedematous. They contain large blood-vessels, frequently of such size as to render removal of the growth a most hazardous operation.

In the *Treatment* of these affections, pressure and iodine applications may be tried in the earlier stages, with the view, if possible, of checking their growth: at a later period they must, if large, be removed by operation, though this procedure is at times an extremely severe one, owing to their great size and vascularity.

Tumours of the *circumscribed variety*, described by Paget as fibro-cellular, are not of common occurrence; and when met with they are most frequently found in the scrotum, the labium, the deep muscular interspaces of the thigh or axilla, and on the scalp, in which situation they may form large masses, sometimes weighing many pounds. When seated in the subcutaneous tissue these tumours may become pedunculated, as in Fig. 359, which represents a tumour of this kind which I removed from the side of a woman. I have removed one weighing nearly four pounds from the axilla of a woman, where it lay between the serratus magnus and the ribs. When they occur about the scrotum and labium, these tumours must not be confounded with

Fig. 359. — Pendulous soft Fibroma.

elephantiasis of these parts, from which they may be distinguished by the fact that they are limited and circumscribed masses, and not mere outgrowths. Paget observes that, when occurring about the genital organs, they are found in young women and in old men. They occur only in adults who otherwise are in good health, and grow quickly, forming soft, elastic, rounded, and smooth tumours; they are not attended with any pain. After removal they are found to possess a thin capsule, to be of a yellowish colour, and to contain a large quantity of infiltrated serous fluid, which may be squeezed out abundantly, and coagulates on standing. This fluid may be so abundant as to give rise to distinct fluctuation. Thus, I once removed a soft fibroma from amongst the short muscles of the thumb, which had previously been treated unsuccessfully by puncture, under the impression that it was cystic in nature.

Under the microscope these tumours display a beautifully delicate network of white fibrous tissue, arranged in undulating filaments and fibrous bands, in the midst of which stellate, spindle-shaped, oval or round cells are found. These cells are similar to those normally found in fully developed or growing fibrous tissue. They vary in abundance, but never exceed the fibrous tissue in amount. The cells are rendered more apparent by the addition of acetic acid. These tumours sometimes appear to grow rapidly, when, in reality, the increase in size is due to a rapid increase of the fluid, and not to a new deposit of a solid character in the tumour. As these tumours are perfectly innocent, no hesitation need be felt about their removal.

2. Firm Fibromata—Fibroid or Desmoid Tumours.—These tumours are met with in various situations, the most common of which are the bone and periosteum, the subcutaneous connective tissue, and in connection with nerves. In the uterus, "fibroid" tumours are exceedingly common, but in this situation they contain not only fibrous tissue, but also a variable amount of non-striated muscular fibre. Amongst the best known examples of firm fibromata may be enumerated the simple or fibrous epulis, the fibrous tumours of the antrum or lower jaw, the fibrous polypus of the nose, the ordinary or false neuroma, and the painful subcutaneous tubercle. Fibrous tumours are also seen in the neck, especially in the parotid region. In shape these tumours are irregularly oval or rounded; they are smooth, painless, and, except when growing from bone, freely movable; they increase slowly, but may attain an enormous size, equal to that of a coconut or water-melon. Liston removed one from the neck, which is in the Museum of the College of Surgeons, that weighed twelve pounds; they have, however, been found weighing as much as seventy pounds. They are almost invariably single: they are excessively firm and hard, but yield slightly on pressure, in this differing from bony tumours. When cut into, they present a white glistening fibrous structure, often showing, to the naked eye, bands of interlacing fibres. Sometimes the fibres show a concentric arrangement (Fig. 360); an appearance which, according to Billroth, is due to the fibrous formation taking place around nerves and vessels. On microscopic examination, pure fibromata are found to be composed of interlacing bundles of white fibrous tissue, scattered amongst which are cells, few in number, and spindle-shaped, stellate, or oval in form (Fig. 361). These are often rendered apparent only by the addition of acetic acid. In most cases the vessels are not abundant, but frequently these tumours can be shown by injection to be very vascular. Sometimes coarse cavernous spaces may be

found. The vessels are intimately adherent to the fibrous structure of the tumour, and consequently, being unable to contract or retract, they pour out enormous quantities of blood if opened by wound or ulceration. This is especially the case in those fibrous tumours which grow from the bones of the head or face, as in the fibrous polypi growing from the body of the sphenoid bone.

Fibromata form most commonly about middle life, and may remain stationary for years. They may, however, suffer various changes. They may undergo disintegration, becoming oedematous, and softening in the centre, or at various points of the circumference; they then break down into a semi-fluid mass, the integuments covering them inflame and slough, and pus, mixed with disorganized portions of the tumour, is poured out, leaving a large and sloughy chasm, from which fungating growths may sprout, readily bleeding on the slightest touch, and giving the sore a malignant appearance; the patient

Figs. 350, 361.—Fibrous fibromata (188 diam.). Fig. 360, from a small Fibroma of the buccal, shows the circular arrangement of the fibres. Fig. 361, from a naso-pharyngeal polypus, resembles ordinary fibrous tissue.

eventually falling into a cachectic condition, and becoming exhausted by the hæmorrhage and discharge. In other cases these tumours may calcify, or more rarely they undergo true ossification. In rare cases the central parts may undergo a process of softening, so as to form large cysts containing fluid of various shades of colour. Paget relates a case in which a very large cyst of this kind, formed by the hollowing out of a fibroid tumour of the uterus, was tapped by mistake for ovarian dropsy.

Some of the forms of fibroma require further mention here, though they will be mentioned again under the diseases of the organs in which they occur.

Fibromata of Bone.—These may grow in the centre of the bone, as is not unfrequently seen in the lower jaw, or beneath the periosteum. The diagnosis between these latter and the firmer varieties of sarcoma can be made only after removal. Virchow lays great stress upon the fact that periosteal fibromata do not penetrate into the structure of the bone, or show any tendency to infiltrate the surrounding soft parts, while the reverse is the case with the sarcomata.

Fibromata of Nerves.—These are commonly spoken of as neuromata,

although this term would be more properly limited to these tumours in which newly formed nerve-filaments are found. They form rounded tumours, over which the fibres of the nerve are stretched: they are frequently multiple, sometimes extremely numerous, very hard and dense, and almost invariably painless, and not affecting the function of the nerve upon which they grow. They are more movable in a direction transverse to the course of the nerve upon which they are seated than in any other, when the limb is put in such a position as to tighten the nerve; a symptom which is of some importance in their diagnosis.

Painful Subcutaneous Tubercle is a peculiar form of fibroma, found beneath the skin, usually of one of the extremities, but very rarely of the trunk. It is seldom more than half an inch in diameter, and is so small as scarcely to cause a prominence on the surface; yet it gives rise to pain of the most agonizing character, usually called forth by some slight touch or pressure, and then lasting perhaps for an hour or more. These tumours are not neuromata; at any rate, no connexion has as yet been traced between them and nerve-filaments. They are far more frequent in females than in males.

Fibromata of Glands are rare, being almost confined to the mamma.

The *Treatment* of fibromata is in some cases merely palliative: but when they are so situated as to admit of removal, as in the neck, lower jaw, antrum, mamma, or subcutaneous tissue, they should always be extirpated.

Tumours closely resembling fibromata in naked-eye appearance and in consistence have been known to recur after removal with a great tendency to ulceration, sloughing, and hæmorrhage. They may even give rise to secondary deposits in internal organs. These tumours will always be found on microscopic examination to present the signs of one of the forms of sarcoma to be described hereafter. Pure fibromata are invariably benign.

c. **Enchondroma — Chondroma — Cartilaginous Tumours.**— These tumours form an exceedingly interesting group, being of comparatively frequent occurrence, and sometimes attaining a large size.

In structure, a chondroma closely resembles normal hyaline cartilage. The cells vary much in size and shape. In the most typical form they are large ($\frac{1}{1000}$ to $\frac{1}{500}$ inch), round, oval, or polygonal in shape, contain a single large nucleus and nucleolus, and are sometimes enclosed in a capsule as in normal cartilage. Occasionally the cells are found to be irregular in shape and branched, the processes of one cell communicating with those of another, as in a myxoma. This form resembles the cartilage normally found only in the cuttle-fish. The matrix may be hyaline, as in normal fetal or articular cartilage, or may contain a few fibres. It varies much in density, occasionally being so soft as to give the tumour a false feeling of fluctuation. This softness is usually found in the more rapidly growing varieties. The tumour may consist of a single mass of cartilage, or may be composed of innumerable lobules, bound together by vascular bands of fibrous tissue. It is this vascularity that often forms the most striking difference between normal cartilage and enchondroma. Its surface may be covered by a distinct fibrous layer, sharply limiting it from the surrounding tissues, or the mass of cartilage may be surrounded by a vascular zone of embryonic tissue, sometimes composed of round, and sometimes of spindle-shaped cells, which may infiltrate and invade the surrounding structures. It is this variety, which is more properly classed as a

chondro-sarcoma, that assumes the characters of malignancy. Enchondromata are liable to various secondary changes. Thus they may undergo true ossification. The ordinary pedunculated or spongy exostosis is usually found to be covered with a thick layer of cartilage, so that it may be spoken of as an ossifying chondroma. Calcification is a far more common change than true ossification (Fig. 362). Not unfrequently mucous softening takes place in the matrix. The cells in this condition float free in the fluid, and undergo degeneration, becoming filled with large globules of fat. This mucous softening may be so extensive as to give the once solid tumour the appearance of a thick-walled cyst. In a case of a very large enchondroma of the ribs under my care a few years ago, I was enabled to make the diagnosis by microscopic examination of a small quantity of such fluid, removed by means of the aspirator. Cartilage may also be found mixed in one tumour with other structures. Thus

Figs. 361, 362. Enchondroma (188 diam.). Fig. 361.—From a small tumour near, but distinct from, an ossifying enchondroma of the femur, shows the variety in shape of the cells and capsules. At the lower part calcification is taking place involving first the matrix and then the cells. Fig. 362.—From an enchondroma of the finger, matrix faintly fibrillated.

the cartilaginous tumours of the parotid region are seldom, if ever, pure, but contain mingled together the structures of myxoma, adenoma, and enchondroma. Enchondroma and sarcoma are not unfrequently found combined. Encephaloid cancer and enchondroma are said to have been found combined in the testis.

Cartilaginous tumours when composed of pure cartilage are always benign; when mixed with embryonic tissue, as in the chondro-sarcoma, they frequently run a malignant course. The simple chondroma occurs as a hard or slightly elastic tumour, ovoid or round in form, sometimes smooth on the surface but more often lobulated, of small or moderate size, seldom exceeding that of an orange, and growing slowly without pain. The chondro-sarcoma grows rapidly, often attaining an enormous size in a few months, and giving rise to secondary growths in internal organs.

When cartilaginous tumours attain a large size and soften as above described, the skin covering them may become dusky inflamed, and eventually slough, forming fistulous openings, through which a thin, jelly-like matter is discharged.

Locality.—Most frequently chondroma occurs in connection with some bone. It is most commonly seen in the metacarpus and phalanges of the

fingers (Figs. 364, 365). It is rare, in this situation, to find only one bone or phalanx affected; the tumours are almost invariably multiple. They form hard or elastic rounded knobs, seldom larger than a walnut or a pigeon's egg. Large chondromata are most commonly met with in or upon the head of the tibia or the condyles of the femur, forming in these situations rapidly increasing growths of considerable magnitude. Chondromata are found also on the ribs and the bones of the pelvis, in the intermuscular spaces of the neck, thigh, and leg, in connection with the sheaths of tendons, and occasionally in glands; but in this last situation they are seldom, if ever, pure, being mixed with myxoma, adenoma, or sarcoma, and when in the testicle, occasionally with carcinoma. It is a curious fact, that chondromata never arise in connexion with pre-existing cartilage. When connected with the bones, chondroma may spring from the periosteum, gradually enveloping, absorbing, and eventually destroying the osseous structures, though at first not incorporated with them. It has then been distinguished as "perichondroma." This is its usual mode of origin

Fig. 364. — Large Enchondroma of Index Finger.

Fig. 365. — Ordinary Enchondromata of Finger.

when occurring in the femur or tibia; but when seated on the short bones especially on the metacarpus and phalanges, it commonly springs from the medullary canal, which becomes expanded by gradual absorption of the compact tissue, with a constant growth of new bone beneath the periosteum. Thus the tumour remains long covered by a thin shell of bone. Finally the growth perforates its bony covering at one side, and then advances more rapidly in that direction. These tumours occur in childhood or young adult life. They never assume a malignant form, nor do they ossify. Calcification is common, and mucous softening occasionally, but rarely, takes place in their interior, leading to ulceration of the skin.

The *Treatment* consists either in excision of the tumour, or in amputation of the affected part. Excision may be practised when the tumour is seated in the parotid region, or is otherwise unconnected with bone. When forming part of the osseous structures, it cannot well be got rid of without the removal by amputation of the bone which it implicates. When it occurs in the hand, removal of the affected fingers and metacarpal bones, to an extent proportioned to the amount of the disease, will be required; but it should be remembered that in this situation enchondromata are always perfectly innocent, and consequently the operation should not be performed if the finger be useful to the patient, unless he is willing to sacrifice a useful finger to get rid of an unsightly deformity.

In Fig. 87 may be seen the kind of hand left after operation in the case from which Fig. 364 was taken. If, in these circumstances, excision of the tumour only be attempted, it will be found that the whole mass cannot be removed, and that it rapidly grows again; or that the wound formed by the operation remains fistulous and open.

Removal of a pure chondroma is followed by a permanent cure. The mixed cartilaginous tumours, as chondro-sarcoma or adeno-chondro-sarcoma, sometimes return after removal, both locally and in internal organs.

d. Osteoma. Exostosis. Bony Tumour.—To render the review of the different tumours complete, it will be necessary to mention the osteomata here, though their clinical characters will be more fully treated of in the Chapter on the Diseases of Bones. In the first place, it is necessary to distinguish mere calcification from the formation of true bone. The former is extremely common, the latter somewhat rare. Bone appears in tumours under four chief conditions: 1st, as the result of the ossification of a fibroma; 2ndly, of a sarcoma; 3rdly, of a chondroma; and 4thly, as a special growth covered by a firm layer of periosteum. Only the last two of these forms are properly spoken of as bony tumours or exostoses. They differ from each other in their seat and consistence, as well as in their mode of growth. Those developing from cartilage—spongy exostoses—are situated almost invariably in the immediate neighbourhood of an epiphysis, and rarely, if ever, start into growth after the twenty-fourth year; those developing from a fibrous periosteal covering—ivory exostoses—are of extreme and remarkable density, and are usually seated on flat bones, such as those of the head, face, scapula, and pelvis. Both these growths closely resemble normal bone in structure, the spongy exostosis exactly agreeing with the cancellous tissue of the extremity of a long bone, and the ivory or hard exostosis corresponding to the petrous portion of the temporal, or the compact tissue of a long bone. Both forms are non-malignant.

Spongy Exostoses, sometimes called from their shape pedunculated or canli-flower exostoses, are most common at the upper end of the humerus and the lower end of the femur, and on the ungual phalanx of the great toe (Fig. 364 A). If observed during the stage of growth, they are found to be covered by a perfectly developed hyaline cartilage, which apparently grows from the perichondrium covering it, and quickly undergoes ossification at its deep surface. If the tumour be observed when all growth has ceased, it will be found to be completely bony, being composed of a pedunculated mass of cancellous tissue, thinly covered by a layer of compact bone. The cancellous tissue of the tumour is continuous with that of the bone upon which it grows, the compact tissue of the shaft being absorbed beneath the base of the tumour. Sometimes these tumours are hereditary and multiple. They scarcely ever reach a great size, and probably cease to grow if they become completely ossified.

a. Hyaline cartilage.

b. Layer of imperfect ossification.

c. Well formed spongy bone.

d. Periosteum.

The drawing illustrates the different proportions which the various constituents of the tumour may bear to one another.

Ivory Exostoses.—These tumours form flat rounded elevations, usually seated on the bones of the skull or face. They are covered by a fibrous membrane and are of extreme hardness. Occasionally they are multiple and grow to a considerable size, and when seated on the facial bones distort the features horribly, and at last after years of suffering possibly cause death by pressure on the brain.

c. Myxoma. Mucous Tumour.—These tumours are classed by some writers under sarcomata, as the tissue of which they are composed closely resembles the rudimentary fat of the foetus. In the adult, the vitreous body of the eye is the only part in which mucous tissue is normally found. Many tumours formerly described as colloid cancer belong to this class. Myxomata usually form round, oval, or lobulated masses, distinctly surrounded by a loose capsule of connective tissue. They are tense, elastic, and gelatinous, frequently giving rise to a feeling of fluctuation so distinct as to lead to their being mistaken for cysts. They are usually of slow growth. On section they

Fig. 367.—Myxoma, from a large tumour in the skin of the back (188 diam.). It will be noticed that even the round cells are connected with those which are more branched.

Fig. 368.—Mucous Polypus of Nose (100 diam.). The round cells vary in size and are distinct from the branched ones. The branched cells are very irregular, and the matrix mucous and fibrous.

are found to be of a delicate pink colour, sometimes stained by hæmorrhage, or they may exhibit a uniform yellowish tint. The most marked peculiarity they present on section is in the fluid which flows from the cut surface. This is abundant, glairy, and tenacious, having the appearance of thick gum-water. On chemical examination it is found to contain mucin; microscopic examination shows (Fig. 367) in the purest forms of myxoma a beautiful network composed of large stellate or branched cells, the processes of which freely communicate with one another. These cells are imbedded in an almost homogeneous intercellular substance, in which vessels can be clearly seen to ramify. It is seldom, however, that this structure is found so pure as this. In addition to the stellate cells, numerous small round cells (Fig. 368) are usually present, and the intercellular substance is in most cases traversed by delicate bundles of fibrous tissue, sometimes containing yellow elastic fibres. The stellate cell may be smaller in some cases than in others. The peculiar feature of the growth is the mucous intercellular substance, and without this being present no tumour should be called a myxoma. Frequently, tissue appearing in all respects with that of a pure myxoma is found mixed with that of sarcoma,

enchondroma, or adenoma. The tumours are spoken of as myxo-sarcomata, myxo-chondromata, &c. Myxo-chondroma, frequently containing portions of adenoma, forms the ordinary parotid tumour. Occasionally a development of true fat cells may take place in the central parts of a myxoma, thus indicating, as Virchow thinks, the relation of these tumours to embryonic fat. A few years ago I saw a case of an enormous abdominal tumour which proved after death to be a pure myxoma, weighing at least thirty pounds, the central parts of which contained an abundance of true adipose tissue. Such tumours as these have been spoken of as myxo-lipomata. I have since seen a similar abdominal tumour in a young man. After death it was found to be composed almost entirely of pure myxoma tissue. A few small nodules of spindle-celled tissue were found in it, but no fat. Myxomata may occur in any part of the body. When superficial they often assume a polypoid form, as in the ordinary mucous polypus of the nose. Myxomata are not unfrequent in the subcutaneous cellular tissue; in nerves they form one variety of false neuroma, and they are occasionally met with in glands. They are usually non-malignant, but occasionally they occur locally after removal. If left untreated, they may cause death by ulceration of the skin taking place over them, leading to the sloughing of the tumour with profuse hæmorrhage and foul discharge. Occasionally they may prove fatal from pressure on important organs, as in the case of the abdominal tumour above mentioned. The *Treatment* consists in the removal of the growth whenever possible.

III. TUMOURS WHICH RESEMBLE IN STRUCTURE, MORE OR LESS PERFECTLY, ONE OF THE MORE COMPLEX TISSUES OF THE BODY.

A. Myoma. Muscular Tumour.—These tumours are of two classes: those containing striated muscular fibre, or *rhabdomyoma*, and those containing non-striated muscular fibre, or *leiomyoma*. Striated muscular fibre has, at present, been found only in a few congenital tumours, chiefly in large growths in or near the kidney, in which it is mixed with spindle-celled sarcoma and cysts lined with epithelium. Non-striated muscular fibre is found in abundance in the so-called fibroid tumours of the uterus and of the prostate, but it is always associated with large quantities of fibrous tissue, so that the tumour is more properly spoken of as a fibro-myoma. The older tumours are found to be composed almost entirely of fibrous tissue, the muscular fibre cells having undergone atrophy. Pure myomata have, in very rare cases, been found in connection with the muscular coat of the alimentary canal and urinary passages. Fagge has recorded an interesting case of myoma of the œsophagus, which was accidentally discovered after death, at Guy's Hospital. It gave rise to no symptoms during life, although the tumour was as large as a good-sized egg. Myomata are always non-malignant.

Fibro-Myoma of the Uterus.—These tumours are composed of long spindle-shaped muscular fibre cells and fibrous tissue in varying proportions. According to the position of the tumour in the wall of the uterus they are described as subserous, interstitial or submucous. In the tumours of old women the muscle cells often atrophy, and the growth then presents the appearance of a pure fibroma. They are liable to softening and ulceration, and are often accompanied by much hæmorrhage when they assume the

polypoid form. They frequently calcify and occasionally, as above stated, soften, forming enormous cysts.

B. Neuroma. True Neuroma. Nervous Tumour.—The term "neuroma" is applied clinically to any tumour growing on a nerve, whether it be a fibroma, myxoma, sarcoma, or true neuroma. The term should strictly be limited to those rare tumours in which there is an actual new growth of nervous tissue. Neuromata composed of grey matter (non-medullated fibres and ganglionic tissue) have been described, but they are so infinitely rare that they need no further mention here. The vast majority of true neuromata are composed of bundles of medullated or white nerve fibres, interlacing with each other, or sometimes rolled up into masses, and separated by connective tissue, more or less rich in small cells. True neuromata occur only in connection with nerves. As examples may be mentioned the bulb which forms on the central end of a divided nerve or on the nerve in a stump; the latter is called an "amputation neuroma." True neuromata occur also without previous injury of the nerve. They are then frequently multiple. They cannot be diagnosed from other firm tumours of nerves. They are sometimes painful and tender, and sometimes not. The most characteristic sign of any tumour seated on a nerve is, that when the nerve upon which it is seated is put on the stretch by the position of the part, the tumour is almost immovable in a direction parallel to the course of the nerve, while it is more or less freely movable in the transverse direction. True neuromata are always non-malignant, and should not be interfered with unless they give rise to serious inconvenience from pain.

A peculiar and very rare form of tumour has been described under the name of *plexiform neuroma*. It consists of a group of small nerves the terminal twigs of which are thickened by the growth of new fibrous tissue convoluted and twisted upon one another and bound together by areolar tissue. If unravelled the separate cords present a varicose nodular appearance. According to Bruns, the tumour is partly composed of new nerve fibres. It is most commonly met with in the face and neck, and may be congenital.

C. Angioma. Nævus. Vascular Tumour.—Under the name of angiomata are included only such tumours as are composed of vascular tissue of new growth, and not such swellings as arise from the dilatation of pre-existing vessels. The so-called cirroid aneurism, or aneurism by anastomosis, being supposed to be due chiefly to a dilatation of pre-existing arteries, although doubtless accompanied by some new formation of vessels, is not usually included amongst angiomata, nor are the swellings formed by convoluted masses of varicose veins. True angiomata are usually divided into two classes:—the *plexiform angioma* or *telangiectasis*, and the *cavernous angioma*. The *plexiform angioma* is composed of a mass of tortuous and dilated capillaries bound together by connective tissue (Fig. 349). The blood-vessels comprising it are normal in structure. This forms the ordinary superficial nævus, "mother's mark," or "port-wine stain." It is, probably, always congenital. The *cavernous angioma*, or erectile tumour, resembles in structure the corpus cavernosum penis, being made up of spaces, communicating freely with each other. The walls of the spaces are composed of fibrous tissue, and are lined with an endothelium resembling that of a vein. These tumours are sometimes distinctly circumscribed, and enclosed in a loose capsule of connective tissue; in other cases they are diffuse. They are sometimes congenital,

but often arise in young adult life. They are most common in the subcutaneous tissue, but have also been met with in muscles, and in the liver, spleen, and other internal organs. The mode of origin of these tumours is doubtful. They appear sometimes to develop as a result of an injury.

The symptoms and treatment of vascular tumour will be fully described in a subsequent chapter.

1). Lymphangioma. Lymphatic Nævus. Tumour composed of Lymphatic Vessels.—These excessively rare tumours are composed of a network of fine lymphatic vessels or of dilated lymphatic spaces communicating with each other, like those of the cavernous angioma, the cavities containing lymph instead of blood. Congenital forms of lymphangioma are met with in the conditions of hypertrophy of the tongue (macro-glossia) and

Fig. 369. - Nævus (454 diam.) The endothelium apparently almost obstructs the lumen of the vessels as the result of their contraction.

Fig. 370. - Nævus (188 diam.) infiltrating fat. The shaded bands represent vessels out of focus, the ends of some of them being shown in transverse section.

of the lips (macro-cheilia); also in the neck and occasionally elsewhere as a multilocular cystic tumour—the *cystic hygroma*. This tumour is situated in the subcutaneous tissue, and also forms one variety of congenital sacral tumours. It is composed of a number of thin-walled cysts, sometimes completely closed and sometimes communicating with each other; the separate cysts are held together by areolar tissue, in some cases containing fat. The contents are clear and serous. The walls of the cysts are lined in some cases with an endothelium like that of the lymphatics. These tumours often attain a great size in the neck and sacral region, but in other situations they are seldom very large. If their size permits, they can be removed: other modes of treatment have not proved successful.

E. Lymphadenoma. Tumour composed of Lymphatic Tissue. Lymphoma.—Lymphadenomata are composed of tissue exactly resembling that of the follicles of the lymphatic glands, lymphoid or lymphatic tissue, the so-called "adenoid tissue" of His; but to avoid confusion, the term "adenoid" should never be used in connection with this structure, but reserved for tissues resembling those of the secreting glands. Lymphoid tissue (Figs. 371, 372) is characterized by a delicate reticulate stroma, in the meshes of which are

packed cells, in every way resembling the white corpuscles of the blood. The stroma is composed of fibrous tissue containing a few oval nuclei scattered through it, especially where the bands cross each other. The stroma may, in some cases, be increased in amount and thicker than that normally found in lymphatic glands. The vessels are abundant and in close connection with the stroma. The tumours are white or grey in colour, sometimes stained by hæmorrhages. They vary considerably in consistence; sometimes they are soft and brain-like, and sometimes hard and tough. This difference depends upon the proportion borne by the cells to the stroma. The softer forms yield an abundant milky fluid on scraping, resembling the juice of a cancer. The lymphoid character of the cells in the fluid, however, at once shows the true nature of the growth. The development of these tumours forms the essential feature of the general affection known as "Hodgkin's disease." In this affection there is an enlargement of the lymphatic glands, accompanied in some cases by disseminated lymphoid tumours in the liver, spleen, kidneys, and

Fig. 371. Lymphadenoma (454 diam.). Some of the cells have been removed to show the arrangement of the stroma.

Fig. 372. Lymphadenoma (188 diam.). Shows general arrangement.

other organs, and occasionally in the medullary tissue of bones. To this general form of the disease, Gowers applies the name of *lymphadenosis*. The chief general symptom is marked and progressive anaemia. The red corpuscles of the blood are diminished in number, and the white may or may not be increased. The increase in the white corpuscles is met with chiefly in those cases in which the tumours are soft and disseminated throughout the viscera, and more especially when the spleen is enlarged. The disease may occur at any age, but is most common in young adults. For the further symptoms, the reader must refer to works on medicine. Lymphadenoma comes under the care of the Surgeon only as it occurs in the lymphatic glands. The glands of the neck and axilla are most frequently affected. They form painless swellings, usually firm in consistence, and of slow growth, and are at first indistinguishable from simple hypertrophy or chronic inflammatory enlargement. The glands remain distinct till they have acquired a considerable size; but later on they may fuse together, forming a large lobulated mass. While they remain distinct, they form no adhesions to surrounding parts, and can easily be removed; but when the growth extends beyond the capsules of the glands, it may infiltrate surrounding structures. They show no tendency to caseation, and never soften or suppurate. The skin covering

them is not adherent and retains its natural colour. The affection may remain for a long time, or even permanently, limited to one set of glands. In these cases, as a rule, the stroma is in great excess, and the tumours are hard and fibroid. After a time they may cease to grow. When large numbers of glands are affected and disseminated growths are present in the viscera, the growths are usually, but not always, softer, and the case almost inevitably terminates fatally after two or three years. Death may take place from the general disease, or from the effects of local pressure, especially when the growth extends beneath the sternum, or presses on the trachea or recurrent laryngeal nerve.

Lymphadenoma frequently comes under the observation of the Surgeon affecting a single gland or group of glands unaccompanied by any constitutional disturbance. In these cases the disease seems to be a mere hypertrophy of the affected glands; and perhaps, strictly speaking, should hardly be classed with tumours. The diagnosis of lymphadenoma in the early stages is practically impossible. At a later period, the great enlargement of the glands, and the constitutional symptoms, indicate the nature of the case. The absence of a local cause of irritation, and the want of any tendency to caseation or suppuration, serve as a rule to distinguish it from chronic inflammation of the glands. The question of removing the enlarged glands often comes before the Surgeon. If the affection is local, and the general health fairly good, the operation may safely be undertaken. If there is very marked anæmia, or if there be a high temperature, and especially if the tumours are very numerous, the spleen enlarged, and the white corpuscles distinctly increased in number, any operative interference should be avoided unless it seems possible to relieve the patient from imminent death from pressure on the trachea.

F. Papilloma. Tumour resembling the Papillæ of Skin or Mucous Membrane.—A papilla is a more or less pointed projection composed of connective tissue, surrounding a capillary loop and covered by epithelium, which may consist of many layers, as in the skin, or of only one, as in the intestine. Lymphatic spaces and capillaries are present in the areolar tissue. The tumours which pass under the name of papillomata are usually mere hypertrophies of the normal papillæ of the part on which they grow, and are covered by the variety of epithelium natural to the part. The papillæ of which they are composed differ from those normal to the part in size, shape, and vascularity. Thus, instead of merely microscopic papillæ, such as are normal to the skin, we may have growths sometimes reaching the size and presenting the appearance of the head of a good-sized cauliflower. Instead of simple papillæ, we may have branched growths subdividing again and again, and connected with the parent tissue only by a narrow stalk. The vessels of these growths are always abundant, and frequently dilated to a considerable size. The connective tissue forming the basis of the papillæ is more or less crowded with small round cells, according to the rapidity of the growth. Sometimes the deeper layers of the epithelium are darkly pigmented. Malignant tumours of various kinds when seated on a free surface may assume a papillary form, but these must not be confounded with papillomata. On the other hand, a papilloma may by invisible degrees merge into a squamous or columnar carcinoma, the distinction between them sometimes being difficult, even with the help of the microscope. So long, however, as the tumour maintains a simple papillary form, the epithelium being

altogether superficial, and showing no tendency to burrow between the papillae into deeper parts, the tumour is non-malignant. In other cases, such as the common warts or gonorrhoeal warts, the growth is always simple. Papillomata vary in hardness and softness, according to the parts on which they grow, and the amount and nature of epithelium with which they are covered. Thus the common corn or wart, being thickly covered with horny epithelium, is hard, while the papillomata of the rectum, being thinly covered with columnar epithelium, are soft.

The chief forms of papilloma are :—corns, simple warts, condylomata and mucous tubercles, and some forms of polypi and villous tumours.

Corns consist of an undue development of cuticle, with slightly increased vascularity of the subjacent cutis; subsequently the papillae themselves become enlarged, especially when the irritation has been prolonged or con-

Fig. 373. —Papilloma of Soft Palate. (40 diam.)

- a. Superficial epithelium.
- b. Younger epithelium: in the deeper parts the cells are more deeply stained and radiate from the centre.
- c. Connective tissue forming the papillae, into the ramifications of which it is prolonged.
- d. Vessels cut obliquely.

siderable. A soft corn is merely one which from its situation is kept constantly moist, so that the newly formed scaly epithelium, instead of forming a dense crust, peels off, leaving the vascular and sensitive papillae but thinly covered.

Warts are the result of a primary hypertrophy of the papillae, accompanied by the formation of new vessels, and a great increase in the development of the epidermis, which forms laminated strata, and sometimes produces, in the hollows between the papillae, masses with a concentric arrangement of the cells, closely resembling the nest-like structures seen in squamous carcinoma. The true warts are most commonly found on the skin, and are then often very hard and horny; sometimes they may develop a long horn-like growth. Softer varieties are, however, found on the muco-cutaneous surfaces, especially of the prepuce and vulva, and are usually of specific origin. They may also occur on the mucous membrane of the mouth or soft palate (Fig. 373), and they are not uncommon in the larynx.

Warty growths on the vulva, the result of gonorrhoeal irritation, may reach the size of a fetal head. Simple cutaneous warts are often pigmented, being of

a bluish-black colour. In these the papillæ may not be evident to the naked eye, the spaces between being filled up with epithelium, but the papillary structure is readily demonstrated by the microscope.

In **Condylomata and Mucous Tubercles** the enlarged papillæ are soft, and contain a great abundance of small round cells, giving evidence of their rapid growth. They occur about the anus and in the perineum and folds of the nates, as well as occasionally in the larynx and fauces. They are always dependent on a syphilitic taint. When situated on the mucous membranes, they are often pointed, somewhat pendulous, nodulated on the surface, very vascular, and bleed readily when touched; but when they occur on a mucocutaneous surface, they are flattened, expanded, soft, and white, constituting the true condylomata or mucous tubercles.

Some forms of **polypi** are properly classed amongst papillomata. Thus the simple polypus of the rectum may be a soft papilloma bearing columnar epithelium. In some rare cases, the epithelium has been found to be scaly. The papillæ may branch again and again, the pedicle being comparatively small. It is difficult, however, to draw any accurate line between such papillomata and the columnar carcinoma to be described hereafter.

Villous tumours of the bladder, formerly described as "villous cancer," are also papillomata. These tumours are composed of long delicate processes floating freely in the cavity of the bladder. They each consist of a dilated capillary loop, surrounded by an almost homogeneous connective tissue, containing a few scattered round or oval cells, and covered with an epithelium of an irregular shape, often resembling spindle cells in form, and similar to that naturally lining the bladder. This epithelium is very difficult to find, as it soon separates by maceration in the urine after death. The base from which the villi grow is composed merely of fibroid tissue tunnelled in all directions by dilated vessels. These tumours, if left unrelieved, invariably terminate fatally from the abundant hæmorrhage to which they give rise, and the interference with the escape of urine from the bladder; but they never give rise to secondary growths nor invade surrounding structures, and are consequently non-malignant. They will be more fully described under diseases of the bladder.

The general principles of *Treatment* of these affections consist in their removal by excision, ligature, or caustics, according to their size, situation, and attachments. Excision is usually preferable when they are of large size. If they are seated on a mucous surface, and are pedunculated, the ligature is the safest means of removal. In many cases Paquelin's cautery will be found very useful in removing large papillary growths. Small warty growths on the skin or on a mucocutaneous surface can usually be cured without difficulty by the application of salicylic collodion. (Salicylic acid, gr. 100, flexible collodion [$\frac{1}{2}$ strength], one ounce.) Extract of Indian hemp is sometimes added to this to prevent pain, and the preparation is then known by the name of "Solvine." (Salicylic acid, 60 grains, extract of Indian hemp, 8 grains, and flexible collodion [$\frac{1}{2}$ strength], one ounce.) If the cuticle be very thick the wart may be cured by the application of a saturated solution of potassa fusæ in water.

The term "**polypus**" may conveniently be defined here. It is purely clinical, and has no pathological meaning. It merely means a tumour growing from the mucous surface lining a cavity, having a distinct peduncle and a

rounded, oval, or papillary form. Thus the ordinary polypus of the nose is usually a myxoma, and the malignant polypus a sarcoma. Polypus of the uterus is a fibro-myoma, and polypus of the rectum often a papilloma, and sometimes a form of cancer. Simple polypi are usually covered by a prolange-

Fig. 374.—Adenoma (adeno-fibroma) of Mammary, of slow growth (188 diam.). Stroma bears a large proportion to the spaces; it consists of well-formed fibrous tissue. Tubes contain more than one layer of epithelium.

tion of the mucous membrane from which they grow. Thus the mucous polypus of the nose is covered by a membrane bearing ciliated epithelium.

(*G.* **Adenoma. Glandular Tumours.**—These tumours resemble secretor-

Fig. 375.—Adenoma (adeno-sarcoma) of Mammary, rapid growth (188 diam.). This is sometimes spoken of as adeno-sarcoma; the epithelium in the acini is arranged in several layers, the stroma contains many cells and some fibres.

glands in structure. Secreting glands are racemose or tubular, and consequently adenomata are divided into two corresponding classes.

The **Tubular Adenomata** are composed of masses of tubules resembling those of the structure in which they originate, some closed and some open on the surface. In the rectum or intestine the tubes resemble the crypts of Lieberkuhn. These tumours are usually papillary. They often form polypoid

growths. When simple and with well marked papillæ, they might perhaps be more properly spoken of as papillomata, and they were consequently mentioned under that class. When showing the well marked malignancy so common to these growths, they are classed with carcinomata, either under the name of columnar epithelioma, columnar carcinoma, or adenoid cancer. They will therefore, be more fully described hereafter.

In the skin a tubular adenoma is occasionally met with arising from the sweat-glands. It forms a flattened elevation, arising about one-tenth of an inch above the level of the surrounding parts, and somewhat coarse on the surface. A section shows it to be composed of closely packed tubular glands exactly resembling those of the normal sweat-glands. These growths are very rare. They may ulcerate in the centre after reaching a certain size and by invading the surrounding parts show a local malignancy, but they never give rise to secondary growths.

The **Racemose or Acinous Adenomata** resemble in structure more or less perfectly a racemose gland, and are always found in connection with such organs (Figs. 374, 375). They are composed of rounded or irregular spaces lined with a peculiar small epithelium, somewhat square or rounded in form, and frequently many layers deep. The spaces communicate with each other, either directly or by means of duct-like channels. The acini, which are more or less widely separated, are bound together by fibrous tissue, bearing vessels, and containing cells varying in shape and number. In the most typical forms the cells are merely such as are seen in ordinary connective tissue; but if the tumour be growing rapidly, large numbers of small round or oval cells are found (Fig. 375). Sometimes the tissue between the acini may be composed entirely of spindle cells, in fact, may have the structure of a spindle-celled sarcoma; the tumour is then often spoken of as an adeno-sarcoma. Sometimes tissue resembling that of a myxoma may be found. Very frequently the acini become dilated into cysts, varying in size from a pin's head to a walnut, or larger; this forms the so-called cysto-sarcoma of the mamma. Not unfrequently in such cases cauliflower-like intra-cystic growths, similar in structure to the rest of the tumour, may be found projecting into the cysts. These tumours are most frequent in the mamma, but they are sometimes seen in connection with the parotid, and have been recorded as growing from the racemose glands of the soft palate, from the lachrymal gland, and from the sebaceous glands of the skin. In the parotid they are often mixed with myxoma and enchondroma. They are rounded or oval in shape, perfectly circumscribed, and surrounded by a fibrous capsule. They are hard and elastic, occasionally presenting points of fluctuation when containing large cysts. They are always non-malignant, and there is no reason to believe that they ever assume a carcinomatous character. Their clinical features and treatment will be fully discussed in the chapters on the diseases of the organs in which they occur.

IV TUMOURS COMPOSED OF TISSUE WHICH IS EITHER PURELY EMBRYONIC, OR IS UNDERGOING ONE OF THE PRIMARY MODIFICATIONS SEEN IN THE DEVELOPMENT OF ADULT CONNECTIVE TISSUE: SARCOMATA.

The large group of tumours classed under the name of **Sarcomata** includes many which were, till comparatively recently, known by a variety of other

names, and grouped in other divisions: and the term "sarcoma," which has now received a definite meaning, was formerly applied to almost any soft fleshy growth. Almost all soft sarcomata of bones, the glioma or glio-sarcoma of the eye, sarcomata of secreting and lymphatic glands, were formerly called soft cancer; the melanotic sarcoma,—melanosis or melanotic cancer; the ossifying sarcoma,—osteoid cancer; and the chondrifying sarcoma,—malignant enchondroma. Many firm sarcomata have been described as scirrhus, and soft sarcomata broken down by hæmorrhage as blood-cysts. Lastly, the tumours known as fibro-plastic, fibro-nuclear, recurrent fibroid, malignant fibroid, and myeloid, have all been brought into the great class of sarcomata. These tumours may grow in any part of the body. They may present every variety of consistence, colour, and shape; they may be circumscribed or diffuse: they may be as innocent as a fatty tumour, or as malignant as the worst form of cancer. The anatomical type of sarcoma is found in embryonic tissue, a description of which has been given in a former page (p. 1002). Its pathological analogue is seen in the products of inflammation, but between these and sarcoma are many differences. The products of inflammation, supposing they live, show a tendency towards development into some more perfect tissue; but in a sarcoma the older parts of the growth show no higher development than the most recent, the same type of structure being as a rule maintained throughout. The ossifying and chondrifying sarcomata and some fibro-sarcomata are, however, exceptions to the rule. Inflammatory new growths tend speedily to limit themselves, sarcomata to grow indefinitely. In sarcoma, the individual elements are often larger than those seen in inflammation.

The cells of sarcomata vary greatly in shape and size, and it is chiefly according to these variations that this group is subdivided. The cells consist simply of a mass of protoplasm surrounding one or more nuclei, and not enclosed in a cell-wall. They may be small and round, exactly resembling the white corpuscles of the blood, or large and round, looking almost like epithelium cells; they may be oval, spindle-shaped or fusiform, stellate or tailed; giant cells crammed with nuclei may be found, and occasionally the cells are pigmented. The intercellular substance may be scanty or abundant, homogeneous or fibrous, but whenever it is recognizable it is seen to penetrate between the individual cells in the greater part, if not in the whole of the tumour, and thus a broad distinction is established between these growths and carcinomata, in which the stroma forms alveolar spaces, the cells lying free within them. Occasionally the growth may ossify or chondrify. The blood-vessels of sarcomata are usually abundant and thin-walled, resembling those of newly formed granulations; whilst in some tumours the blood-vessels are little more than clefts bounded by the actual cells of the tumour. This makes these tumours prone to bleed, both into their own substance and externally, and may perhaps account for the readiness with which many sarcomata propagate themselves in the direction of the circulation. In some forms the vascularity is such that the whole mass pulsates expansively, and on auscultation a loud bruit may be heard, and thus the tumour may easily be mistaken for an aneurism. No lymphatics have been demonstrated in sarcomata. These growths are usually prone to early degeneration. They most commonly undergo fatty degeneration in their central parts, but occasionally they may calcify; mucous softening also may take place. When they reach the surface

they may slough and ulcerate, forming foul cavities, sometimes of great size; but more commonly, when relieved from the pressure of the skin, they form large fungating protrusions, often bleeding profusely, the so-called "*fungus hæmatodes*." Cysts are of frequent occurrence in some forms of these tumours. On scraping after a section has been made, sarcomata do not yield a milky juice when fresh, but after about twenty-four hours it can often be obtained. Some sarcomata are distinctly circumscribed and enclosed in a fibrous capsule; others infiltrate surrounding parts like the carcinomata. Sarcomata are most frequent in youth and middle life, but may occur at any age. As a rule, it may be said that sarcomata infect the system through the medium of the blood-vessels, while carcinoma is disseminated chiefly by the lymphatic system. This rule has many exceptions, yet nothing is more common than to see secondary growths of sarcoma in the lungs, liver, and other organs, without the lymphatic glands having ever been affected. The reverse is the rule in carcinoma. It may also be broadly stated that, the more closely a sarcoma approaches to fully developed connective tissue in its structure, the less likely it is to prove malignant; but this rule is not free from exceptions. Sarcomata vary greatly in their rate of growth, some proving fatal in less than a year, others lasting many years without attaining any considerable size. Sarcoma tissue sometimes occurs mixed with other kinds of growth.

VARIETIES OF SARCOMA.—Small-Round-celled Sarcoma. Granulation Sarcoma. Encephaloid Sarcoma.—These tumours were formerly included among soft or encephaloid cancers. They resemble in structure the superficial layers of granulations, being composed of small round cells about the size of a white blood-corpuscle, or a little larger, each containing a round or oval nucleus, and imbedded in a homogeneous intercellular substance (Fig. 376). Sometimes the intercellular substance is scarcely perceptible, sometimes it is more abundant, as shown in the accompanying figure. It may be more or less distinctly fibrillated. These tumours are soft, sometimes even pulpy, and grey or whitish in colour. They usually infiltrate surrounding parts. They are excessively vascular, and often present scattered patches of hæmorrhage or cysts resulting from extravasation of blood. They may pulsate forcibly, and have more than once been mistaken for aneurisms. They yield no milky juice when quite fresh, but when decomposition sets in, it can easily be obtained by pressure or scraping. Their chief seats are the skin, bones, subcutaneous areolar tissue, muscles, and occasionally glands. The diagnosis cannot be accurately made till after removal. They show a malignancy equal to that of the worst carcinomata. Their growth is rapid, and they early give rise to secondary deposits, especially in the lungs, and the lymphatic glands are frequently affected.

One form of small-round-celled sarcoma has been described by Virchow under the name of **Glioma**, from its resemblance in structure to the neuroglia or connective tissue of the brain and spinal cord, from which it always springs. It is composed of an excessively delicate areolar stroma, having round cells imbedded in its meshes. Ziegler states that the apparent areolar stroma is in fact composed of numerous branching processes going off in all directions from the cells. These tumours vary much in consistence, being sometimes soft and sometimes quite firm. They are never circumscribed, always invading the surrounding parts. They occur in connection with the nerves or nervous centres. The tumour formerly known as soft cancer of the eyeball is in fact

a glioma arising from the retina. It is most common in young children, and frequently runs a malignant course, projecting beyond the eyeball, infiltrating surrounding parts, and giving rise to secondary growths.

Another variety of small-round-celled sarcoma is the **Lympho-sarcoma**. It is distinguished by the character of the stroma, which consists of a fine reticulum. After pencilling or shaking a thin section in order to remove some of the round cells, it will be found that the reticulum is formed by the branching processes of small nucleated cells. The structure of the tumour thus closely resembles that of a lymphadenoma. Lympho-sarcomata occur chiefly in mucous membranes and lymphatic glands, but occasionally affect the tonsil and testis. They tend to cause secondary disease of the lymphatic glands at an early stage of their growth.

Spindle-celled Sarcoma. Fasciculated Sarcoma. Recurrent Fibroid Tumour. Fibro-plastic Tumour.—These tumours are composed of spindle-shaped, fusiform, or oat-shaped cells, either lying closely in contact with each

Fig. 376. Round-celled Sarcoma, from a large tumour in the muscles round the upper end of the femur (188 diam.). The cells vary in size and have a very clear nucleus and nucleolus; the matrix which has shrunk away from the cells is faintly granular.

Fig. 377. Spindle-celled Sarcoma, from subcutaneous tissue of groin (188 diam.). Cells of medium size, no intercellular fibres.

other or separated by a homogeneous or fibrous intercellular substance (Fig. 377). The cells vary greatly in size in different tumours, but are usually tolerably equal in the same growth. They may be little more than $\frac{1}{1000}$ inch in length, or they may reach entirely across the field of the microscope. This has given rise to the distinction between large and small spindle-celled sarcomata. The intercellular substance is usually more abundant and more fully developed into fibrous tissue in the small than in the large-celled growths; and it is the former, therefore, that gradually merge into fibromata, so that it is often difficult to determine under which heading to class them, and some writers have given them the name fibro-sarcoma. All spindle-cells, large or small, contain an oval nucleus with one or more nucleoli. The cells are usually arranged in bands crossing each other in various directions, often giving the growth a fasciculated or fibrous appearance, and if a band happens to be cut transversely it presents the appearance of a group of small round cells. The vessels, as in other sarcomata, are abundant and thin-walled.

The *small-spindle-celled sarcomata* are usually firm in consistence, and of a pinkish or whitish colour, the central parts being yellow from fatty degeneration. Occasionally they contain cysts filled with straw-coloured fluid, and they may closely resemble in aspect the common fibroid tumour. They grow

by preference in fibrous structures, as fasciæ, skin, or tendons; they may occur in intermuscular spaces, or occasionally in the sheaths of nerves. Thus I have amputated a leg for a large tumour of this kind seated on the posterior tibial nerve. Though these tumours are usually distinctly circumscribed and sometimes encapsuled, and run a perfectly innocent course, in many cases they show an extraordinary tendency to local recurrence after removal; but it is rare for them to give rise to secondary deposits in internal organs. Paget described these growths under the name of *recurrent fibroid tumours*, and related several instances of them. One was a tumour of the upper part of the leg, which between 1846 and the end of 1848 had been removed five times, and reappeared for the sixth time after the last operation, when, as it had become large and ulcerated, amputation was deemed advisable; this procedure, however, was followed by death. The examination of the third tumour presented "very narrow, elongated, caudate, and oat-shaped nucleated cells, many of which had long and subdivided terminal processes;" in the tumour last removed, the cells were generally filled with minute shining molecules, as if fatty degeneration had taken place. In another case, a tumour of the shoulder had been removed, and returned four times between May, 1848, and December, 1849, reappearing in the following year for the fifth time; it, however, after a time became stationary, and many years afterwards the patient, but for the presence of the tumour, might be considered a strong and healthy man. Paget also relates a case in which, between 1839 and 1851, Syme removed a tumour of this kind five times from the upper part of the chest: a sixth recurrence was followed by death. He refers also to a case by Gluge, in which a similar tumour was five times removed from the scapula, its sixth reappearance being followed by death. The most interesting of all is a case by MacLagan, in which four removals were performed in the course of thirty-six years, twenty-three years intervening between the second and third removals, and eleven between the third and fourth. The recurrent tumours appear to be more malignant in the later than in the earlier recurrences, becoming more painful, rapidly degenerating, and giving rise to an ulcerating fungus, which eventually proves fatal by exhaustion and hæmorrhage. The cells will then be found to have become larger, and the intercellular substance softer and devoid of fibrillation; and, in fact, they merge into the large-celled form of spindle-celled sarcoma. This is clearly shown by a case which occurred under my care at University College Hospital. A tumour as large as a full-sized turnip was removed from the shoulder of a middle-aged man, and was found to be slightly connected with the spine of the scapula. On examination it presented all the characters of a spindle-celled sarcoma, consisting almost entirely of densely packed fusiform cells, with oval or oat-shaped nuclei. A small mass reappeared before the wound had completely healed, and on examination presented a much larger proportion of oval cells and spindle cells, now having double nuclei. It recurred a second time, and now but few well formed spindle cells were found, but the tumour was chiefly composed of oval and disk-shaped cells, or rather masses of protoplasm, in which numerous nuclei of the spine of the scapula, removed with the growth had sprung from the cancellous tissue.

mata, formerly often spoken of as fibro-plastic in the variety last described. They are usually dark-red in parts from extravasations

of blood, and if of any size, their central parts are opaque and yellow from the effects of fatty degeneration. They yield more or less transparent viscid juice on scraping, mixed with fragments of the growth. They may be distinctly circumscribed and encapsuled, but not unfrequently they invade surrounding parts. They often contain cysts of some size, sometimes filled with straw-coloured fluid and sometimes with blood or a blood-coloured liquid. These tumours frequently form in connection with bones, especially commencing under the periosteum of the shafts of long bones or about the bones of the face or nose. I once amputated a thigh at the hip-joint in University College Hospital, for a large tumour of this kind growing beneath the periosteum of the femur; and in another case the arm was removed by Heath for a similar growth. Both had caused spontaneous fracture of the bone, and both ultimately proved fatal from secondary internal growths. These tumours when affecting bone, must not be confounded with the myeloid, which they closely resemble. Large-spindle-celled sarcomata also grow in fasciæ and intermuscular spaces, and not unfrequently in glands, especially the mamma; and they may be found in rare cases in almost any situation. They very often run a malignant course, giving rise to secondary growths in internal organs. Their tendency to local recurrence after removal is very great.

From what has been said above, it will be seen that the spindle-celled sarcomata form a very large and important group of tumours, varying greatly in clinical characters and structure, but all resembling each other in the broad feature of the spindle cell forming the predominant element. As to their *prognosis*, it may be stated generally that the more they approach the structure of the spindle-celled growth found in cicatrizing wounds, the less likely they are to give rise to general infection of the system; but that even the simplest may recur locally after removal, and consequently too guarded a prognosis cannot be given in such cases.

Oval-celled Sarcoma

FIG. 378. Oval-celled Sarcoma.
(See diam.)

(Fig. 378) may be looked upon as merely an extremely rapidly growing and malignant spindle-celled tumour. Thus we saw in the case above mentioned, that, as the rapidity of the growth increased with each recurrence, the spindle cells were replaced by large oval cells with two or more nuclei. But similar growths may occur primarily. They are soft, rapidly growing, rarely completely circumscribed. They are of a delicate pinkish colour, and yield an abundant shiny albuminous fluid on section. I have twice had occasion to remove such growths from the neighbourhood of the mamma. In one case the disease recurred

locally after the wound had healed, and in a short time formed an enormous tumour, larger than the patient's head. She refused a second operation, and the case soon terminated fatally. In the other, although a large portion of the pectoral muscle was removed with the tumour, it recurred before the wound healed, and, in spite of the free application of caustics, grew with enormous rapidity, in a few weeks forming a fungating mass as large as a foetal head.

Myeloid or Giant-celled Sarcoma was formerly often classed under fibroplastic tumours, and sometimes probably as soft cancer. It was described by Abernethy under the name of "albuminous sarcoma." It was less fully

described by Lebert, and its clinical and anatomical characters have been carefully investigated by Paget. It is nearly related to the spindle-celled group of sarcomata.

The most characteristic feature of myeloid tumours is the presence of large, many-nucleated masses of protoplasm—the so-called myeloid cells—somewhat resembling the cells found in the marrow of foetal bones (Figs. 379, 380).

Fig. 379.—Myeloid Sarcoma from the Lower Jaw (400 diam.). The small cells have shrunk away from the myeloid cells; the former vary from round to spindle shape.

Fig. 380.—Constituents of a Myeloid Tumour (454 diam.).
a, b, c, From a fresh scraping.
d, From a stained section.
d, Transparent nuclei from a fresh scraping.

They are often of great size, sometimes $\frac{1}{4}$ inch or even $\frac{1}{2}$ inch in diameter, and extremely irregular in shape, having processes projecting from them in all directions. The nuclei vary from eight or ten to thirty or forty in number, and are oval in shape, with distinct and highly refracting nucleoli. These myeloid cells are imbedded in masses of spindle-shaped or roundish cells, between which there is either no intercellular substance, or merely a small quantity of homogeneous gelatinous material. These growths are extremely vascular; so much so, that the whole mass may pulsate distinctly. Myeloid tumours frequently contain cysts, often of considerable size. On section they present a soft gelatinous appearance and brittle structure; they usually yield a slimy fluid on scraping, mixed with fragments of the tumour; they are of a pink colour at their growing margin, while the central parts are of an opaque yellow from fatty degeneration. The intermediate parts usually present patches of a dark maroon colour, caused by extravasation of blood. Occasionally patches of ossification may be found. Myeloid tumours grow almost exclusively from bone, and by far most frequently from the medullary cavity or cancellous tissue at the head of a long bone. They attain a large size, sometimes slowly and gradually, and at other times with very great rapidity. The growth gradually causes absorption of the bone, but at the same time a new deposit takes place from the periosteum, so that the tumour

Fig. 381.—Myeloid Tumour of Radius.

is enclosed in a thin bony shell, which, on pressure, yields the peculiar sensation known as "egg-shell crackling." On reaching a cartilage-covered surface it pushes the cartilage before it, but rarely if ever perforates it. On examination of such a tumour after removal, a bony plate will frequently be found separating it from the medullary canal. In other cases it may extend a long distance, infiltrating the medulla. Myeloid tumours are most common at the lower end of the femur, the upper end of the tibia, and the upper end of the humerus. They also, when growing from the jaw-bones, form one variety of epulis. I have removed them from the lower end of the radius, and

Fig. 382.—Myeloid Tumour of the Metacarpal Bones of the Index and Middle Fingers. Successful Removal of these Bones and Fingers.

from the metacarpal bones (Figs. 381, 382). In the majority of cases they may be safely removed without the prospect of recurrence, but occasionally they return after removal. The true myeloid rarely, if ever, gives rise to secondary deposits in the lymphatic glands or internal organs. Myeloid tumours are said to have been seen in the parotid region and the mamma, but this is doubtful.

Ossifying and Osteoid Sarcomata.—These tumours were formerly

classed amongst the cancers, under the name of "osteoid cancer." Almost any form of sarcoma may undergo ossification. Thus round-celled, spindle-celled, and myeloid sarcomata may occasionally show abundant formation of bone. The development of bone in these growths seems to give rise to no radical change in their nature. They still show the same tendency to unlimited growth and sometimes the same liability to recur locally or to give rise to secondary deposits in distant parts. The secondary deposits develop bone like the original growth. The bony parts of these tumours usually present the appearances of true bone, but somewhat irregular in structure. Occasionally tumours growing from bone are met with, which present the structure of the growing tissue found beneath the periosteum in inflammation or in normal growth; that is to say, small round or polygonal cells (osteoblasts), with single nuclei, separated by a small amount of homogeneous or fibrillated intercellular substance. These are arranged in a layer or laminae of newly formed bone. Sometimes the whole growth may resemble a mass of callus. These *osteoid sarcomata*, as they have been termed, form under the periosteum, and the bone beneath is often thickened, so that the medullary canal may be obliterated. They show a considerable tendency to local recurrence after removal. In rare cases, ossifying sarcomata are found unconnected with pre-existing bone.

The **Chondrifying Sarcoma or Chondro-Sarcoma.**—These tumours were formerly classed with chondromata, and were regarded as malignant cartilaginous tumours. Microscopic examination, however, shows that their growing margin is distinctly sarcomatous, composed most commonly of spindle-shaped or round cells. These become separated by a homogeneous ground-substance forming the matrix of the cartilage, the cells remaining as cartilage cells. Irregular patches of ossification may be scattered through the growth. These tumours are not circumscribed, the sarcoma tissue invariably invading

neighbouring parts. They commonly run a malignant course, and the secondary tumours may show the same tendency to the development of cartilage. They are met with almost exclusively in connection with bone, and most commonly commence under the periosteum of one of the long bones near its articular end. They are also not uncommon in the upper and lower jaw, and are occasionally seen in the testicle. They are distinguished from simple chondromata by their more rapid growth and their tendency to invade surrounding parts.

Alveolar or Large-Round-celled Sarcoma.—In this rare tumour, which was first clearly described by Billroth, the cells are of considerable size, sharply defined, and each contains a large round nucleus (Fig. 383). They thus closely resemble epithelium cells in appearance. They are separated from each other by a distinct and somewhat abundant fibrous stroma, but on careful examination this will be found to penetrate between the individual cells. In some parts, probably from the pressure of the growing cells, the stroma may be partially absorbed, so that the cellular elements seem to lie in alveolar spaces in immediate contact with each other, but further examination of the tumour will always show parts where the stroma and cells are closely intermixed. On carefully pencilling out the cells from a thin section, a delicate stroma is brought into view, passing between the individual cells and subdividing the spaces formed by the bands, which give the growth its alveolar and cancer-like appearance (Fig. 383b). In some cases, however, the distinction between these tumours and

Fig. 383.—Alveolar Sarcoma from Skin of Leg (185 diam.).

A. To show general arrangement.

B. After prolonged pencilling shows the intercellular as well as the alveolar stroma.

scirrhus is very difficult. Alveolar sarcomata occur chiefly in the cutis, bones, and muscles, and occasionally in the breast. In the cutis they form hard rounded tumours, often multiple, of tolerably slow growth, and free from pain. They lead ultimately to ulceration of the skin and the formation of an intractable sore. In the bones, they are more often single and of more rapid growth. Three cases affecting the cutis have occurred in University College Hospital during the last few years. In the first, three amputations were performed for recurrence of the growth after removal, by Christopher Heath, commencing with one finger and ending with the forearm. The tumour, when first removed, was supposed to be a specimen of scirrhus of the skin. Finally similar tumours appeared on the cheek and sculp, and two further operations were performed. The man died shortly afterwards, and there was reason to believe that the cause of death was a similar growth in the lung. The whole history of the case lasted more than seven years, and at no time had the lymphatic glands been affected. In the second case, Berkeley Hill amputated the leg for a number of similar tumours situated below the knee, from one of which the accompanying drawing (Fig. 383) is taken; and in the third, half the foot was amputated for a similar growth, which commenced at the roots of the second and third toes, and had recurred three times after removal.

Plexiform Sarcoma or Cylindroma.—A rare form of tumour has been described by Billroth, Sattler, and others, under this name. It consists of small cells of a polygonal form arranged in cylinders communicating with each other in a plexiform manner, between which is a varying quantity of hyaline, or finely fibrillar connective tissue. Knob-like projections or globe-like masses of the cells are also met with. The individual cells are in immediate contact with each other, without any apparent intercellular substance. The peculiar appearances are supposed to be due to a hyaline or mucoid degeneration of the walls of the vessels and the neighbouring cells of the tumour. The remaining cells are squeezed together, and thus assume the form of columns of polygonal cells. Great doubt exists, however, as to the exact mode of origin of these growths. At first sight a microscopic section of a plexiform sarcoma closely resembles that of an epithelioma, but a careful examination with a higher power shows its true nature. The tumours seldom reach any great size. They are

soft and gelatinous, and of a dirty white colour. They are most commonly met with in the brain, the orbit, and sometimes in the salivary glands. Butlin has recorded a case in which the tumour formed in the popliteal space. It recurred after removal, and its true nature was shown by the fact that the recurrent growth assumed the form of the ordinary round-celled sarcoma.

Melanotic sarcoma is usually of the spindle-celled variety, but frequently contains large numbers of round or oval, intermixed with the fusiform, cells (Fig. 384). The spindle cells are of large size, and there is no fibrous stroma between them. More rarely it presents the structure of an alveolar sarcoma. The

pigment is seen as brownish granular matter in the interior of a certain number of the cells, the rest remaining colourless. The proportion of coloured cells varies in different specimens. In the secondary tumours, it has been shown by Godlee that the new cells follow the lines of the vessels. These tumours are usually sharply circumscribed, both to the naked eye and the microscope. They are soft, sometimes almost pulpy, round or oval in shape, and vary in colour from dark brown to the most intense black. They arise especially from structures in which pigment naturally exists, namely, the skin (Fig. 384) and choroid coat of the eye (Fig. 386). They appear, however, occasionally to arise primarily in the lymphatic glands, and primary melanotic sarcoma of the liver has been recorded. They are of rapid growth, and occur usually in middle life. Melanotic sarcoma is one of the most malignant of all

forms of tumour. The secondary growths occur in every organ and tissue of the body, and they may apparently be propagated entirely by the vascular system, the lymphatic glands escaping any contamination, or they may be distributed by both the vascular and the lymphatic systems. It may be broadly stated that if a melanotic sarcoma reach the size of a filbert, secondary deposits have in all probability occurred, and no local treatment can cure the patient, although, by relieving him of one source of infection, it may retard death. Although showing this terrible general malignancy, the local malignancy of melanotic sarcoma is not great. It may reach a large size without ulcerating; it is frequently distinctly encapsuled, and, if removed freely, often does not return in the scar. The secondary tumours form in every part of the body; constantly in the lungs and liver, almost constantly in the brain and spinal cord, spleen, kidneys, and subcutaneous tissue; very often in the heart, intestines, medulla of bones, and lymphatic glands. Like the cells of the primary tumour, some of the secondary growths are found to be pigmented and some not. The *diagnosis* of melanotic sarcoma is made by

FIG. 185.—Melanotic Sarcoma from a Secondary Tumour in the Heart. Figure to left (188 diam.) shows the different degrees of pigmentation and variety of shape in the different cells. Figure to right (454 diam.) from a fresh scraping, illustrates the differences in the size of the pigment granules.

FIG. 186.—Melanotic Sarcoma of Eye—natural size. The eye has been divided in the antero-posterior diameter. The tumour started from the choroid and afterwards burst through the sclerotic.

the colour and rapidity of the growth. It must not be confounded with the simple pigmented wart. This is always of slow growth, more or less firm, pedunculated and lobulated. It must be remembered, however, that melanotic sarcoma may start from a wart of this kind, or from a congenital mole. As to true melanotic cancer, that is to say pigmented encephaloid or epithelioma, it is doubtful if such a growth exists; at any rate, it must be of extreme rarity. The only *Treatment* of melanotic sarcoma is the immediate removal of the tumour, unless secondary tumours can already be recognized.

Psamomma is a rare form of tumour found only in connection with the membranes of the brain. The chief characteristic of this growth is the presence of small concentric calcareous globules, the so-called "brain-sand." The tumour is composed chiefly of peculiar flattened cells. It gives rise to no symptoms, except in infinitely rare cases.

Sarcomatous Blood-cysts or Hæmatomata.—Tumours have frequently been described under the name of "blood-cysts," of which the most characteristic feature is the presence of a large collection of fluid or partly coagulated blood in a cyst, the walls of which are imperfectly defined. If the blood is evacuated by puncture or incision, free hæmorrhage, difficult to

control, or, at least, speedy re-accumulation of the fluid, is the only resort. If seated on a limb, free excision of the cyst and its contents, or amputation, is justly looked upon as the only mode of treatment holding out any prospect of success. With regard to the nature of these tumours, it has been shown that in all probability they are, in the great majority of cases, soft sarcomata, broken down by hæmorrhage into their structure. The walls of these cysts are formed of a thin layer of sarcoma tissue, either of the round or spindle-celled variety. A very interesting case of this kind came under my care in University College Hospital in 1874. A healthy man, aged 40, had noticed, for about nine months, a soft swelling on the upper and outer part of the leg, which he attributed to a strain. It fluctuated distinctly; and when I first saw it, a dark red fluid was coming from two discoloured points. It was altogether about three inches in diameter, and of a dark purple colour. It had previously to admission been treated, first by the passage of a seton, and secondly, by being laid open and dressed from the bottom; which latter treatment had been repeated twice. On two occasions it was reported that nothing but blood escaped. I laid the tumour freely open, and turned out a large quantity of what was apparently ordinary blood-clot and then dissected away the cyst-wall. The supposed blood-clot was found, on microscopic examination, to be composed of a mixture of the

a. Recent Hæmorrhage.
b. Blood-corpuscles becoming granular.

cells of a round and spindle-celled sarcoma, with coagulated blood (Fig. 387). The wall of the cyst was found to be composed of pure sarcomatous tissue. The growth recurred before the wound was completely closed, and amputation at the knee-joint was performed, the patient making a good recovery.

Mixed Sarcomata.—Tumours are frequently seen which combine in themselves structures properly belonging to two or more distinct forms of growth. Several of these have already been mentioned. Thus the growths standing on the doubtful line between small-spindle-celled sarcoma and fibroma are spoken of as *fibro-sarcomata*. In very rare

cases some of the cells of a sarcoma may develop into true fat cells; we have then the *lipo-sarcoma*. Occasionally large tracts of a tumour, the chief part of which is purely sarcomatous, may undergo mucous softening, and the cells may be more or less stellate or branched, as in a myxoma, and we have then the *myxo-sarcoma*. As before stated, the tissue between the acini of an adenoma may present exactly the structure of a spindle-celled or even round-celled sarcoma: these tumours are then sometimes called *mixed-sarcomata*. Lastly, the stroma of a cancer may be composed of cells like those of a large-spindle-celled sarcoma. In tumours which are purely sarcomatous it is, moreover, very common to find a mixture of the various kind of cells which have been described as characterizing the different varieties mentioned in the preceding pages.

V. TUMOURS COMPOSED OF CELLS OF AN EPITHELIAL TYPE ARRANGED IN SPACES IN A STROMA CONSISTING OF MORE OR LESS PERFECTLY DEVELOPED FIBROUS TISSUE.

The members of this group constitute the **Carcinomata** or **Cancers**, and are uniformly malignant. Before proceeding to the individual growths forming this class, it will be desirable to say a few words upon the subject of cancer generally. The term has been very vaguely applied, the older pathologists placing under this class all malignant growths: thus all malignant sarcomata were formerly considered to be cancers. Statistics and general statements with regard to "cancer" which date back beyond 1870 must therefore be taken to refer to malignant tumours in general and not to what we now recognize as true cancers.

Although the various forms of cancer differ greatly from each other in structure, they all possess certain features in common. The essential element of every cancer is an exuberant growth of epithelium. Every exuberant growth of epithelium is not, however, a cancer. The distinguishing feature of carcinoma is that the epithelium no longer merely covers a surface or lines the acinus of a gland as in its normal state, but forces its way into deeper structures or surrounding parts. The advancing cells form bud-like processes or columns which communicate with each other by lateral branches. At the growing edge of any cancer these processes of cells can be seen advancing into the spaces of the tissue into which the growth is spreading. The pressure of the new growth, and possibly some chemical substance derived from it, irritate the surrounding tissues to such a degree that they become infiltrated with small round cells. These have all the appearances of migrating white corpuscles, but it is not impossible that they may in part arise from multiplication of the cells of the connective tissue. In some forms of cancer in which the epithelial cells are small and rounded, it is not easy to distinguish these from the surrounding small round cells, and thus there has been much diversity of opinion as to the origin of the cells of cancer; but in other varieties, as the squamous carcinoma, the different forms of cells are easily recognized, and in these there can be no doubt that the cancer cells arise from the pre-existing epithelium. If we examine a portion of a cancerous tumour, in which the structure is fully developed, we find that the original tissues of the part which has been invaded by the growth have disappeared during the process of small round cell infiltration, and that a new connective tissue has been formed which surrounds the branching columns of epithelium cells. We have thus developed an alveolar stroma, the spaces of which are filled with cells of an epithelial type, and this forms the characteristic structure of a carcinoma. The fibrous stroma must be looked upon as an essential element in the structure of the growth, and not merely as the remains of the connective tissue of the part which the cancer cells are invading. As in normal glands or epithelium-covered structures, the line of demarcation between the epithelium and the stroma is sharply defined; the cells lie closely in contact with each other without vessels or stroma penetrating between them. They are but loosely connected with the stroma and with one another, and in many cases are separated from each other by a very small quantity of fluid. If a thin section of a carcinoma be gently brushed under water with a camel's hair pencil, or shaken in a test-tube half full of water, the cells may be washed away and the stroma

left. Its alveolar nature will then be distinctly apparent, and the fibrous stroma will be seen to bound spaces which by their communication form a cavernous system.

The stroma is composed of coarse fibres, sometimes almost hyaline in appearance. Between the fibres are flattened or elongated cells, like ordinary connective tissue corpuscles. In some cases it is less perfectly developed, and may contain numerous small round cells, or even be composed almost entirely of spindle cells. The vessels traverse the stroma in all directions. They vary much in number and size. In some very rare forms of cancer they are so abundant that the whole growth may pulsate; in others they are comparatively scanty. In all cancers as the growth advances the vascular supply becomes insufficient to maintain the vitality of the central parts of the tumour, and fatty degeneration, first of the cells and subsequently of the stroma, takes place. If the tumour is superficial the tissues break down, and ulceration results.

The process above described is now acknowledged to be that by which cancer arises and spreads. It was first clearly described by Thiersch and Waldeyer. It explains the fact, that primary cancer never arises except in connection with pre-existing epithelium. The branching columns of cells probably invade the surrounding tissues by the lymphatic spaces and vessels. The proliferating epithelium, having burst through the wall of the acinus when the disease commences in a gland, or having forced its way into the deeper parts when it starts from a surface, enters the lymph-spaces and grows into them. This view is confirmed by the general arrangement of the epithelial columns, and Waldeyer believes that he has demonstrated lymphatic endothelium lying on the surface of the advancing processes of epithelium. It also explains the great readiness with which carcinoma infects the lymphatic glands. The microscopic appearances of the tissues surrounding the advancing columns of cells are identical with those of inflammation. The vessels are dilated and full of blood, and the normal structures are concealed by an abundant small cell infiltration before which the original tissues disappear as in the process of ulceration. The quantity of lymph returning from the hyperæmic tissues will necessarily be greatly increased in quantity, and the lymph-spaces and lymphatic vessels will be dilated, and thus the dissemination of the cells of the cancer will be greatly facilitated should any of them become disengaged from the general mass and enter the lymph-stream.

From the above remarks it will be seen that a carcinoma is characterized by the absence of any definite surrounding capsule. It is indeed intimately connected with the tissues in which it lies, and around the tumour there is a zone of variable extent in which infiltration is progressing but which to the naked eye does not necessarily appear to be diseased.

The cells of a carcinoma always more or less accurately resemble those of the normal epithelium of the part from which the primary tumour springs. Thus the cells of carcinoma of glandular organs belong to the type of spindle or glandular epithelium; those of the skin are squamous, and those of the intestine columnar. In rapidly growing cancers or secondary growths the cells may show a tendency to revert to the primitive type of epithelium, a simple rounded or irregular cell with a large oval nucleus. Thus the cells of a rapidly growing squamous carcinoma may be oval, or even rounded, and show but little flattening, or in a columnar carcinoma they may be shorter and oval and lose their wedge-shaped form. Still, in the great majority of cases,

there is no difficulty in recognizing the type to which the cell belongs. In other cases the cells may be larger and show a more exuberant growth than the normal epithelium, but their general characters remain the same. The old idea that there existed a peculiar specific "cancer cell" is now completely abandoned, and it is universally recognized that no certain opinion can be pronounced as to the cancerous nature of a tumour without a careful examination, not of the cells only, but of the stroma, and of the relation of the cells to the stroma. The cells of all cancers are prone to early fatty degeneration. In some forms they undergo a colloid change.

Varieties of Carcinoma.—Cancers are classified primarily according to the variety of epithelium that enters into their composition, and certain subdivisions are made according to the modifications in the stroma or in the mode of growth of the tumour. The following classification is that usually adopted:—

1. Cancers the cells of which are derived from glandular or spheroidal epithelium. *Spheroidal or Glandular Carcinoma.*

a. With abundant dense stroma. *Scirrhous, or Hard Cancer.*

b. With a small proportion of stroma forming large alveolar spaces. *Medullary, Encephaloid, or Soft Cancer.*

c. One of the above forms (a or b), with colloid degeneration of the cells. *Colloid Cancer.*

2. Cancers the cells of which are derived from squamous or stratified epithelium. *Squamous Carcinoma.*

3. Cancers the cells of which are derived from columnar epithelium. *Columnar Carcinoma*; sometimes also called inaccurately *Adenoid Cancer*.

The above form the typical and universally recognised varieties of cancer. There are, however, two other morbid growths which must be included in the same class: thyroid cancer and rodent cancer, or as it is more commonly called rodent ulcer.

Thyroid Cancer is an extremely rare malignant growth, commencing in the thyroid body and closely resembling the normal gland tissue in structure. It gives rise to secondary growths in the lymphatic glands, the lungs, and the bones, accurately repeating the structure of the primary growth. (See *Diseases of the Thyroid Body*, Vol. II., Chap. LV.) Its general malignancy forms the most marked feature of the disease.

Rodent Cancer or Ulcer is a cancer in structure, being composed of columns of epithelial cells in a very imperfectly developed stroma, like a true carcinoma. Its malignancy is, however, purely local, and although it slowly invades and destroys every structure with which it comes in contact, it never gives rise to any secondary growths. (See *Rodent Ulcer*, Vol. II., Chap. XXXVII.)

The special clinical and pathological features of the various forms will be considered after the general facts which are common to all varieties.

Secondary Carcinomatous Growths.—The most marked feature of a cancer is its tendency to give rise to secondary growths of a similar nature in various parts of the body. These may occur in three situations. First, in the lymphatic glands which receive the lymph from the affected part; secondly, in the cellular tissue in the immediate neighbourhood of the growth; and thirdly, in distant parts, especially in internal organs. The secondary growths always resemble the primary growth in structure. The secondary tumours from a glandular cancer contain glandular epithelium, those from a squamous

carcinoma, squamous epithelium, and those from a columnar carcinoma, columnar epithelium. The epithelium may be slightly modified from growing in a situation where it is far less exposed to surrounding pressure, or more abundantly supplied with blood, but its general characters always remain the same. In like manner the stroma of the secondary growth may be less abundant than that of the primary, and may thus cause some modification in the consistence of the tumour; but the broad fact remains—that the secondary tumours are of the same structure as the primary.

The mode of origin of the secondary tumours has given rise to much diversity of opinion. The view now usually accepted is that the secondary growths arise from the entrance of the cells of the cancer into the lymphatics or blood-vessels, by which they are carried to distant parts, and there lodging develop into tumours of the same nature as that from which they sprung. According to this theory, the cells of the new tumour are the descendants of the original cell which started from the primary growth. Simon, Creighton, and others believe that the new growth arises from the cells of the part in which the cancer cell has lodged, and upon which it exerts what they term a "spermatic influence," but this view is not generally accepted. The view of the direct transference of the cells of the tumour to different parts of the body is known as the *implantation theory*. Opposed to it is the *infection theory*, according to which the system is poisoned by the juices of the primary growth. There is yet another theory maintained by those who believe cancer to be a primary "disease of the blood," of which the tumour is merely the local manifestation. Those who hold this view believe that the secondary growths are merely a further effect of the constitutional condition from which the primary growth originated. Thus Paget is of opinion that in some cases, in which a rapid multiplication of cancers takes place, this may arise from an increase in the cancerous diathesis or morbid condition of the blood. But he believes that in most of these cases there has been a conveyance of cancerous material by the blood, in the form of emboli, which have determined the local seat of the secondary growth; and he supports this view by referring to the analogy pointed out by Walshe as existing between the secondary deposits in cancer and the secondary abscesses in pyæmia; the liver and lungs in both cases being principally affected. He, however, thinks that it is not necessary to suppose that entire cancer cells are thus transferred: cancer juice, or minute fragments of cancer-plasma, may be as efficient as entire cells. Virchow considers that the fact that the secondary deposit does not necessarily occur in the organ through which the blood must first pass, militates against the theory that cancer cells are carried onward by the circulation, and become impacted in the smaller vessels of the part, in the manner of emboli. He inclines to the belief that the cancerous juices are absorbed and enter the circulation either directly by the veins or indirectly through the lymphatics, and that they give rise to changes in the nutrition of certain parts, leading to the development of cancerous growths.

In favour of the simple transplantation theory is the important fact that in the secondary growths epithelium arises in situations in which it is not normally present, as in the lymphatic glands and bones; and when the growth is situated in an organ in which epithelium is normally present, as in the liver or kidney, the cells of the new growth are not those natural to the organ, but correspond to those of the primary cancer. Thus the tumours in the liver secondary to

cancer of the great intestine have shown distinct evidence of their origin in being composed of a structure resembling in appearance the crypts of Lieberkuhn. That the cells may pass along the lymphatics is sometimes shown by finding lymphatic vessels distended with nodules of cancerous growth. It is difficult to imagine juice or granular *debris* which could cause the development of glandular epithelium in bone or columnar epithelium in the liver.

The fact that the secondary growths do not invariably arise directly in the course of the lymph or blood-stream—as for instance when secondary tumours are found in the liver or bones and not in the lung—may be explained by supposing that the transplanted cells do not grow with equal facility in all structures. The experiments of transplantation of one kind of tissue into another, as of periosteum into the subcutaneous tissue, have shown that although it may grow for a time, it eventually perishes and is absorbed. This power shown by a tissue of resisting the growth of a foreign structure within it is called by Cohnheim *the physiological power of resistance of the tissues*. Cohnheim therefore assumes that in cancerous subjects this resisting power is diminished, possibly in consequence of the poisoning of the system from the primary growth, or as a part of some constitutional condition which predisposed to the development of the original tumour, and that this plays an important part in the development of secondary growths as the transplantation of cells. Against the theory that the secondary growths are entirely the result of some constitutional condition which gives rise also to the primary growth it may be urged that, if this were the case, the secondary tumours would appear in the favourite seats of the primary growth, and that each tissue should produce the form of cancer natural to itself, which, as we have seen, is the reverse of that which really occurs.

Some forms of cancer show a much greater power of reproduction than others. Thus glandular cancers recur rapidly throughout the body, while squamous carcinoma seldom infects beyond the nearest lymphatic glands. Whatever may be the exact mode of formation of the secondary growths, the balance of evidence may be said to be greatly in favour of some form of the transplantation theory, and therefore we may hope that, if the tumour could be removed sufficiently early, dissemination of the disease might be prevented. The theories here put forward with regard to cancer apply equally to the malignant sarcomata.

General Clinical History of Carcinoma.—All forms of cancer present numerous points of resemblance in their progress. When once formed, the tumour continues progressively to increase in size, with a degree of rapidity, and to an extent, that vary according to its kind. Its growth is usually accompanied by pain, varying with the situation of the tumour and its variety. When the tumour has reached a certain size, the process of decay commences in the central parts, while growth continues at the circumference. The mass softens at some point, the skin covering which becomes dusky, inflamed and ulcerated, and an irregular sloughy aperture forms, through which the *debris* of the mass are eliminated in an ichorous or sanious fluid, having often the peculiar fetid smell usually accompanying the putrefaction of epithelium. The ulcer then rather rapidly increases, with raised and everted edges, a hard and knobby, or soft and fungating surface, and the discharge of a dark fluid, often attended with hæmorrhage, and occasionally with sloughing of portions of the mass at an early period. The pain in the tumour usually

becomes more severe during ulceration. The lymphatic glands are affected most commonly at an early period in the case, but sometimes not until after ulceration of the cancer has commenced. In external cancers, such as come under the care of the Surgeon, the general health as a rule suffers but little until the presence of the foul ulcerating sore gives rise to chronic septic poisoning, or to exhaustion from pain and want of rest, and sometimes also from loss of blood. In fact at the time the patient first presents himself he is often in the rudest health except for the local disease. In cancers of internal organs, and in the later stages of external cancers when secondary internal growths have formed, the general health becomes gravely affected, and the condition known as the *cancerous cachexy* is developed. In this cachexy the countenance is peculiarly pale, drawn, and sallow, so that the patient has a very anxious and care-worn look. The general surface of the body commonly acquires an earthy or yellowish tint, and not unfrequently large spots of chloasma make their appearance on various parts of it; the appetite is impaired, the voice enfeebled, the muscular strength greatly diminished, and the pulse weak. The patient complains of pains in the limbs, of lassitude, and of inability for exertion, and he emaciates rapidly; and at last dies from exhaustion, induced by the conjoined effects of weakening discharges, general debility, and pain. Various views have been held concerning the nature of this cancerous cachexia. It has been assumed that it is an indication of a constitutional condition or blood-disease of which the tumour is merely a local manifestation. It has also been suggested that it may be due to the entrance into the blood-stream of some noxious material generated in the cancerous growth; and lastly, that it is merely the effect of the pain of the tumour, the want of rest, the exhausting discharges, and the implication of important internal organs by secondary growths. The first theory is negatived by the fact that cachexia is certainly wanting in the early stages of all external cancers, and in squamous carcinoma is often absent till near the end of the case. The second theory is a pure hypothesis; and the last is therefore that which seems most worthy of acceptance.

Causes.—The causes of cancer, as of all other diseases, may be divided into two great classes, viz.: the constitutional or predisposing, and the local or exciting.

Constitutional or Predisposing Causes.—It is difficult to connect any distinct or recognizable constitutional condition with a tendency to the disease. Cancer, indeed, commonly shows itself in persons apparently in perfect health, of florid complexion, and robust habit of body.

The *hereditariness* of cancer has, however, been established beyond a doubt. Velpeau states, as the result of his researches, that it is traceable hereditarily in one-third of the cases. Paget, amongst hospital patients, found evidence of hereditariness in about 1 in 6, but amongst private patients, whose family histories are better known, it amounted to 1 in 3; thus agreeing with Velpeau's estimate.

The hereditary tendency is in some cases not only to cancer generally, but to the same form of cancer. Thus, Paget records a case in which three generations were affected by uterine cancer. Sibley records an instance in which a mother and five daughters suffered from cancer of the left breast. It is not, however, by any means always so. Paget states that it is only in about one half of the cases of hereditary cancer that it is thus transmitted, and then almost exclusively in the breast and uterus. He relates one striking instance

of the opposite mode of transmission. A lady died of cancer of the stomach; one of her daughters died of cancer of the stomach, another of cancer of the breast; and of her grandchildren, two died of cancer of the breast, two of cancer of the uterus, one of cancer of the bladder, one of "cancer of the axillary glands," one of cancer of the stomach, and one of cancer of the rectum. The hereditary tendency transmitted from parent to offspring would seem therefore to be not purely local, as in the case of a peculiar feature, a fifth finger, or the like, but to affect the whole of the epithelial tissues, the particular spot at which the cancer appears being dependent on local causes usually unknown. Admitting the hereditary nature of cancer to the fullest extent, however, it still leaves two-thirds of the cases unaccounted for.

Age exercises a marked influence on the occurrence of cancer, both as to its frequency and its mode of growth. The statistics published before 1870 in this country, and perhaps a few years earlier in Germany, cannot be relied upon as giving a just notion of the influence of age on the occurrence of true cancer. Before that time all soft rapidly growing sarcomata were described as cancers. The malignant glioma of the eyeball, and sarcomatous tumours of the testicle and bone, being formerly classed as encephaloid cancer, that disease was said not to be uncommon in children. Now that these are excluded, all forms of cancer may be said to be almost unknown under 20. Gurlt, who possesses the patience and industry necessary for the collection of statistics to a degree rarely if ever equalled, has obtained from various sources the records of 16,600 cases of tumours of all kinds. Of these, 11,131 were cancers. In 4,769 cases of cancer, of which the age is recorded, only 0.4 per cent. occurred under the age of 20. As some of the statistics extend back to the year 1855, it is possible that even this number is in excess of the truth. In the opposite extreme of life there is no limit to the age at which cancer may occur. According to Walshe the proportion of deaths from cancer per thousand living at each age increases steadily up to 80. Gurlt shows that the absolute frequency of cancer reaches its maximum between 41 and 50, 31.68 per cent. of all cases occurring between those ages. Age influences also the liability to cancer in special organs. Thus, in extreme old age cancer of the breast is less common than in younger women, while old men are more liable to cancer of the bladder and prostate, and to squamous cancer of the lip. Thus, Walshe states that proportionally to the number living, cancer is more common in men than in women after 80. Sibley states that the average age of patients with uterine cancer is 48, and with mammary 48 years. The age of the patient exerts a considerable influence on the rate of growth and malignancy of the tumour. As a rule, the younger the patient, the more rapidly does the tumour grow, the earlier does it affect the lymphatic glands, and the more widely disseminated are the secondary growths. This rule has, however, many exceptions.

Statistics tend to show that there has been a steady increase in the mortality from cancer during recent years. According to Spencer Wells the deaths from cancer in England and Wales numbered 7,245 in 1861 or 360 per million, whilst in 1887 the deaths were 17,113 or 606 per million. Such statistics doubtless include many cases of sarcoma, but putting aside various possible sources of error I have no doubt that the disease is on the increase.

Mental Emotions of a depressing character, if long-continued or frequently repeated, may possibly predispose to the occurrence of cancer. I have seen so many cases of cancer, more particularly of the abdominal organs, in

persons who have suffered much from grief or anxiety of mind for years before the development of the malignant disease, that, although the doctrine is incapable of proof, I cannot but look upon it as probable that the cancer was the result of the antecedent long-continued mental disquietude. We know, by every-day experience, that functional derangement of the abdominal and pelvic organs of the most inveterate character may be occasioned by mental disturbance; and it appears to me not improbable, that such functional derangement may at last lead to perversion of nutrition, terminating in malignant growth in such organs, as the uterus, the liver or the stomach, as are more readily influenced by the condition of the patient's mind.

Sex.—The influence of sex is well marked, not only in the absolute frequency of cancer, but in its occurrence in organs that are special to each sex. Cancer is absolutely far more frequently met with in women than in men, simply because cancers of the uterus and mamma constitute by far the largest proportion of these diseases, being infinitely more common than cancers of the male organs. But when we come to cancers of organs that are common to both sexes, as the tongue, the lip, the intestinal tract, &c., we shall, I think, find that they are more frequent in men than in women; the difference, however, not being sufficient to counterbalance the preponderance in the female reproductive organs. Von Winiwarter states, that in Billroth's hospital and private practice from 1867 to 1876, 278 cases of cancer of the skin and mucous membrane of the face and mouth came under observation. Of these 226 were men, and 52 women.

Exciting Causes. The nature of the essential cause of carcinoma is not known. It is, however, certain that direct external violence, and more especially long-continued irritation of a part, often stand in some important relation to the development of the disease.

A blow on, or other injury of a part, often appears to be the direct determining cause of the development of a primary cancer. Scirrhus of the mamma is commonly attributed by the sufferer to the infliction of an injury. Long-continued irritation of a part also may cause a cancer to develop. This is a matter of every-day observation in the development of cancer of the tongue from the persistent irritation of a broken or jagged tooth, or the production of cancer of the lip by the constant use of an unprotected clay-pipe. But, perhaps, the most marked instance is that of the cancer of the scrotum in chimney-sweeps, developed by the irritation of the soot lodged in the rugæ of the part. Butlin brings forward three reasons for believing that in this case the soot itself is really the determining cause of the tumour: first, that in two recorded cases cancer has occurred on the hand in persons habitually handling soot; secondly, that other equally dirty trades do not cause it; and thirdly, that a warty condition of the skin is often met with in parts with which the soot comes in contact. Workers with coal-tar, and crude paraffin also show some liability to the same disease.

Local irritation is more likely to produce cancer if it be applied to a part that has already been for some time the seat of structural epithelial change. Thus, in a common wart, mole, or cicatrix, cancerous growths are very apt to develop under the influence of persistent irritation.

Every part of the body in which epithelium (as distinguished from endothelium) is naturally present is liable to become the seat of cancer. But

it occurs more frequently in some parts than in others. In the female it is most common in the mamma and uterus; in the male, epithelioma of the lip, tongue and penis is the most common form of the disease. In the alimentary canal it is most common at the narrowest parts, which presumably are most exposed to mechanical injury. Thus commencing at the mouth we find the common situations of cancer are, the lip, the tongue, the fauces, the œsophagus behind the cricoid cartilage, the cardiac orifice and the pylorus. Then follows the small intestine in which the contents are fluid, and the diameter almost uniform, and here cancer is extremely rare. It is less rare at the ileo-colic valve, and becomes common at the sigmoid flexure, which is the narrowest part of the great gut and contains solid feces. In the rectum it occurs usually where the gut is slightly narrowed as it passes through the recto-vesical fascia, and finally it is common at the anus. The form of cancer met with in all these places is dependent on the epithelium normal to the part. As far as the cardiac orifice it is squamous, at the cardiac orifice it is usually one form of glandular cancer, at the pylorus and as far as the anus it is columnar, and at the anus it is again squamous. It has been observed that in those organs which have an intermittent functional activity, cancer is more frequent.

Assuming it to be true that the development of carcinoma in a part may be determined by long continued irritation, it is by no means clear what share the irritation actually takes in causing the disease. Chronic irritation of a mucous or cutaneous surface, as well as of glandular organs, produces as one of its effects a proliferation of the epithelium of the part, and it is conceivable that under certain circumstances this proliferation may by gradual stages become an actual carcinomatous growth. There is, however, a gradually increasing belief that carcinoma is the result of some specific irritation of epithelium, probably by the growth of a parasitic micro-organism in it. If this be so, chronic irritation can no longer be looked upon as an exciting cause of cancer, but rather as a local predisposing cause; the epithelial changes which the irritation occasions being not an early stage of cancer, but rather a *precancerous condition*, that is a condition rendering the part favourable to the development of carcinoma.

It is impossible here to make more than very brief reference to the vast amount of investigation which has been carried out in recent years with the object of determining the essential cause of carcinoma. Many pathologists believe that cancer is an infective disease, and that the tumour is the result of an abnormal growth of epithelium excited by the local action of a specific micro-parasite. In searching for evidence in support of this hypothesis, three separate forms of investigation have been made: first, to determine the possibility of the experimental transmission of cancer from man to animals or from one animal to another; secondly, to endeavour to obtain artificial cultivations of living organisms from freshly removed carcinomatous tumours; and thirdly, to endeavour by various methods of preparation and staining to demonstrate the presence of parasitic bodies in the cells of the growth. Hallance and Shattock, in this country, have endeavoured by a long series of most carefully conducted experiments to transmit carcinoma from the human subject to the lower animals. Their results in this direction have so far proved uniformly negative. They transplanted portions of freshly excised malignant tumours, mostly carcinoma of the breast, into the peritoneal cavity, muscles and subcutaneous tissues of monkeys, dogs, rats and other animals.

Small portions of tumour were gradually and completely absorbed, whilst larger portions became surrounded by an inflammatory capsule and underwent coagulation necrosis. Some success has, however, attended the many attempts which have been made to transmit cancer experimentally from one animal to another of the same species. Hanan of Zurich transplanted fragments of a squamous carcinoma of the vulva of a rat beneath the skin of the scrotum of two other rats. In one case the experiment was followed by the development of cancerous nodules along the line of one vas deferens and in the omentum: in the other case a mass of growth formed in connexion with one epididymis. It must, however, be allowed that the successful transmission of cancer by transplantation cannot be looked upon as any proof of its infective nature, but only, as Shattock has pointed out, as an example of successful grafting.

The attempts which have been made to obtain artificial cultivations of living organisms from fresh carcinomatous tumours have almost uniformly failed to give any positive result. Ballance and Shattock have transferred fragments of fresh cancer into various solid and fluid cultivating media, which were kept for long periods at about the body temperature. In almost every instance no growth of micro-organisms occurred, the cultivating medium and the fragment of growth within it remaining sterile, and in some cases unchanged in appearance for several years. Little importance can be attached to the fact that in one or two experiments a growth of micrococci took place in solidified human blood-serum. In 1887 Scheuerlen stated that he had succeeded in obtaining an artificial cultivation of a bacillus from cancerous tumours, but the observation was afterwards proved by Baumgarten and others to be erroneous.

Microscopic examination has altogether failed to demonstrate the constant presence of any vegetable micro-organism in carcinomata, and indeed it is at the present time thought probable that the micro-parasite of cancer, if such exists, is more probably of the nature of a protozoon. This theory has been to a large degree suggested by the study of a very common and often fatal disease in rabbits, in which a marked proliferation of the epithelium of the bile-ducts is the most constant lesion. In an animal dead of the disease in question the liver is found more or less extensively infiltrated by small greyish-white tumours, varying in size from a pin's head to a pea. The microscope shows that the appearances are due to changes in the bile-ducts, which are dilated and occupied by branching papillary growths covered with proliferating epithelium. The disease is produced by a protozoon—the coccidium *oviforme* of Leuckart—which gains access to the body by the alimentary canal. The encysted form is found in large numbers as oval bodies (*psorosperms*) in and between the epithelium cells of the growths in the bile-ducts, whilst it is believed that a certain stage of development is passed outside the body. Darier and Wickham in France, and Bowlby and Hutchinson in this country, have described *psorosperms* in the epithelium cells in cases of Paget's disease of the nipple, an affection which certainly stands in an important relation to carcinoma of the breast (see Chapter I.X., Vol. II.). It is, however, by no means certain that the bodies in question are really parasitic in nature. Of the many observers who in the last few years have described parasitic protozoa in the cells of carcinoma, may be especially mentioned Malassez, Russell, Soudakewitch, and Ruffer and Walker; the researches of the last-named observers have been confirmed by Galloway, and extended by Ruffer and Plimmer. Ruffer and

Walker describe round bodies in the epithelium cells, varying from 0.001μ to 0.004μ in diameter. A central nucleus, which stains deeply with certain dyes, is surrounded by a layer of protoplasm, sometimes radially striated, the whole being enclosed by a capsule. Reproduction, usually by division, has been described, the process commencing with the division of the nucleus. Ruffer and Walker have almost constantly been able to demonstrate the bodies in question in the large numbers of carcinomata which they have examined, and they appear to be present in greatest abundance at the spreading margin of the tumour. Although the parasitic nature of these bodies seems highly probable, it must be remembered that certain other conditions of epithelium cells may present appearances not altogether dissimilar. Thus Virchow long ago called attention to the fact that as the result of the division of a cancer cell one of the resulting cells may remain included within the other, a process called by him endogenous division. Again, very misleading appearances may be presented by the transverse section of an epithelium cell into which an adjacent cell has become partially invaginated, as well as by cells which have undergone colloid and other degenerations. The greatest caution is indeed necessary before deciding that bodies of various kinds included within cancer cells are really parasitic. Lastly, it must be remembered that even supposing the presence of true parasitic protozoa in cancer cells be definitively established, their causal relation to the disease cannot be proved until they have been successfully cultivated outside the body, and by inoculation have reproduced a carcinomatous growth. The important share which chronic irritation so often takes in the development of carcinoma in a cutaneous or mucous surface suggests that, even if cancer be a micro-parasitic disease, the specific virus will fail to act unless the part to which it is applied be prepared for it by a course of long-continued irritation.

The Geographical Distribution of Cancer is a most important element in the problem of its origin, and by a closer study of it than has hitherto been made, I believe that much light may be thrown on this.

Cancer appears to be a disease favoured by the aggregation of individuals under the influence of an advanced civilization; it seems to be much more common in civilized countries than amongst savage tribes.

The dwellers in large towns also seem more prone to cancer than those who live in thinly populated districts.

Cancer is rare in the frigid zone. The Esquimaux in the Western, and the Samoeds and other migratory tribes in the Eastern hemisphere, are to a large extent exempt from it. It is rare in the tropics generally, but McLeod, of Calcutta, informs me that it is far from uncommon in India. Cancer is certainly more common in Europe than in any other part of the civilized world. In some parts of the United States of America and in China also it appears to be of frequent occurrence, whilst in South America, in Africa (except Egypt), and in the greater part of Asia, it is not common.

Haviland, who has investigated the tables of mortality of this country with regard to the distribution of cancer in Great Britain, concludes that geological formation, soil, and resulting endemic conditions exercise a marked influence on the development of the disease. He finds, with regard to England, that cancer is most common in the western and north-western parts of the kingdom, including Wales; and that generally throughout the more elevated upland and southern districts it is not common. It is less frequent on the

older geological formations, towards the sources of rivers, and in dry well-drained districts. He points out, on the other hand, that the sites of the great cancer fields of England are the tertiary formations and the alluvial districts; that cancer surrounds the course of the great rivers after their fall formation, when they are passing through valleys and low-lying lands liable to floods and to the consequent accumulation of alluvial deposits. These districts are also the most densely populated. Hence it may be inferred that density of population favours the production of cancer, and that wherever social organization is highly developed, there cancer becomes proportionately rife. But this view is not quite borne out by statistics. Thus we find that the development of cancer does not depend on mere population, as the mortality from cancer in Norwich and Great Yarmouth, comparatively small towns, is to that in such great centres of population as Liverpool and Manchester as 141 to 84, or nearly double; that in Philadelphia it is to that in the much larger city of New York as 15 to 7, or more than double; while in Maryland it is very far higher than in the capital of Pennsylvania. In these conclusions we must not, however, omit to take into account the increased tendency to hereditary transmission amongst a comparatively settled population, such as that of the east of England.

It is interesting to note that not only are certain areas especially favourable to the development of cancer, but that evidence is not wanting to show that the same may be true even of individual houses. Law Webb has related how in a small village in Shropshire are "two houses under one roof, with a drain system and water supply common to both." In one house a man died of cancer of the rectum, and a married couple who next occupied the house died, the man of cancer of the stomach and his wife of cancer of the breast. Meanwhile a woman had died in the other house of cancer of the breast. Subsequently the first house was occupied by three maiden ladies, one of whom died of cancer of the uterus and another of cancer of the breast.

Is Cancer a Disease of Constitutional or of Local Origin? The question has led to much discussion among pathologists, and there are at least three theories with regard to it:—*a.* Cancer is a blood-disease. *b.* It is purely local in its origin. *c.* If local in its origin, it can be developed only in a constitution that is fitted in some way for its formation.

We will consider these views separately; and in so doing I may observe that it will be extremely difficult, if not impossible, to separate the two questions as to the origin and development of cancer from one another; for, however essentially distinct and separate they may be, they blend in such a disconcerting manner as this in an almost inextricable manner.

a. The doctrine that cancer is a blood-disease has been made to include two distinct propositions: the first that the blood itself is charged with the poison of cancer which is ready to burst forth in any part of the body on the application of the necessary local irritation; the second, that "blood-disease" and "constitutional disease" are synonymous terms. This latter is undoubtedly an error. It is quite possible to hold the view that the tissues are imbued with a cancerous tendency, without having recourse to the hypothesis that they derive this from the blood. The germinal membrane of the chick, as was pointed out by Gull, takes on changes antecedently to the formation of the blood; and so we may take it as possible that the tissues of the body may inherently possess morbid proclivities, independently of the blood by which

they are nourished. But if by blood-disease be meant a disease in which the blood actually contains the elements of cancer, as in gout it contains uric acid circulating through the body and capable of deposit in some favourable locality, this hypothesis is certainly untenable. There is no evidence either chemical or microscopic to support such a theory, and every phenomenon that occurs in connexion with cancer may be explained without it. But though the doctrine of cancer being a blood-disease is untenable in this sense, the same cannot be said of the theory that it is a constitutional affection.

The doctrine of the constitutional origin of cancer cannot be more clearly expressed than in the words of Paget:—"Cancers are manifestations of certain specific and morbid states of the blood; and in them are incorporated peculiar morbid materials which accumulate in the blood, and which their growth may tend to increase." "The existence of the morbid material in the blood, whether in the rudimental or in the effective state, constitutes the general predisposition to cancer; it is that which is by some called the predisposing cause of cancer. The morbid material is the essential constituent of the cancerous diathesis or constitution; and when its existence produces some manifest impairment of the general health, independently of the cancerous growth, it makes the primary cancerous cachexia." For the local manifestation of this constitutional disease, the part where it is developed must be put into a favourable condition by irritation, injury, or other similar cause. The blood-disease and the local conditions may compensate each other; thus, with an intense cancerous diathesis, tumours may be formed in such a way and in such numbers as to be apparently independent of local conditions; while in cases where the constitutional element exists in a low degree, a long continuance of irritation may be required to bring out its local manifestations. Paget believes that by this theory of compensation the opposing views as to the local or constitutional origin of cancer may be reconciled.

b. The theory that cancer is of local origin appears to be more generally adopted. The arguments on which it is based may be summed up as follows, and they are certainly sufficient to account for all the phenomena of cancer; and many of these phenomena do not admit of explanation on any other theory.

1. Cancerous tumours spring up in individuals who have always enjoyed perfect health, and who are to all appearance perfectly well at the time of the occurrence of the disease. As in these cases there is no evidence whatever of constitutional affection of any kind, it would be a begging of the whole question to assert that the existence of the local tumour must of itself be taken as an indication of a constitutional cancerous tendency.

2. Such primary tumours are almost invariably single. Primary cancer very rarely occurs at the same time at different seats of election—as the mamma, pylorus, and rectum, as would be the case were it constitutional.

3. Cancers are not unfrequently the result of some local injury or irritation. This is a matter of daily observation in the lip, the tongue, the female breast, &c.

4. The general health does not suffer until the glands have become implicated, or ulceration has taken place, when signs of cachexy may set in. In many cases of cancer, especially of the mamma, the health continues excellent for many months—a year or two even after the disease has declared itself, and so long as it continues to be confined to its primary seat. It is not

until after secondary deposits have occurred that the characteristic cachexy sets in.

5. If the primary tumour be removed before neighbouring parts have become contaminated, the health, if it have suffered, often improves materially.

6. All pathological evidence tends to show that the secondary growths arise directly as a consequence of the primary tumour, first, by extension by continuity of tissue; secondly, by extension along the line of the lymphatics; and thirdly, through the blood-stream, leading to growths scattered throughout the body in the same directions as the secondary abscesses in pyæmia which result from septic emboli.

7. Secondary cancers affect the form of the primary one. Thus, primary glandular cancer leads to deposit of masses of the same structure in the lungs; columnar carcinoma of the rectum to secondary growths in the liver, with identical structural peculiarities. The secondary growths scarcely ever appear in those parts in which primary growths arise; indeed they usually occur in tissues in which primary carcinoma is unknown, as the lymphatic glands and bones.

8. Growth is favoured by local circumstances, as the warmth and moisture of cavities.

9. In some rare instances no recurrence whatever takes place after operation, the disease being eradicated from the system, which could not be the case if it were constitutional.

10. When recurrence does take place soon after an operation, it is almost invariably either in the cicatrix or its immediate neighbourhood, or in the nearest lymphatic glands, owing to cancer cells which had been widely disseminated, escaping removal, and subsequently developing into new tumours. Were the disease constitutional, recurrence would be as likely to take place in other parts, especially in symmetrical parts.

The theory of the local origin of cancer is undoubtedly a very captivating one. It explains in the readiest and the simplest way possible most of the phenomena of the disease; but some pathologists doubt if it is competent to give a satisfactory solution of all.

There are at least four conditions that have been supposed to militate against the theory of the primary localization of cancer, and which have been adduced as evidence of the constitutional origin of the disease.

These are—1. The almost absolute certainty of the recurrence of the disease after the removal of the primary growth;

2. The frequent hereditariness of the disease;

3. The varying degrees of rapidity with which cancers run their course and the different degrees of virulence they exhibit in different individuals; and

4. The geographical distribution of cancer.

Let us briefly examine those conditions which have mainly been relied on in support of its constitutional origin.

1. The *habit* to recurrence after removal can have but little weight, when we consider the rapid tendency to diffusion which characterizes cancers, owing to their peculiar mode of growth, and the relation of the cells to the lymphatics. The fact is, that the cancer cells have already become diffused through the neighbouring structures, and may have entered the lymphatics or the blood long before the primary tumour has attained such a size as to attract attention.

One main source of error in respect to the origin of cancer has been, that it has usually been studied in organs, such as the mamma, in which the tumour often attains the size of a nut, or even a larger size, before it is detected; many months may have been required for the small group of cells from which the disease started to reach such a size, and during this time the surrounding tissues and lymphatics may have been widely infected.

2. The *hereditariness* of cancer is undoubted; but it is a fatal error in etiology to confound hereditariness with constitutionalism. Hereditariness may be local as well as constitutional. The hereditary transmission of a particular feature cannot be considered a proof of a constitutional tendency. So also the hereditary transmission of a malformation, as of supernumerary fingers or exostoses, is certainly purely local. But diseases may also be transmitted through descent without being in any way constitutional. Tumours that are not cancers are hereditary, as warts, lipomata, enchondromata, &c.; sebaceous cysts of the scalp are strongly hereditary, and yet there can be no pretence that these are in any way constitutional or blood-diseases. These are instances of hereditary local diseases that are not congenital, but develop after the body has reached maturity; just, indeed, as a cancer does. All that we can therefore assume is, that it is probable that in some cases there is a pre-disposition of unknown nature, hereditarily transmissible, which may favour the development of cancer; and that this hereditary tendency may be local, as in a certain tissue, or in a particular organ which is the usual seat of election of cancer, as the mamma, the testis, or the pylorus.

3. The *greater virulence* exhibited by cancers in some individuals than in others, and the *varying degrees of rapidity* with which they run their course, would undoubtedly lead to one of two inferences: either that the primary cancer is more active, has greater inherent vitality, or that the constitution in which it occurs is more favourable to its development.

The varying virulence of a cancer depends much more upon its anatomical structure than on any constitutional condition of the patient. All the glandular cancers are more malignant than the squamous or columnar; yet those who hold the theory that cancer is a blood-disease, maintain that it is a mere accident where the primary tumour arises, and consequently what form it assumes.

The locality in which the cancer develops has also much to do with the rapidity with which the glands are affected. H. Arnott pointed out that the softer, the more vascular, and the more movable the primary seat of the tumour is, the more rapidly the secondary growths appear. Thus carcinoma of the tongue always affects the glands very early, while with a similar growth on the skin of the leg the patient may escape glandular affection for many months.

The fearful rapidity of growth and virulence shown by a cancer of the mamma during pregnancy consequent upon the physiological increase of the supply of blood to the gland is another example of a local condition affecting the malignancy of the growth. Moreover, if great rapidity of the growth were due to the presence of the poison in the blood in greater amount than usual, we should expect to find the development of the tumour most rapid in those who showed the most marked cachexia, whereas the reverse is often the case. The younger the patient and the better the general health at the time of invasion, the more malignant as a rule will be the course of the disease.

Still it is highly probable that there is a tendency in the tissues of certain individuals to favour the development of these cancerous growths, originating primarily in some local irritation, whether this be traumatic or functional. Such a constitutional state, whether hereditary or acquired, is necessary to constitute a fitting soil for the cancerous element, in which to form and to develop. The stronger the tendency the more readily will cancer grow in such individuals, and the more rapid and vigorous will be the growth. The constitutional state does not develop a local cancer; it simply favours its development.

4. The *geographical distribution* has been already considered at p. 1057. It cannot be said that this has much bearing upon the question. The influences resulting from race, soil, climate, &c., are concerned in the development of many local diseases, such as simple bronchocele, elephantiasis of the scrota, fibroma in the ears of negroes and the like, none of which are supposed to be due to the presence of a morbid material in the blood. We have no definite knowledge to guide us to any conclusion with regard to the effect of these influences on the development of cancer; and, in its absence, it is just as easy to suppose that these causes act locally on certain gland or epithelial surfaces as to imagine that they give rise to the development of some unknown poison in the blood to which the origin of the cancerous tumour is due.

Having thus described the cancer in general, we are in a position to consider more in detail the special varieties.

1. **GLANDULAR CARCINOMA**, the cells of which belong to the type of glandular or spheroidal epithelium, may arise in any parts in which glandular epithelium is normally present, such as the breast, salivary glands, liver, pancreas, prostate, kidney, and many other parts. Two chief varieties are met with:—1. Scirrhus or hard cancer, in which the stroma is very abundant and firm. 2. Encephaloid or soft cancer, in which the stroma is scanty and the cells abundant. No sharp distinction can be drawn between these two forms: a tumour which one Surgeon would call a rapidly growing scirrhus of the breast, another might describe as an encephaloid. A third variety of glandular cancer arises from colloid degeneration of the cells of either scirrhus or encephaloid, and this is known as colloid cancer, which will be described separately.

The glandular cancers yield on scraping or pressure a milky fluid, termed the *Cancer juice*, in which cells and granules are found in varying proportions. The granules are mostly fatty, and are the result of fatty degeneration of the cells of the tumour. This milky juice, it must be observed, is not absolutely characteristic of cancer. It is yielded by the lymphadenomata and by all the sarcomata, provided that at least twenty-four hours elapse after their removal before they are examined and that decomposition has commenced. The Cells (Fig. 388) are extremely variable in shape and size. They may be round, caudate, and even fusiform. Many varieties of form are usually found in the same tumour, but occasionally great uniformity prevails. The size may vary from $\frac{1}{1000}$ inch to $\frac{1}{100}$ inch. The nuclei are oval and highly refracting, often placed eccentrically; they are of considerable size and frequently double, while in some cases five or six may be found in the same cell. They contain bright shining nucleoli. The size of the cells is not indicative of the variety of cancer. Thus, in some scirrhous tumours the cell may be small, and in others large, and the same may be said of encephaloid. The distinction between

scirrhous and encephaloid is made not by the size of the cells, but by the relative proportions of cells and stroma. All cancer cells are prone to early degeneration, usually becoming filled with fat granules, and ultimately breaking down and in great part disappearing, so that what was once a considerable mass of cells may be represented by a few granules. This is most marked in scirrhous.

The *stroma* in glandular cancers is almost invariably fibrous, but in the softer forms it may be composed partly of spindle cells. The alveolar arrangement is always clearly marked. The cells lie loosely in the spaces, often separated from each other by a small quantity of fluid. This fluid, with the cells, forms the "cancer juice." In the degenerating parts of the growth the stroma frequently contains numerous fat granules, and in very rare cases patches of calcification are met with. The *blood-vessels* are usually abundant, especially in the softer forms. In some rare instances they show curious bud-like processes and dilatations projecting from their walls into the alveolar spaces of the tumour. These may give way and distend the alveoli with blood, thus forming small rounded clots dotted through the growth. The unaided eye of the experienced Surgeon may in many cases recognize a cancer without difficulty, but in every case the tumour should be examined microscopically in order to determine without a doubt what its true nature is.

Hard Glandular Carcinoma. Scirrhous.—This is met with more commonly in the female breast than in all other parts of the body put together, and the cases that come under the care of the Surgeons are almost exclusively in that situation. Thus of cases of scirrhous admitted into the surgical wards of University College Hospital during the ten years 1871 to 1880, 113 were situated in the female breast, 1 in the male breast, 4 in the skin near the female breast, 1 in the kidney, and 3 in the prostate. Nine other cases were admitted as "scirrhous of the rectum," and two as "scirrhous of the sigmoid flexure," but these were not submitted to microscopical examination, and were most probably columnar carcinomata. Scirrhous is also met with in the stomach and pancreas, and a soft form—between the hard and soft cancer, and consequently sometimes called scirrho-encephaloid—is the ordinary primary cancer of the liver. Secondary scirrhous may occur in almost any part of the body, but the most common situations are the lymphatic glands, liver, lungs, kidneys, and bones.

Scirrhous occurs in two forms, the circumscribed and infiltrating. In either case it forms a hard, craggy, incompressible, and nodulated tumour, at first movable and unconnected with the skin, but soon acquiring deep-seated attachments and implicating the integument. It grows slowly, seldom attain-

(44 diam.)

ing a larger size than an orange. At times it is painless, at others painful, generally aching, sometimes with much radiating and shooting pain through it. These sensations vary according to the part affected, and to the sensibility of the individual: the pains are especially severe after the tumour has been handled, and at night are of a lancinating, neuralgic character. The tumour may thus continue in a chronic state for a considerable length of time, slowly increasing, gradually extending its deeper prolongations, and implicating the more superficial parts. In some cases, more particularly in elderly people, scirrhus gives rise to atrophy of the organ in which it is seated, causing wrinkling and puckering of the surrounding skin, which becomes adherent to the tumour; and the cancer may thus continue in a very chronic state.

The ulceration takes place usually by the skin becoming adherent at one point to the tumour, either by dimpling in, being as it were drawn down towards it, or else by being pushed forwards, stretched, and implicated in one of its more prominent masses; it then becomes dusky and livid red, somewhat glazed, and covered by a fine vascular net-work. Softening occurs at one point, where a crack or fissure forms; a clear drop of gummy fluid exudes from this, and dries in a small scab upon the surface; this is followed by a somewhat bloody discharge of a thick and glutinous character; and the small patch of skin from which it issues, becoming undermined, speedily sloughs away, leaving a circular ulcer. This gradually enlarges, becoming ragged and sloughy, with craggy everted edges, having irregular masses arising from its surface, and discharging a fetid sanious pus. The pain increases greatly; and, the lymphatic glands becoming involved, cachexy is fully developed, and the patient is destroyed by it or by the secondary visceral deposits. In old people, ulceration of scirrhus cancers often assumes an extremely chronic character, the growth in them not having the same vitality as in the young. The ulcer in these cases is flat, sloughy, of a greyish-green colour, hard and ragged, with puckered edges, and much wrinkling of the surrounding skin, and exhaling the usual fetid odour. In younger persons, and especially in stout women with florid complexions, the disease usually makes rapid progress. So also, if inflammation be accidentally set up in the neighbouring tissues, cancerous infiltration rapidly takes place in them. Occasionally, but very rarely, scirrhus masses slough out, leaving a large ragged cavity, which may even cicatrize; and thus a spontaneous cure has been said to occur, but this is doubtful. The cancerous infiltration extends to a considerable distance around the tumour into integument which to the naked eye appears quite healthy. In such tissue, however, the microscope may reveal unequivocal evidence of the existence of cancer cells diffused through it. Wherever the small-celled infiltration can be recognized, which surrounds a cancerous growth like a halo, and gradually shades off in the surrounding healthy textures, the tissues must be regarded as infected. It is of great importance in determining the question of operation to bear this in mind, and not to act on the supposition of the tumour being abruptly defined.

The secondary growths in scirrhus cancer form first in the lymphatic glands in almost every case; later on they may occur in the liver, lungs, bones, and other parts. In the lungs and liver they are frequently much softer than the primary growth, so that in some cases they might more properly be termed

encephaloid than scirrhus. In the lymphatic glands they are often almost as firm as the original tumour.

Structure.—On cutting into a scirrhus with the scalpel, it usually creaks somewhat as it is divided, and presents a whitish or bluish-white glistening surface, intersected by white bands, which apparently consist partly of new

Fig. 289. Scirrhus of Breast (188 diam.). The communication of the alveolar spaces between one another and the continuity of the contained masses of cells are well shown.

structure, and partly of included areolar tissue. This section has not inaptly been compared to the appearance presented by a cut through a turnip or an unripe pear.

A curious feature of hard cancer, in which it differs from almost all other tumours, is that it becomes cup-shaped on section. This seems to be due to

Fig. 290. Scirrhus of Breast (183 diam.). In the alveolus which occupies the centre of the figure the intimate apposition of the cancer cells without any intervening stroma is clearly seen.

the fact that a kind of cicatrization often takes place in the central parts, while the peripheral parts are still growing. The cells undergo fatty degeneration and break up. The greater part of the products of degeneration are absorbed, and only a narrow streak of granules may be left to represent a once

large accumulation of cells. It is this shrinking of the growth that draws in the nipple in scirrhus of the breast. On examining a scirrhous cancer microscopically, it will be found to be surrounded everywhere by a zone of small round cells infiltrating the surrounding parts, penetrating between fat cells or muscular fibres, and extending along bands of connective tissue. A little nearer the centre the alveolar arrangement becomes apparent, and groups of rounded or irregular cells, with large oval nuclei, are found unbedded in spaces in a stroma of coarse fibrous tissue (Fig. 389). These spaces communicate with each other like those of a sponge. The stroma and cells here usually form about equal parts of the growth. The stroma shows signs of active growth, having spindle cells scattered here and there through it, sometimes in abundance. A little nearer the centre we find that the stroma has become more

Fig. 391. Scirrhus of Breast (188 diam.). Much contracted, the stroma bears a large proportion to the cells, which are small and granular. In a fully contracted specimen there would be almost alveolar spaces containing only granular debris.

dense, the spindle cells being replaced by elongated tailed cells, with scarcely any protoplasm around the nucleus (Fig. 391). The cells of the cancer are here beginning to degenerate, the nuclei becoming hidden by clouds of fat granules, and a similar change may also be apparent in the stroma. Towards the centre the fatty cells disappear, and only a few granules mark where they were; the stroma becomes dense and hard, and even the nuclei before mentioned are difficult to recognize. The above is a description of the ordinary scirrhus of moderately slow growth. In more vigorously growing specimens the degeneration is delayed, the necratization is less perfect, and the relative proportion of the cells is greater.

It is not always easy to determine the exact mode of growth in scirrhous cancer, as the young spheroidal

epithelium cells closely resemble the small round cells infiltrating the tissues at the growing margin. In the softer and more diffused forms, however, it is often possible to observe the earliest changes in the acini. It will then be seen that the morbid process does not start from a single acinus. Many acini lying near each other may show various stages of overgrowth of the epithelium. As first the new cells are contained within the distended membrana propria of the acinus, but as the process advances, they burst beyond its limits, and penetrate among the surrounding tissues. In the harder tumours of slower growth this often cannot be recognized, as the area of the gland affected is smaller, and by the time it comes under observation the acini have disappeared, and columns of cells only are found extending into the surrounding tissues.

Soft Glandular Carcinoma. Encephaloid.—As before stated, this is not separable from scirrhus. The greater part of the tumours which were formerly classed as encephaloid cancers are now included under the sarcomata. A glandular cancer growing with such rapidity, and of such softness

of structure, as to merit the name of encephaloid is in fact of rare occurrence in surgical practice. During the ten years 1871 to 1880, there were admitted under the care of the Surgeons of University College Hospital only eight cases which were classed as encephaloid cancer. Five of these were in the breast, two in the testicle, and one was believed to have originated in the tonsil or the glands in its neighbourhood. Encephaloid cancer, like scirrhus, arises only in structures containing glandular or spheroidal epithelium. It commences as a tumour, which though occasionally somewhat hard, is usually from the first, or at all events soon becomes, soft and elastic, being more or less lobulated, growing rapidly, and having an elastic and at last a semi-fluctuating feel. The skin covering it is usually at first pale and loose, with a large net-work of dilated veins spreading over it. In some cases, however, at a very early period, a species of inflammatory cedema occurs in the integuments covering a rapidly growing encephaloid tumour. As the tumour

Fig. 392. Encephaloid of Breast (148 diam.). The large-celled variety. Attention is directed to the much larger spaces in this than in Scirrhus.

enlarges, the skin becomes adherent, discoloured, of a purple brown tint, and at last ulcerates at one point. When once the tumour has made its way through, and is relieved from the pressure of the integuments, it may form a large soft fungous mass, rugged, irregular, dark-coloured, and bleeding profusely. This resembles the same condition occurring in some rapidly growing soft sarcomata to which the term *fungus hematodes* was applied by Hey. In other cases the tumour may slough, forming a deep irregular cavity. In either case death rapidly ensues from exhaustion and hemorrhage. Pulsation from extreme vascularity, accompanied by a loud bruit, to be heard on auscultation, has been described as occurring in encephaloid cancer, but in most cases in which this symptom has been recorded, the tumour was probably not a cancer, but a soft sarcoma, as these morbid growths were formerly confounded together.

The constitutional cachexy in encephaloid occurs early and is well marked, and secondary growths speedily make their appearance in the lymphatic glands and viscera.

Structure.—After removal the tumour is found to be very vascular, dis-

playing on injection a close net-work of vessels. On a section being made, it commonly presents a soft pulpy white mass, closely resembling cerebral substance, stained and blotched with bloody patches, varying in colour from a bright red to a maroon-brown, this being dependent on blood that has been infiltrated into its substance. In other cases, its section has been compared to that of a raw potato, or a piece of boiled noddle. On microscopic examination, it will be found to present a structure essentially similar to that of scirrhus, that is to say, an alveolar stroma enclosing groups of free cells of an epithelial type. The cells may in some cases be larger, but are often smaller than those usually seen in scirrhus (Fig. 392). They assume the same irregular forms, and have each one or more highly refracting nuclei and nucleoli. The proportion of the bulk of the tumour composed of cells is, however, infinitely greater in encephaloid than in scirrhus, and the vascularity of the tumour is proportionately increased. The tumour does not show the same tendency to cicatricial contraction, although fatty degeneration always occurs in the central parts.

Colloid, Gelatinous, Gelatiniform or Alveolar Cancer is a variety

Fig. 392. Colloid of Omentum (188 diam.) Shows the concentric rings and the granular masses which have taken the place of the cells; and at one part a few cells still retain their shape.

Fig. 393. Colloid of Breast. Shows the alveolar spaces, and the clear material in some cases, filling the alveoli, others pushing the nucleus to one side or completely surrounding it. *a* Fat granules from the same tumour. *b* Fat granules from colloid of omentum. (404 diam.)

formed by the colloid degeneration of the cells of a glandular cancer, either of the scirrhus or encephaloid form, but most commonly the former. It may occur in distinct masses, often of a very large size, weighing many pounds, or may be infiltrated into the tissue of organs. As it is most frequently met with in the viscera of the abdomen, it does not so often fall under the observation of the Surgeon as the other varieties of cancer. Yet it is not uncommon in the breast, where I have met with it, forming a very large tumour. Colloid cancer consists of alveolar spaces visible to the naked eye, filled with a clear semi-transparent yellowish gelatinous or honey-like material, resembling indeed somewhat the structure of a honey-comb. The septa forming these spaces are distinctly fibrous and regular in their arrangement (Fig. 393). Some of the spaces are completely filled with colloid matter, others may show a few cells containing fat granules in the centre, surrounded by zones of granules resulting from the degeneration of other cells. Cells again may be seen in the pro-

cess of undergoing colloid degeneration (Fig. 394). A globule of colloid matter first appears pushing the nucleus to one side; afterwards the nucleus undergoes a similar degeneration; and finally the cell bursts and disappears, leaving behind it only a few granules. True colloid cancer is merely a degeneration of scirrhus or encephaloid. Many other tumours have been described in former times as colloid, amongst which may be mentioned many myxomata, cedematous soft fibromata, and some glandular tumours which had undergone colloid degeneration.

Diagnosis of Glandular Carcinoma.—In the diagnosis of a cancer the age of the patient is an important consideration, such tumours being very rare before 30. Too much importance must not be attached to an hereditary history of cancer, or it may lead us into error. A most important sign of cancer is that the tumour forms part of the structure it is invading. It may be tolerably clearly defined in outline, but it is not separable from the surrounding tissue. It early becomes adherent to the skin when occurring in a superficial part. In the later stages the adhesion is evident, but at first it can be recognized only by pinching up the skin widely with the finger and thumb when it will be seen to dimple slightly at the part over the tumour. Both these signs, the implication of the surrounding structures and the dimpling of the skin may, however, also be present in chronic inflammation with fibroid induration.

The diagnosis of the different forms of cancer is not always easily made. *Scirrhus*, when not widely infiltrating, may very readily be confounded with fibrous tumours and adenomata, or with chronic inflammatory induration of a part; in many of these cases, indeed, the diagnosis cannot be made correctly until after examination by incision. In other cases, however, the rugged feel, the lancinating pains, the implication of the lymphatic glands, or the affection of the general health, will commonly serve to establish the diagnosis. When ulceration has taken place, the previous condition of the tumour, the general character of the sore, and the microscopic examination of the *débris*, may serve to denote its true character.

Encephaloid may be confounded with abscess, cysts, erectile and sanguineous tumours, and with the various soft varieties of sarcoma. In these cases careful palpation, the existence of elasticity without fluctuation, and the presence of the large and tortuous veins ramifying over the surface of the mass, may establish its true character. When it is fungating, it may be confounded with the sprouting intracystic growths that sometimes spring from the interior of a cystic tumour or with a soft sarcoma. Here, however, the history of the case and the contamination of neighbouring lymphatics, will show the true nature of the affection.

In all cases in which there is doubt as to the nature of the growth an incision should be made into it, if it is a case fit for removal by operation, and, if necessary, a slice should be removed and examined with the naked eye, or a scraping of it, or a section cut after freezing, may be put under the microscope. It is much better to do this than to lose valuable time by waiting till the symptoms become more definite.

2. SQUAMOUS CARCINOMA, OR SQUAMOUS EPITHELIOMA.—Squamous epithelioma, or as it has been called "epithelioma," "epithelial cancer," or "caneroid," was at one time considered to be distinct from true "cancer." There is nothing, however, to justify such a distinction. The term epithelial cancer or "epithe-

lioma" is not a good one, for as has just been pointed out, the scirrhus and encephaloid are equally epithelial growths though arising from a different type of epithelium. Squamous carcinoma arises from any situation in which squamous epithelium is naturally present. The essential feature of the growth by which it is distinguished from a simple wart or papilloma is that the epithelium no longer merely covers the papillæ, but forces its way between them into the structures beneath.

Causes and Situation.—Squamous carcinoma, rare in the young, is common in middle-aged or elderly people, the tendency to it increasing in proportion as age advances. In this respect it follows the course of other cancers. The hereditariness of epithelioma is not so marked as that of scirrhus, so much so that it has been doubted. I have no evidence either way on this point. My impression is that it is not distinctly hereditary. It has been said to have been communicated by contact from the uterus of the female to the penis of the male, but this is extremely doubtful. It is certain that in the great majority of cases in which such contact has taken place no evil consequences follow.

It is frequently occasioned by the long-continued or repeated application of some source of irritation, and may thus be established in constitutions otherwise perfectly healthy. Thus the irritation of a broken tooth upon the tongue or cheek may produce epithelioma of those parts. The scrotum in chimney-sweepers may be the seat of epithelioma, in consequence of the lodgment and irritation of soot in its rugæ. Cancer of the tongue or lip is frequently attributed to the irritation caused by smoking. In some cases epithelioma arises in parts which have long suffered from an abnormal condition of the epithelium. Thus the so-called "smooth or scaly tongue" has a great tendency to terminate in cancer, sometimes after the condition has lasted for ten or even twenty years. Epithelioma not unfrequently originates in old scars.

Its most common seat is on muco-cutaneous surfaces. During the ten years, 1871 to 1880, 123 cases of squamous epithelioma were admitted into the surgical wards of University College Hospital. They were distributed as follows: tongue, 52; lips, 18; skin of limbs and trunk, 10; penis, 8; vulva, 7; cheeks and gums, 7; anus, 4; scars in various parts, 3; skin of face, 3; scrotum, 2; œsophagus, 2; larynx, 2; bladder, 2; soft palate, 1; and antrum, 1. During a similar period 47 cases of cancer of the uterus were admitted into the women's ward, but the hospital report does not distinguish between the different forms of the disease in these cases. Eleven cases of malignant stricture of the œsophagus, probably all epithelioma, were also admitted into the medical wards.

The selection of a particular site by epithelioma appears often to be capricious, though it is doubtless dependent on anatomical peculiarities of the part. Thus it is common in the lower lip, but very rare in the upper. In women it rarely attacks the lip, in men often; when occurring in mucous canals it chiefly affects their ends. Thus the lower end of the pharynx, the upper end of the œsophagus, and the anus are all favourite sites.

Progress.—Squamous carcinoma commences either as a small flat tubercle or a warty growth, which rapidly ulcerates. Sometimes when it first comes under observation, it may already form an intractable fissure, or ulcer, of limited size, with hard everted edges and a foul surface. In other cases,

papillæ of great size may form on the surface of the growth before ulceration takes place. This is especially marked in cancer of the penis, in which the papillæ are sometimes half an inch in length. In the bladder epithelioma may assume a villous form. When ulceration takes place the destruction of tissue slowly spreads, implicating every structure at its circumference. Such an ulcer attacks not only the soft parts, but may extend into a neighbouring bone, penetrating deeply into its structure and eroding it. In a case under my care, in which the ulceration started from a gland secondarily affected after removal of an epithelioma of the lip, the greater part of the symphysis of the jaw was destroyed and the whole floor of the mouth eaten away till the tongue hung out below on the skin of the neck. Epithelioma of the eyelids may invade and destroy the eyeball, and when arising from the mucous membrane of the nose it may form one variety of the so-called malignant polypus. I have seen an epithelioma as large as a small orange, developing in this situation and passing into the orbit and to the cheek. Epithelioma of the scrotum, if left unrelieved by treatment, will at last extend to and implicate the testicle.

After an epithelioma has lasted a certain time secondary growths appear in the nearest lymphatic glands. This takes place with varying rapidity in different cases. It was pointed out by Henry Arnott that the implication of the glands takes place most rapidly when the primary growth is situated in soft, vascular parts much exposed to movement. Thus it takes place much more readily in epithelioma of the tongue, than in the same disease of the skin of the trunk. The affected glands increase in size steadily, but not usually very rapidly, and after a time fresh glands become infected. When they reach the surface they adhere to the skin, the central parts soften and become diffuent, and finally the skin gives way and a ragged, foul cavity is exposed, discharging a thin, blood-stained fluid, which tends to become extremely offensive. Squamous carcinoma differs from glandular carcinoma in one important respect: it has but little tendency to extend beyond the lymphatic glands, and to appear in the viscera or distant parts. It does so, however, with sufficient frequency to show that the absence of secondary tumours in the viscera is not an essential feature of the tumour.

Epithelioma most commonly occurs in otherwise healthy subjects. Even after the glands have become affected the general health may be but little impaired for some time; but sooner or later the patient begins to lose flesh and the so-called "cancerous cachexia" makes its appearance. Epithelioma may prove fatal by the progress of the local disease, and by its external ulceration; by its affecting a part essential to life, as the œsophagus or larynx; by pressure of enlarged glands on important parts; and by the induction of constitutional cachexy and malnutrition with gradual exhaustion.

Structure.—On microscopic examination, a squamous carcinoma will be found to be composed of masses of cells of the type of scaly epithelium, form-

Fig. 205.—Squamous Carcinoma of Lower Lip. Male, about 41.

ing irregularly cylindrical processes communicating with each other. From the irregular course of these processes, they are cut in a variety of directions in every thin section, so that the groups of cells do not give the idea of cylinders, but rather of circular, oval, and irregular masses not in direct connexion with each other. Between these cylinders is a fibrous tissue bearing abundant vessels for the nutrition of the non-vascular epithelium. This fibrous tissue is more or less infiltrated with small round cells, in proportion to the rapidity of the growth of the tumour. It will be seen from the above description that the structure of a squamous carcinoma, although differing in detail, is in the main similar to that of glandular carcinoma: that is to say, cells of an epi-

Fig. 396. Squamous Carcinoma of Anus (40 diam.). Shows the lobules extending down into the connective tissue, which is infiltrated with small round cells; four globes are seen. The isolated masses are probably cylinders cut obliquely.

thelial type, imbedded in spaces in a fibrous stroma, which freely communicate with each other (Fig. 396).

As in normal squamous epithelium covering a papilla of the skin, the cells next to the fibrous and vascular tissue are softer and rounder in form than those of greater age. In the centre of the terminal portion of a cylinder of cells or in a branching process from it, the epithelium often becomes flattened by pressure, and arranged circularly so as to form a globe (epithelial nest, epithelial pearl). These nest-like formations are produced, according to Virchow, by the remarkable tendency to endogenous cell-growth exhibited by some of the central cells, and the development of large "brood-spaces" within them. The pressure produced by this formation of brood-spaces, and the endogenous cell-growth accompanying it, cause the marginal cells to become flattened and to take on a concentric arrangement. Possibly these globes may be formed in both ways; but the appearance usually presented by them rather suggests the former than the latter process, as the central parts are most

frequently dry and hard, and show no signs of active growth. Similar globes are not unfrequently formed in simple warty growths, and must therefore not be considered diagnostic of epithelioma. The fully formed cells often present beautifully serrated edges, the serrations of one joining those of its neighbours. This is well shown in Fig. 397, taken from a small epithelioma of the anus which I removed from a middle-aged man. The individual cells of an epithelioma, as obtained by scraping, differ but little from the healthy scaly epithelium that may be got from the mucous membrane of the cheek or lip. They are often larger, and sometimes contain more than one nucleus. In the older parts of the growth, they are usually filled with fat granules. When an epithelioma has undergone ulceration, the surface is frequently covered with prominent masses like large granulations, and the diagnosis of the nature of the growth can often be made by removing one of them and submitting it to microscopic examination. If in a simple ulcer the skin be completely destroyed, epithelium is never found except at the margins; in an epitheliomatous ulcer, on the contrary, it is found at every part of the ulcerating surface. The *vessels* of epithelioma are abundant, but not so plentiful as those of scirrhus or encephaloid. As to the relation of the growths to the *lymphatics*, there is some difference of opinion. Thiersch and Waldeyer believe that they have demonstrated a lymphatic endothelium covering the cylinders of cells, and consequently are of opinion that the epithelium is actually within lymph-spaces. The anastomosis between the cancer cylinders is said exactly to resemble that normally seen between the lymph-spaces. The secondary tumours present the same general characteristics as the primary growth, but they are usually softer. The cells are sometimes thicker and less distinctly squamous, but most commonly their type is easily recognized. Epithelial nests are always less abundant and sometimes wanting.

The mode of growth of squamous carcinoma can often be observed without difficulty. If, for instance, a small warty epithelioma from the lip be removed in an early stage and examined microscopically, it will be found to be composed of hypertrophied papillae covered with an exuberant growth of scaly epithelium. The papillae increase in size as the centre of the growth is approached. The cutis vera beneath the large papillae and the papillae themselves are infiltrated with small round cells. In the circumferential parts of the growth the epithelium will be found to be entirely superficial, but in the central parts, between two or more papillae, a process of epithelium cells will be seen forcing itself into the cutis vera, which is very abundantly infiltrated at that spot with small round cells. So long as the epithelium is all superficial, the growth cannot be said to be malignant, and would be classed as a simple wart; whenever the epithelium cells can be seen bursting through between the papillae and extending into the tissues beneath, the growth is undoubtedly

FIG. 397.—Squamous Carcinoma of Anus (See page 1072). Illustrates the structure of an epithelial globe, and shows the "prickle cells" which occur normally in the Malpighian layer of the skin.

cancerous. The scaly tongue undergoing conversion into epithelioma also offers a favourable opportunity of observing the same process.

Diagnosis.—The diagnosis of squamous carcinoma from the other forms of cancer is usually easy. The principal points that should guide the Surgeon are: 1. The invariable occurrence of growth on a mucous or cutaneous surface. 2. Its early ulceration—often almost from the very commencement. 3. The rapidity with which ulceration follows on the new growth. 4. The origin of the disease from some evident source of external irritation. 5. The absence of all evidence of contamination of internal organs.

The **Prognosis** of squamous carcinoma is more favourable than that of the glandular varieties. Its superficial origin makes it possible for the Surgeon to recognize it early and remove it before the glands are affected, and even after glandular enlargement has taken place there is hope of completely eradicating the disease by removing the affected glands.

Recurrence after Removal takes place in squamous as in glandular cancer in the scar or its immediate neighbourhood, and in the lymphatic glands, and in these situations is due to the same pathological conditions. Distant recurrence is, as before stated, less common, but when it does take place it is due, as in other forms, to dissemination of cancer elements throughout the body. In one case in which I removed an epithelioma of the tongue recurrence took place in one of the toes and in the lung after a lapse of nearly two years.

Epithelioma, however, presents the peculiarity of re-appearing in some rare cases in the neighbourhood of the primary growth and yet not in connection with it. In these cases it would appear as if there was a tendency to the disease in the particular region of the body. Thus I have seen after the removal of an epithelioma of the lip on one side, a similar growth appear inside the mouth on the other side. The interval between the appearance of the growth is usually longer than in genuine recurrence. Thus, in the case above mentioned, three or four years elapsed between the removal of the epithelioma on the left side of the lower lip and the appearance of that inside the right cheek.

It would appear as if epithelioma were sometimes capable of transplantation or of inoculation so as thus to be locally multiplied. I have seen an epithelioma of one labium apparently inoculate an abrasion on the opposite one where a fresh centre of disease developed, and an epithelioma of the tongue infect the lower jaw through the contiguous alveolus of a loose tooth.

3. **COLUMNAR CARCINOMA OR COLUMNAR EPITHELIOMA.**—This form of tumour has frequently been called "adenoid cancer," but the term "columnar carcinoma" is less likely to lead to confusion and more correctly expresses the nature of the growth. It occurs as a rule at the same age and under much the same conditions as squamous carcinoma. It is confined to those regions which are naturally covered by columnar epithelium, and forms the most common tumour of the pylorus and intestine, including the rectum. During the ten years 1871 to 1880, there were admitted into the surgical wards of University College Hospital twenty-five cases of cancer of the rectum described as columnar epithelioma, and nine in which the form of cancer is not clearly stated, which were probably of the same variety. Four cases are recorded as having been met with in the sigmoid flexure and one in the antrum. It is

met with also in the uterus, ovary, and gall-bladder, and, in rare cases, in the breast, springing from the larger ducts.

Appearance and Progress.—A columnar carcinoma bears the same relation to the papilloma of the intestine that the squamous carcinoma does to the common wart on the skin. A simple papilloma as it increases in size keeps its superficial character, and becomes in most cases pedunculated and shows little tendency to ulcerate. A columnar carcinoma spreads widely with a somewhat firm fleshy base. Its surface remains papillary at the circumference, but soon ulcerates in the central parts, becoming rugged and irregular, and bleeding readily and abundantly. The growth extends through the whole thickness of the gut, and may implicate neighbouring viscera. Columnar carcinoma shows a much lower degree of malignancy than squamous carcinoma. It grows as a rule slowly, and frequently does not affect the lymphatic glands

Fig. 398.—Columnar Carcinoma of Transverse Colon (188 diam.). One tube is cut obliquely, the others transversely; the epithelium is irregular in shape and size, and is sometimes arranged in more than one layer. The stroma is fibrous, containing small round cells.

till a late period of the case. Visceral recurrences are rare, and are met with chiefly in the liver.

Death commonly takes place from the local disease, either from exhaustion from the discharge and loss of blood or from obstruction of the bowel or pylorus.

Structure.—A section of such a growth (Fig. 398) shows it to be composed of tubes lined with columnar epithelium, bound together by a delicate connective tissue, more or less infiltrated with small round cells. The tubes resemble gigantic crypts of Lieberkuhn. By the microscope alone it is not always easy to distinguish these tumours from simple papillomata covered with columnar epithelium, in which the bases of the papillae on section give the appearance of tubes. The irregularity of the structure and the greater cell-infiltration of the connective tissue would lead to a suspicion of malignancy. If the base be examined and the proper structure of the tumour be found implicating the muscular coat or extending to neighbouring parts, its malignant nature is placed beyond a doubt.

The secondary growths met with in the glands and liver maintain the characteristic features of the primary tumour, so that a tissue, looking like crypts of Lieberkuhn irregularly massed together, may be found in the lym-

cancerous. The scaly tongue undergoing conversion into epithelioma also offers a favourable opportunity of observing the same process.

Diagnosis.—The diagnosis of squamous carcinoma from the other forms of cancer is usually easy. The principal points that should guide the Surgeon are: 1. The invariable occurrence of growth on a mucous or cutaneous surface. 2. Its early ulceration—often almost from the very commencement. 3. The rapidity with which ulceration follows on the new growth. 4. The origin of the disease from some evident source of external irritation. 5. The absence of all evidence of contamination of internal organs.

The **Prognosis** of squamous carcinoma is more favourable than that of the glandular varieties. Its superficial origin makes it possible for the Surgeon to recognize it early and remove it before the glands are affected, and even after glandular enlargement has taken place there is hope of completely eradicating the disease by removing the affected glands.

Recurrence after Removal takes place in squamous as in glandular cancer in the scar or its immediate neighbourhood, and in the lymphatic glands, and in these situations is due to the same pathological conditions. Distant recurrence is, as before stated, less common, but when it does take place it is due, as in other forms, to dissemination of cancer elements throughout the body. In one case in which I removed an epithelioma of the tongue recurrence took place in one of the toes and in the lung after a lapse of nearly two years.

Epithelioma, however, presents the peculiarity of re-appearing in some cases in the neighbourhood of the primary growth and yet not in connection with it. In these cases it would appear as if there was a tendency to the disease in the particular region of the body. Thus I have seen after the removal of an epithelioma of the lip on one side, a similar growth appear inside the mouth on the other side. The interval between the appearance of the growth is usually longer than in genuine recurrence. Thus, in the case above mentioned, three or four years elapsed between the removal of the epithelioma on the left side of the lower lip and the appearance of that inside the right cheek.

It would appear as if epithelioma were sometimes capable of transplantation or of inoculation so as thus to be locally multiplied. I have seen an epithelioma of one labium apparently inoculate an abrasion on the opposite side where a fresh centre of disease developed, and an epithelioma of the tongue infect the lower jaw through the contiguous alveolus of a loose tooth.

3. **COLUMNAR CARCINOMA OR COLUMNAR EPITHELIOMA.**—This form of tumour has frequently been called "adenoid cancer," but the term "columnar carcinoma" is less likely to lead to confusion and more correctly expresses the nature of the growth. It occurs as a rule at the same age and under most the same conditions as squamous carcinoma. It is confined to those regions which are naturally covered by columnar epithelium, and forms the most common tumour of the pylorus and intestine, including the rectum. During the ten years 1871 to 1880, there were admitted into the surgical wards of University College Hospital twenty-five cases of cancer of the rectum described as columnar epithelioma, and nine in which the form of cancer is not clearly stated, which were probably of the same variety. Four cases are recorded as having been met with in the sigmoid flexure and one in the antrum. It is

met with also in the uterus, ovary, and gall-bladder, and, in rare cases, in the breast, springing from the larger ducts.

Appearance and Progress.—A columnar carcinoma bears the same relation to the papilloma of the intestine that the squamous carcinoma does to the common wart on the skin. A simple papilloma as it increases in size keeps its superficial character, and becomes in most cases pedunculated and shows little tendency to ulcerate. A columnar carcinoma spreads widely with a somewhat firm fleshy base. Its surface remains papillary at the circumference, but soon ulcerates in the central parts, becoming rugged and irregular, and bleeding readily and abundantly. The growth extends through the whole thickness of the gut, and may implicate neighbouring viscera. Columnar carcinoma shows a much lower degree of malignancy than squamous carcinoma. It grows as a rule slowly, and frequently does not affect the lymphatic glands

Fig. 398.—Columnar Carcinoma of Transverse Colon (125 diam.). One tube is cut obliquely, the others transversely; the epithelium is irregular in shape and size, and is sometimes arranged in more than one layer. The stroma is fibrous, containing small round cells.

till a late period of the case. Visceral recurrences are rare, and are met with chiefly in the liver.

Death commonly takes place from the local disease, either from exhaustion from the discharge and loss of blood or from obstruction of the bowel or pylorus.

Structure.—A section of such a growth (Fig. 398) shows it to be composed of tubes lined with columnar epithelium, bound together by a delicate connective tissue, more or less infiltrated with small round cells. The tubes resemble gigantic crypts of Lieberkuhn. By the microscope alone it is not always easy to distinguish these tumours from simple papillomata covered with columnar epithelium, in which the bases of the papillae on section give the appearance of tubes. The irregularity of the structure and the greater cell-infiltration of the connective tissue would lead to a suspicion of malignancy. If the base be examined and the proper structure of the tumour be found implicating the muscular coat or extending to neighbouring parts, its malignant nature is placed beyond a doubt.

The secondary growths met with in the glands and liver maintain the characteristic features of the primary tumour, so that a tissue, looking like crypts of Lieberkuhn irregularly massed together, may be found in the lymph-

phatic glands or in the liver. In the lymphatic glands of the groin these tumours may break down and ulcerate, as in squamous carcinoma.

Diagnosis.—The diagnosis of the nature of the growth can be made only when it is situated in the rectum. It is then often possible to remove a small portion for microscopic examination.

The **Prognosis** is always very grave on account of the situation in which the tumour forms. Limited growths may be safely removed from the rectum, and lately such tumours have been excised both from the colon and pyærus, the parts being united by suture of the intestine.

Other Forms of Cancer were formerly described, the chief of which were Osteoid Cancer and Melanotic Cancer. Osteoid Cancer was the name given to the tumour now known as Osteoid or Ossifying Sarcoma (see p. 1012). The growths formerly described as Melanotic Cancer are also now classed with the sarcomata. It is possible that there may be a pigmented form of squamous carcinoma, but if such a tumour does exist it must be of great rarity.

TREATMENT OF CANCER.—The treatment of cancer will necessarily be in a great measure dependent on the view that is taken of its origin. The constitutionalists would naturally endeavour to discover some method of preventing the development of or of eradicating that blood-poison, or that general tendency which they suppose to underlie the local affection. They would necessarily discard operation as being not only useless, but erroneous in principle—as erroneous as it would be to amputate the foot to cure the gout. The localists, on the other hand, necessarily rely on the removal of the primary local disease at as early a period as possible, as the only means of preventing secondary growths and constitutional infection. Hence the discussion as to the origin of cancer has a most important practical bearing on the treatment of the disease. All **Curative Constitutional Treatment** is certainly useless, no constitutional remedies appearing to exercise any material influence on the disease. I am not acquainted with any case of cancer, either from my own observations, from conversation with other Surgeons, or from published statements, that affords satisfactory evidence of cure by an internal remedy. It is true that many so-called cures of cancer have, at various times been stated to have been cured by different medicines; but it must be born in mind that, at one time, almost all hard chronic tumours were called “scirrhus,” and many intractable ulcers “cancers:” mistakes which are sometimes unavoidably committed, even with the improved means of diagnosis that we at present possess. Not one of the many remedies that have been vaunted as being specific in this disease, and by which cures have been stated to have been effected, has obtained the confidence of the profession, or has, on further trial, corresponded in its effects to the statements of those who introduced it. I therefore think it but waste of time to discuss the supposed benefit to be derived from hemlock, sanguinaria, condurango, China, turpentine, iron, arsenic, iodine, cod-liver oil, or lemon-juice, in the treatment of cancer. But though curative treatment can effect nothing, much may be done by proper *Palliative Treatment* towards retarding the progress of the cases that do not admit of operation. With this view, the diet should be mild, nutritious, easy of digestion, unstimulating, and sufficient to support the strength under the wearing influence of pain and discharge; and the preparations of opium, conium, and hyoscyamus, must be freely administered in order to relieve the patient’s sufferings, and to procure rest.

The **Local Means** are those upon which the Surgeon justly places the chief reliance. The **Palliative Local Treatment** consists in the use of means calculated to retard the growth of the tumour, to lessen the pain attending it, and to remove the factor that arises if it be ulcerated. It is important to remember that the rapidity of the growth and the pain will usually be increased by anything that causes hyperæmia of the part. All irritating applications such as tincture of iodine must therefore be avoided: they only hasten the growth of the tumour and the implication of the skin. If the tumour be painful, and the skin covering it still unbroken, great relief may be obtained by the application of belladonna plasters. In some cases I have found powdered conium, spread on cotton-wadding, useful in the same way. As it is of importance to prevent, as long as possible, any breach of surface, the application of these sedative plasters and powders should be persevered in with the view of supporting the integument. The local application of ice was recommended by J. Arnott; but there is no evidence to show that it is of any real service. When the tumour is ulcerated, the factor must be diminished by the application of weak solutions of carbolic acid, chloride of zinc, chloralum, or permanganate of potash, to which cocaine or opiates may advantageously be added with a view of lessening the pain. Thymol and menthol both prevent decomposition and allay pain. Iodoform sprinkled over the ulcerating surface will often be found to diminish both the factor and the pain. If the smell of the iodoform is unpleasant to the patient, an ointment may be used composed of iodoform 5j, eucalyptus oil 3j, paraffin and vaseline à à 3iiss. This may be applied on a piece of muslin and the parts covered with a sheet of salicylic wool. Von Mosetig-Moorhof has recorded cases of extensive malignant disease in which shrinkage of the growth has followed the local application of methyl-violet. A 1 in 500 solution was used and frequent injections of from 3 to 6 grammes of the solution made into the diseased tissues.

The **Curative Local Treatment** of cancer consists in a free removal of the tumour, together with such a margin of the surrounding tissues as is likely to be already in process of invasion.

Before proceeding however to consider the methods now usually employed for this purpose, it is necessary to say a few words regarding two methods which were formerly recommended, viz., the use of caustics, and compression.

The employment of *caustics* for the destruction of cancers has, in all ages and countries, been resorted to by empirics, who profess to remove tumours of a malignant nature, by secret remedies, less painful and more effectual than the knife. In this country they have never enjoyed any very extended reputation; and now that anæsthetics have removed the pain of an operation and antiseptic treatment has reduced its dangers to a minimum, it is very rarely that the Surgeon is justified in using them. Of the very numerous caustic substances which have been employed the following may be mentioned:—the concentrated mineral acids, especially the fuming nitric and anhydrous sulphuric acids; caustic alkalies, especially potash and lime, either alone or in combination in the form of Vienna paste; certain mineral salts, such as the chlorides of antimony and zinc, the acid nitrate of mercury, sulphate of zinc, and arsenious acid.

At the present day caustics are occasionally useful in the treatment of certain forms of carcinoma in which the complete removal of the growth by operation is impossible. Thus in some cases of cancer of the jaws in which

the disease is found to have extended too far to allow of its complete excision, caustics may with advantage be applied when the accessible part of the growth has been removed. For this purpose the most efficient material is a paste containing one part of chloride of zinc to four parts of flour, moistened with a little water, to which one-twentieth part of extract of opium may be added to diminish pain.

Again, in certain forms of fungating carcinoma of the cervix uteri temporary relief may be afforded by freely scraping the growth and then applying a strong solution of chloride of zinc.

Compression is a plan that was at one time greatly extolled and at another much depreciated, and may now be said to be of merely historical interest. It was fully tried at the Middlesex Hospital, by Young, more than sixty years ago, and unfavourably reported upon by Charles Bell at that time; it consequently fell into disuse in this country, but was revived by Récamier in France, and employed largely by him. Although he published a favourable account of this practice, it made but little progress amongst French surgeons: the only one who seems to have used it to any extent being Tanchou, who employed a peculiar topical medication conjoined with it. In this country the practice fell into complete oblivion, until J. Arnott invented a mode of employing pressure by means of an elastic air-cushion; after which time it was often employed, but with no real success as a means of cure.

I have employed all the different plans, but have never found permanent advantage from any of them.

That indurated masses in the mamma have disappeared under this treatment cannot be denied. Walshe records such a case in his *Treatise on Cancer*, but the well known difficulty of diagnosing a chronically inflamed lobule, which would probably be absorbed under pressure, from a small cancer, makes these few isolated cases of no value when we contrast them with the large number of failures in undoubtedly cancerous growths.

Excision.—With regard to the question of removing cancers by the knife, a difference of opinion necessarily exists between the constitutionalists and the localists, the former holding the view that however completely the primary disease be removed recurrence is almost inevitable, and the latter, that if the Surgeon can only get the case early enough and remove the diseased parts sufficiently widely a cure may be effected. That recurrence after removal is the rule cannot be denied. Astley Cooper stated that in only nine or ten cases out of a hundred did the disease not return in three years; Benjamin Brodie found that it generally proved fatal in two or three years after the operation, and Paget has expressed the same opinion. Since anesthetics have made it possible to spend a longer time over the operation, and antiseptic treatment has removed the fear of large wounds, many Surgeons have advocated a more free removal of the affected parts than was formerly practicable. Thus Kuster, Kocher, and Mitchell Banks have advised that whenever it is practicable the nearest lymphatic glands should be removed with the primary growth. Operating in this way on mammary cancers with very free removal of the skin and extirpation of the axillary glands, Mitchell Banks has obtained excellent results. Out of forty-six cases operated on by him, ten patients were alive and free from recurrence at different periods, varying from two to ten years, after the operation, and in five more no recurrence had taken place from one to two years after

the operation. Kiister states that in 26 per cent. of his cases no recurrence had taken place three years after the removal of the breast.

In determining as to the advisability of operating in cases of cancer, several questions of great importance present themselves to the consideration of the Surgeon. He has first to consider whether the operation is likely to rid his patient completely of the disease; or, in the event of its not doing so, whether life may not be prolonged by the removal of the cancerous tumour; or, lastly, whether the patient's sufferings may not be much lessened by the removal of the local affection, although there be no prospect of really prolonging life.

The two following questions will therefore present themselves to the Surgeon in considering this subject:—

1. Can cancer be cured, or, rather, completely extirpated from the system by excision?

That in some cases a cancerous tumour may be removed with every expectation of the patient being completely freed from the disease, cannot, I think, be doubted. Velpeau stated that he had perfectly cured patients by the removal of cancerous tumours—at least, that no return had taken place for 12, 15, or 20 years after extirpation. The evidence of Brodie on this point is extremely valuable. Writing in 1846, that eminent Surgeon says: "So long ago as 1832, I removed a breast affected with a scirrhus tumour, and the lady is still in good health—at least, she was so last year. Since the operation she has married, and had children. Last year I was called to see a lady on account of another complaint, on whom I performed the operation thirteen years ago, and found that she continued free from the old disease; and, very lately, I have heard of another lady whose scirrhus breast I removed six years ago, and who continues well." The opinion of Fergusson is also very positive on this point, and he speaks in a tone with which I perfectly agree. He says: "Nevertheless, as excision gives the only chance of security—a point on which most parties seem to agree—an operation should always be resorted to, provided the knife can be carried beyond the supposed limits of the disease; and, moreover, I deem it one of the duties of the practitioner to urge the patient to submit to such a proceeding." The results obtained by Banks and Kuster still further illustrate the possibility of occasionally eradicating the disease by operation. In squamous and columnar cancers the prospects of cure are very much greater if the case be taken in time.

2. If cancer cannot be actually cured by excision, may not life be prolonged and health improved by an operation?

I am decidedly of opinion that this is possible; and that, though a patient may at last be carried off by some of the recurrent forms of cancerous disease, health may be improved, life may be prolonged, and much suffering may be spared, by a timely operation. It may often be observed that, after the cancer has been removed, the digestion becomes stronger and the patient gains flesh; the colour of the complexion returns, and the spirits greatly improve, the system being relieved from a source of local irritation, and the mind from a cause of disquietude that has undermined the general health of the patient.

I think that the introduction of anæsthetic agents into operative surgery has very materially affected the bearings of this important question. So long as an operation was a source of great pain, and of much consequent anxiety and dread, a Surgeon might very properly hesitate to subject his patient to severe suffering with so doubtful a result; but now that a patient can be

freed by a painless procedure from a source of great and constant annoyance and suffering, the Surgeon may feel himself justified in thus affording him a few months or years of comparative ease, though he may be fully aware that, at the expiration of that time, the affection may return, and will then certainly prove fatal. Even under these circumstances, the patient's condition may be much improved; for the recurrent is frequently less distressing than the primary disease; since, as it often takes place in internal organs, it is not attended with the same amount of local pain and distress.

In discussing the propriety of operating in a case of cancer the Surgeon can, however, have little to do with general or abstract considerations. It will serve him little, in coming to a conclusion as to the line of practice that he should adopt, to refer to the statistics of the gross results of operations, or to general comparisons between the results of cases that are not operated upon and those that are. The whole question narrows itself to the point, as to what can best be done in order to prolong the life or relieve the suffering of the particular individual whose case is being considered. In order to come to some definite conclusion on this, it is necessary to classify the different cases of cancer, and to arrange them under the heads of those in which no operation is justifiable; those in which the result of any such procedure would be very doubtful; and those in which an operation is attended with a fair prospect of success.

Most of the following rules apply equally to true cancers and the malignant sarcomata formerly classed as such.

In no case should any operation be undertaken till the liver has been examined by percussion and palpation and found free from disease. If there are no symptoms such as cough, pleuritic pain, or hæmoptysis, it is probable that a secondary tumour in the lungs, even if present, would be too small to be recognized by any method of physical examination. Still it is always safer to examine the chest also. I have seen a case in which a Surgeon removed the upper jaw for a tumour which turned out to be a secondary scirrhus, when by palpation of the abdomen the primary tumour of the pancreas and secondary nodules in the liver could easily have been felt. I know also of another case in which the eyeball was removed for a melanotic sarcoma, when the liver was studded with secondary growths which could readily have been felt through the abdominal walls. In such cases operation is clearly improper. The urine should also in every case be examined for albumen and sugar.

Another error which the Surgeon must endeavour to avoid is that of mistaking a secondary carcinomatous deposit for the primary tumour. It sometimes happens that the primary tumour is small and so situated that it escapes the notice of the patient and the Surgeon, whilst one of the secondary deposits may present itself as a large and conspicuous growth. Thus I have known a case in which amputation was performed at the shoulder for a tumour of the upper end of the humerus which was believed to be a primary sarcoma of the bone. The microscope, however, revealed its carcinomatous nature, and subsequent examination showed that the tumour was secondary to a small carcinoma of the cervix uteri which had caused no definite local symptoms.

1. Cases not proper for Operation.—(a) It is a rule in surgery which should never be deviated from, that no operation should ever be undertaken for the removal of a malignant growth, unless the whole of the tumour and the tissues infiltrated by it can be completely removed. It is necessary to remove

not only the tumour but the surrounding tissues to some extent, even though apparently healthy. (b) The operation ought never to be performed in cases in which several malignant tumours exist in different parts of the body at the same time. Here the disease has evidently affected the constitution, and cannot be removed by any series of operations. In those very rare cases in which more than one primary carcinoma exists operation may, however, be undertaken if there is reasonable hope that each tumour can be completely removed. (c) If the cachexia be strongly marked, it is useless to remove the local affection, as probably some secondary visceral tumour is already forming. (d) If the tumour be of very rapid growth and soft, and its margin very ill-defined, it has probably infected the surrounding tissues so widely that it will speedily reappear in the cicatrix if removed. (e) If the whole of the affected organ cannot be taken away, as a bone, or if the skin or mucous membrane be so widely affected that it cannot be removed, or if lymphatic glands are enlarged which cannot be dissected out, it is useless to attempt the excision of the primary growth, as a speedy relapse will certainly ensue. (f) In the very chronic and indurated glandular cancers of old people, it is often well not to interfere, as in these cases the affection makes such slow progress that it does not in any way shorten life, whilst the operation might be attended with serious risk at an advanced age.

2. Doubtful Cases.—Those cases in which the result of an operation is extremely doubtful, but in which no other means offer the slightest prospect of relief, have next to be considered. (a) Malignant sarcomata of the eye, and cancers of the tongue, larynx, and testis, belong to this category; for, though more likely to return than similar affections of any other part of the body, yet they may be fit cases for operation, inasmuch as in no other way has the patient the slightest chance of being relieved of his disease. (b) In cancers that are already ulcerated, the Surgeon may sometimes operate in order to give the patient ease from present suffering or perhaps with a view of prolonging life; but he can have little expectation of effecting a permanent cure. (c) If the tumour be so large, or be so situated, that its removal cannot be undertaken without an operation so serious as to occasion in itself considerable risk to life, the propriety of operating is always very doubtful.

3. Cases proper for Operation.—The cases in which an operation is, in my opinion, not only perfectly justifiable, but should be urged upon the patient, are those in which the disease has originated in a person otherwise in good health, and in whom there is so far no cachexy. In scirrhous carcinoma, if the disease be slow in its progress, single, distinctly circumscribed, without adhesions to or implication of the skin or glands, and more especially if it be attended with much pain, or with immediate risk to life from any cause, and if the whole of the growth, together with a sufficient quantity of the neighbouring healthy tissues, in which it is imbedded, can be removed, the case may be looked upon as a fit one for operation. If the glands are affected to a limited degree, and only to such an extent that they can be removed without danger, the operation should still be urged on the patient, provided the general health be unimpaired. In encephaloid carcinoma, or soft malignant sarcomata, the rapidity of the growth need not deter the Surgeon from operating provided the whole primary tumour and the enlarged lymphatic glands, if present, can be removed; early operation should be practised, with the view of prolonging life, if nothing more. In squamous carcinoma the removal of the primary tumour with the

glands in an early stage of infection is a more hopeful proceeding than in either of the forms of glandular cancer.

There is no fact in Surgery more certain than this, that other things being equal, *the earlier a malignant tumour is removed the better is the chance of prolonged or permanent relief*. In the preceding pages it has been pointed out how strong is the evidence that carcinoma is primarily local, and that the glands and afterwards the viscera become infected by actual particles of the tumour transplanted to them from the original growth. Accepting this as true, it necessarily follows, as was pointed out by De Morgan, that the disease may be local and capable of complete removal up to a certain moment, and the next it may have extended beyond the reach of operative interference. We cannot possibly tell when this eventful change takes place. All we can do is to try to anticipate it by operating at the earliest possible time. Not a day should be lost after the disease is recognized. In doubtful cases it is far better not to wait till unequivocal signs of the malignant nature of the growth appear, but to cut into it, and if necessary remove a slice for examination at the earliest possible time, proceeding immediately to complete removal if it is found to be malignant. Errors will arise, do what we will to prevent them, and it is far better to err by making an unnecessary incision, or even removing a mass of chronically inflamed tissue or a syphilitic gumma, than to leave a cancerous growth till its complete extirpation becomes impossible.

EXCISION OF TUMOURS.

In describing the different forms of cysts, the operative procedures necessary for their removal have been adverted to. We may now conveniently consider the steps that are generally necessary for the extirpation of solid tumours from the soft parts.

Tumours may be removed by the knife, by the écraseur, by the cauter, or by ligature.

Removal of Tumours by the Knife.—In the removal of tumours, the first point to be attended to is the arrangement, shape, and direction of the necessary incisions. These should not only have reference to the size of the growth, but must also be planned with due regard to subjacent parts of importance. As a general rule, they should be carried in the direction of the axis of the limb or part, and parallel to the course of its principal vessels; they must extend not only over the whole length of the tumour, but also a little beyond it at each end: no cross-cuts should be made, if they can be avoided, and this may usually be done by attention to the proper position and extent of the linear incisions. In removing a simple tumour, no skin should, as a rule, be taken away, a simple cut being made; but if the integumentary tissues be either very abundant and loose, or adherent, an elliptical portion of them may be excised together with the tumour. In other instances, again, a semilunar flap of integument may with advantage be turned up from the tumour, the surface of which is then fairly exposed; this, however, can be done only in some simple tumours, such as fatty growths. In excising malignant tumours the skin must in most cases be freely cut away. It is better to leave a healthy surface to heal by granulation, than not to take away any part of the skin which may be infected by the growth. The flap covering the growth should be freely but cautiously dissected back, so as to

expose its sides and base ; as these are approached, and the Surgeon reaches the neighbourhood of its more important and deeper connections, increased care will be necessary, as it not unfrequently happens that the tumour is in closer relations with deep-seated blood-vessels and nerves of a large size than would at first appear.

When practicable, the *deep dissection* will best be commenced and carried out from that part of the base of the tumour into which the principal blood-vessels appear to enter ; they are thus early cut, and being once ligatured, or seized in catch-forceps, give no further trouble, which they would do were they divided from the direction of their branches towards the trunk, when at each successive stroke of the knife a fresh portion of the vessel would be touched. In carrying on this deep dissection, the operator should proceed methodically from one side of the tumour to the other, the assistants holding aside the skin so as to give as much room as possible, while the Surgeon himself, seizing the mass with his left hand, or with a large double hook or vulsellum, and dragging it well forward, uses the knife by successive strokes, but in a leisurely and careful manner, avoiding all undue haste, until he completely detaches the tumour from its connections. The safety of contiguous important structures will be best secured by keeping the edge of the knife constantly directed towards the tumour, if this be non-malignant ; by attention to this rule, tumours may be removed with remarkable safety and ease from the neighbourhood of most important parts. If, however, the growth be malignant, the incisions must be made wide of the disease into the healthy structures around ; unless this be done, portions of the tumour may be left from which fresh growths will rapidly sprout, or tissues apparently healthy may be left which are in reality impregnated with cancer cells.

After the tumour has been removed, it must be *carefully examined*, with the view of ascertaining whether it be entire ; and, if any portions have been left, these must be properly dissected out. In some situations, as the axilla, the side of the neck, or the groin, where the relations are of great importance, the less the edge of the knife is used the better, and the growth should be enucleated by the Surgeon's fingers or by the handle of the scalpel.

In removing tumours from the neck or axilla the danger of the entrance of air into a half-divided vein, held open by the traction on the tumour, must never be forgotten. (See p. 489.)

The Surgeon should rarely undertake the removal of tumours that cannot be completely extirpated, as the part left will always grow with greatly increased rapidity, often assuming a fungous character ; this is especially the case with malignant tumours, the rapidity of increase of which is greatly augmented by partial operations. The only exception to this rule is that a large ulcerating and necrosing mass may occasionally be removed with the view of giving the patient temporary ease.

Should, however, the Surgeon have begun the operation with the intention of removing the whole, and have been deceived as to the depth and connexions of the mass ; if, for instance, he find, after commencing his operation, that the tumour extends more deeply than had been anticipated, and comes into close relation with important vessels, as at the summit of the axilla or in the perineum, thus preventing him from dissecting it out without imminent risk of destroying the patient, the only alternative left is one that I have seen Liston adopt, and have had occasion myself to practise ; viz., to throw a

strong ligature, above the apex of the growth as high up as practicable, and then to cut off everything below this. On the separation of the ligature, any portion of the tumour that has been included will be brought away as if it had been removed by the knife.

In some cases it will be found, after dividing the fascia covering the tumour, that the attachments of the growth are not so firm or deep as had previously been expected; this is especially the case in some large tumours springing from the side of the neck and the parotid region, or in the groin. The growth may then often be removed in a great measure by separating the areolar tissue with the handle of the knife, merely dividing those portions of the deeper attachments that are peculiarly dense.

If very free bleeding takes place during the operation two courses are open to the Surgeon: he may either finish the operation with the greatest possible rapidity, even perhaps cutting through outlying lobules of the growth and leaving them to be taken out afterwards, or he may arrest the bleeding as he goes on by force-pressure forceps (p. 427) or ligature. The former plan is best if the bleeding is from multitudes of small vessels; the latter, if it proceeds from a few large trunks. In difficult dissections the parts should, when possible, be rendered bloodless. Where this is impossible the oozing is best arrested by the application of hot water (p. 420).

The wound that is left after the removal of a tumour usually unites readily by first intention if properly drained and dressed by one of the antiseptic methods described in the chapter on the treatment of wounds. If imperfectly drained, and if the cavity be allowed to become filled with decomposing discharges, severe fever and prolonged suppuration will almost certainly result.

Removal of Tumours by the Écraseur.—The écraseur was invented by

Fig. 399.—Chassaignac's Steel Chain Écraseur.

Chassaignac. It consists of a loop of chain of fine steel or twisted wire (thick piano wire is the best), which, having been passed over the tumour or through the tissues to be removed, is gradually tightened by a mechanism in the stem to which it is attached. In applying this instrument it is often necessary, first of all, to insulate and raise the tumour to be removed by passing a thread through or under it; and then, having applied the loop of the chain round its base, to tighten this and effect the strangulation by working the handle every ten or fifteen seconds, until the mass is detached.

By means of the *Écraseur* (Fig. 399), cancerous and other growths of considerable size are removed with little or no hæmorrhage, in the course of a few minutes, by a process of rapid strangulation and crushing. The resulting wound is small and puckered in, and often heals with but little trouble. If the mass to be removed be large, two or more écraseurs may be used at the same time, the chains having been passed through the tissues by means of a needle. The action of the écraseur differs according to the kind of instrument used. Chassaignac's original écraseur, armed with a steel chain,

and having a to-and-fro movement, acts like a saw. That which is now sometimes employed (see Vol. ii., Diseases of the Tongue) acts as a simple constrictor; and its use is therefore less likely to be followed by hæmorrhage. This instrument was at one time largely employed in the removal of carcinomata of the tongue, but in this and other instances it has been almost entirely superseded by improved methods of excision with the knife or scissors. Experience has not shown, as was once believed, that pyæmia is less likely to follow removal by this instrument than by the more ordinary means.

A modification of the *écraseur* in which the wire was heated by electricity at the same time that the noose was gradually drawn in was much in use a few years ago. The galvanic *écraseur* has, however, fallen somewhat into disrepute. The increased rapidity with which it cut the tissue, and the perfect absence of hæmorrhage during the operation, seemed at first great points in its favour; but experience showed that the wound left was more likely to slough, and secondary hæmorrhage occurred much more frequently than after the use of the simple *écraseur*.

The *écraseur* is undoubtedly a useful and valuable instrument, but it should never be employed when the knife can be safely used.

Paquelin's Cautey is in some cases employed in the removal of tumours. The red-hot knife of this instrument divides the tissues cleanly, and efficiently arrests hæmorrhage. The heat at which it can be used may be easily regulated, and if not raised above a dull red heat secondary hæmorrhage rarely follows its employment. In removing superficial growths, such as a carcinoma of the vulva, it can be used at a higher temperature. It then arrests the parenchymatous oozing, but leaves the large vessels spouting, so that they can easily be secured by ligature. When used at this temperature it cuts more quickly and cleanly, and chars the tissues more superficially, and leaves a surface on which a scarcely appreciable layer of slough is formed. One great disadvantage in the use of the cautey is that the charring of the divided tissues prevents the detection of fragments of an infiltrating tumour which have escaped removal.

The **Ligature** is now never used except for pedunculated growths or for *nævi*. It was formerly applied to small epitheliomata of the tongue, but the presence of the foul sloughing tumour in the mouth was not only unpleasant but a positive source of danger to the patient. When the ligature is applied, the part, having been well insulated, and effectually strangled by a stout whipcord ligature, sloughs and separates in a few days.

A modification known as the *elastic ligature* was introduced into practice by Dittel some years ago. It consists of a thin band of india-rubber, which is tied round the mass to be removed, and gradually tightened as it cuts its way through. It is possible that such a means may be useful in certain small pedunculated growths, which dry on being strangled; but its application to large tumours, as of the breast, is simply a revival of mediæval barbarism with the aid of modern appliances. The slowness of its action, the pain as it cuts through, the large wound that is left, the factor from the necrosed tumour, and the chance of septic infection from this cause, all tend to make it a method that should be avoided whenever the knife can be employed. Far more tedious, and certainly not safer than the knife, it is also inferior to caustics, which at all events arrest putrefaction, and many of which, as chloride of zinc, have a powerful antiseptic action.

CHAPTER XXXV.

TUBERCULOSIS. ACTINOMYCOSIS.

TUBERCULOSIS.

TUBERCULOSIS is an infective disease resulting from the invasion of the tissues by a specific micro-organism—the bacillus tuberculosis. The disease is characterized by the formation of chronic inflammatory tissue—the so-called *tuberculous tissue*—in the affected part; the nature of the disease can as a rule be recognized with more or less certainty by the naked-eye and microscopic characters of the lesions, but only with absolute certainty by the demonstration of the specific micro-organism. Tuberculosis is met with both as a local and a general affection. The Surgeon is chiefly concerned with the different varieties of **local tuberculosis**; and in his treatment he endeavours to arrest the disease before it has extended beyond his reach. **General tuberculosis** on the other hand is associated with the widespread development of tuberculous deposits throughout the body, and is of interest to the Surgeon chiefly as a not unfrequent fatal termination of the local forms of the disease. In the consideration of this important subject it will be convenient first to describe the typical microscopic changes presented by tuberculous tissue, and, in the next place, the naked-eye appearances to which they give rise.

Microscopic Characters of Tuberculous Tissue.—The structure which has generally been regarded as the essential element of the tuberculous lesion is the so-called *tubercle*, a small rounded nodule just visible to the naked eye. Watson Cheyne, who may justly be considered the greatest authority on the subject in this country, has however clearly shown that this view is erroneous, and that in many instances of undoubtedly tuberculous disease no “tubercles” are present. Two distinct forms of tuberculous tissue are indeed met with—the nodular form, which is characterized by the presence of discrete tubercles or “tubercle-systems” (Fig. 400), and the infiltrating form, in which no such separate tubercles exist.

The “tubercle” which is characteristic of the nodular form of tuberculous tissue is described by Cheyne as “a microscopic nodule, generally round or oval in shape, composed of a central portion made up of epithelioid cells, and sometimes giant cells, surrounded by a layer consisting of cells of inflammatory origin, or of more completely formed fibrous tissue.”

The “giant cell” is usually the most striking feature of the tubercle, but it is not invariably present. It is a large, many-nucleated cell, with more or less well marked branching processes (Fig. 401). The nuclei are most commonly arranged round the outer border of the cell, or may be collected together at one end; they are large and clearly defined, of oval form, and contain one or two nucleoli. The protoplasm is coarsely granular, and often vacuolated. Around the giant cell is a zone composed of “epithelioid cells.” These cells are so named from their resemblance to young squamous

epithelium; they are large and consist of granular protoplasm, containing usually a single clearly defined oval nucleus, similar to those of the giant cell. The branching processes of the giant cell can often be recognized amongst the cells of this zone. The outer part of the tubercle is composed of ordinary lymphoid corpuscles, differing in no respect from the migrating leucocytes observed in other forms of inflammation. These cells are readily distinguished from the epithelioid cells by their small size and their behaviour to staining reagents, by which they are much more deeply coloured than the epithelioid cells. Some difference of opinion exists as to the presence of a reticular stroma between the cells of the outer zones; Watson Cheyne, who has paid especial attention to this point, has not been able to demonstrate any reticulum beyond such as is formed by the branching processes of the giant cells and by "bands of fibrous tissue in connection with the wall of the tubercle." The appearance of a fine reticulum may also be produced by coagulation of a homogeneous intercellular substance by the reagents used in hardening the specimen. No

Fig. 400.—A group of Tubercle Nodules in a mass of soft granulation tissue from a tuberculous knee.

Fig. 401.—A Tubercle Nodule more highly magnified, showing a giant cell surrounded by epithelioid cells and lymphoid corpuscles.

vessels penetrate amongst the cells, and this want of vascularity forms one of the most important and distinctive features of tubercles. In the condition known as "tuberculous infiltration" no discrete tubercles are present, but epithelioid cells with or without giant cells are scattered irregularly or in broad tracts through the affected tissue. Baumgarten and Cheyne have independently arrived at the conclusion that the epithelioid cell is the most characteristic element of tuberculous tissue. The lymphoid cells differ in no respect from those met with in simple inflammation, whilst the giant cells are not invariably present. The epithelioid cells on the other hand are constantly present, and, as we shall see, it is in association with them that the bacillus is most usually found. It must, however, be remembered that very similar cells are met with in other chronic inflammatory processes. Ziegler and Tillmanns have also shewn that similar cells are produced when granulation tissue is made to grow between two thin glass slides inserted into the peritoneal cavity or beneath the skin of a rabbit; these cells, which Ballance and Sherrington, in repeating Ziegler's experiments, speak of as "plasma cells," have already been described in the chapter on Repair.

The giant cells of tubercle present certain peculiarities which usually make it possible to identify them with some degree of certainty. There are four forms of multinuclear cells from which they have to be distinguished: first, those of simple chronic inflammation; secondly, those of syphilitic growths; thirdly, the large cells found in the destructive processes in bone (osteoclasts); and, fourthly, the many-nucleated cells of a myeloid tumour. From the first and second they may commonly be distinguished by their greater size and by the processes extending from them into surrounding parts. Osteoclasts are smaller, have no processes, and lie in immediate contact with the bone, filling a hollow in its substance (Howship's lacuna), while a tuberculous giant cell is always surrounded by leucocytes. In myeloid cells the masses often reach a great size and the protoplasm is less granular. The great distinctive feature however is in the arrangement of the nuclei. In all forms of giant cell, except the tuberculous, the nuclei are scattered more or less uniformly through the protoplasm; in the tuberculous they are gathered together either at the circumference or at one end or at both with their long axes directed more or less uniformly towards the centre of the cell.

The observations of Villemin, Wilson Fox, Cohnheim, and many others, had shown clearly that tubercle is an infective process, but the whole subject was involved in great obscurity till in 1882 Koch, by a new method of staining, discovered in the tuberculous tissue a specific microscopic organism to which he gave the name of *bacillus tuberculosis*. It is a non-motile, rod-shaped

fungus with a slight longitudinal curve, and about equal in length to one-third of the diameter of a red blood-corpuscle, and its breadth is about one-fifth of its length. Clear bright dots are often seen in it which there is every reason to believe are spores.* The bacilli are found in the giant-cells, and in or among the epithelioid cells. In slowly growing tubercle the organisms are very few in number and almost exclusively contained in the giant cells, sometimes only one in each. Under these circumstances it is evident that the bacilli can be discovered only with great difficulty, and unless the section through the giant cell happens to hit the exact situation of the organism, and to be parallel to its long axis, it may appear that none is present. In more acute processes the cell may be crowded with bacilli (Fig. 402), and they may burst beyond its limits extending amongst the surrounding epithelioid and lymphoid cells. Koch has demonstrated the curious fact that the nuclei of the giant cell lie as far removed from the bacillus as possible, so that the idea involuntarily arises in the mind that there must be some kind of antagonism between them and the parasite.

The proof that the bacillus is the actual virus of tubercle has been obtained in the same manner as in the case of other pathogenic organisms. Its presence has been demonstrated in the diseased tissues, first by microscopic observation, and secondly by cultivation experiments. The bacillus has been cultivated

The proof that the bacillus is the actual virus of tubercle has been obtained in the same manner as in the case of other pathogenic organisms. Its presence has been demonstrated in the diseased tissues, first by microscopic observation, and secondly by cultivation experiments. The bacillus has been cultivated

* For the details of the mode of preparation and cultivation of the bacillus of tubercle the reader is referred to Koch's paper, translated by Reed (Micro-organisms in Disease, New Sydenham Society, 1884) and to Cohnheim's Bacteriology.

Fig. 402. Tubercle. Bacilli in a giant cell.

to many generations out of the body, and then inoculated on animals with the effect of giving rise to genuine tubercle, in which again the organism was found on microscopic examination. The media which have been chiefly employed are solidified blood-serum, and agar-agar peptone to which 6 or 8 per cent. of glycerine has been added. Cultivation from human tubercle is not easy, and requires much special management and apparatus, and in many tuberculous diseases it is very difficult to find the bacillus by the microscope. Its presence has, however, been proved by the inoculation of the doubtful material into the anterior chamber of the rabbit's eye. This is followed, if the bacillus is present, by tuberculous disease of the iris, and subsequently by general tuberculosis, the bacillus then being found in the diseased tissues. This method is free from error, as the rabbit's eye is never the seat of spontaneous tuberculous disease.

The explanation which may be given of the process up to this point is, therefore, that the bacillus, either in its fully developed state, or as a spore, becomes lodged at the point at which the tubercle subsequently forms. It may come there by the blood or lymph stream, and is possibly carried by a white blood-corpuscle which has taken it up into its substance. When it lodges it causes a local irritation, and the formation of the tubercle represents the effort of the tissues to expel or destroy the invading parasite. The first effect of the irritation is to cause an abundant migration of leucocytes from the surrounding vessels. At the same time some proliferation of the fixed tissue cells occurs, and thus the epithelioid cells are formed, in large measure no doubt from the endothelium of the small blood-vessels and lymph spaces. Many views have been expressed concerning the origin of the giant cells. It has commonly been believed that they are formed by fusion of a number of leucocytes round the bacillus. That such a process is possible is suggested by the observations of Metchnikoff on certain molluscs in which he watched the fusion of cells round bacilli experimentally introduced. Other views have, however, been held as to their origin, and Treves has maintained that they are merely lymph-coagula enclosing some of the smaller cells. Cheyne believes that the giant cells are derived from the epithelioid cells either by hypertrophy of individual cells or by coalescence of neighbouring cells. The lymphoid cells around are merely migrated corpuscles. If the cells destroy the bacillus the process comes to an end, the migrated cells disappear, and repair takes place in the ordinary way, probably from the original cells of the part, a small fibrous nodule remaining in the site of the tubercle. If the bacillus overpowers the cells, it multiplies, and subsequently spreads by invasion, into the surrounding parts. The evident irritation of the tissues round the bacillus is supposed to be due to the chemical products formed by the organism in its growth.

If the morbid process continues to advance, the next change observed in the tubercle is the fatty degeneration of the central part. Granules appear, first clouding the cells and obscuring the nuclei, and subsequently complete degeneration takes place, and the central part of the tubercle becomes merely a granular cheesy mass in which no cell structures are recognizable. In the process of degeneration the lymphoid corpuscles become withered and shrunken and granular before complete disintegration. In this state they were observed by Lebert and believed to be characteristic of tubercle, and hence he named them *Tubercle-Corpuscles*. This is the process of **Caseation of Tubercle**.

It has been asserted that this caseation may be the result of a simple chronic inflammatory process arising from various causes, and that the bacillus finds a nidus for its growth in the degenerated tissues. Koch distinctly denies this. He asserts that the bacilli can be recognised only before caseation takes place, and that as degeneration progresses they either perish or break up, leaving their spores behind. That the latter is probably the case is shown by the fact that although no bacilli can be recognised in the cheesy mass, it still retains its virulent properties when inoculated on an animal. Two causes probably determine the caseation of tubercle: it is partly due, no doubt, to insufficient blood supply resulting from the absence of any newly formed vessels; and secondly, it is thought probable that it is also caused by various irritating chemical substances produced by the bacillus.

Even after caseation recovery may take place. The bacillus may perish, the cheesy nodule may gradually become dryer and firmer and be encapsuled in a zone of fibrous tissue formed from the surrounding parts; or lime salts may be deposited in it and it may become calcified, and this may remain harmlessly imbedded in fibrous tissue. In bone it may be surrounded, according to Nelaton, by a thin capsule of dense osseous tissue.

In other cases, after caseation, it may soften, inflammation and suppuration may occur round it, and it may be expelled as a foreign body. However widely the tuberculous process spreads, it consists merely of a repetition and extension of the changes here described. The more acute the process the less clearly will the individual nodules be marked, and the more it will take the form of a uniform small-celled invasion of the surrounding structures. If the morbid process continues to extend, invading surrounding parts, it often causes extensive destruction of tissue.

The **Extension of Tubercle** takes place in various ways. It is, of course, evident that it can occur by direct infection of contiguous parts. The bacillus itself is non-motile and cannot migrate, but Koch believes that the organism may be taken up by wandering cells which subsequently enter the lymph stream and are thus carried to other parts, either near the original focus or at a distance, bearing the organism with them. The actual presence of bacilli in the corpuscles has been demonstrated by Koch after injection of the organism into the blood-stream. In this way we may find the new tubercles dotted closely round the primary focus. The well known frequency with which the disease implicates the nearest lymphatic glands is further evidence of this mode of propagation. Again, it easily spreads over a surface such as the synovial membrane of a joint or a mucous membrane. Thus we see in white swelling of the knee that after infection of the joint from a small tuberculous centre in the bone the whole synovial surface quickly becomes affected, and in tuberculous disease of the kidney we find infection of the ureter and bladder.

Lastly, the virus may enter the blood-stream, and general dissemination occur throughout the body as an acute disease. There is no reason to believe that this ever occurs as a primary condition, or that it is due to an infection of the blood, and to an increase of the virus in the blood. Tubercle is always primarily a local disease, and although the virus may be disseminated by the blood, it probably does not multiply in it. The acute disease is due to the entrance into the blood stream of softened tuberculous matter from a local centre, either indirectly through the lymphatics or directly through the veins.

It then gives rise to the formation of tuberculous tissue in various situations throughout the body. Each tubercle is surrounded by its zone of irritation, and thus in a membrane we may get an apparently diffuse inflammation as in tuberculous meningitis. It is probable that some constitutional condition is necessary for the development of acute tuberculosis as well as the local source of infection, for it seems most likely that in all local tuberculous diseases the virus must frequently enter the blood-stream, and yet acute general tuberculosis is not a common termination of local disease.

From the foregoing description, therefore, it will be seen that tubercle is a form of chronic infective inflammation caused by the invasion of the tissues by the bacillus tuberculosis; it gives rise to the formation of non-vascular cellular nodules, destroying and occupying the place of the original tissues of the part in which they lie. It spreads locally by invasion of surrounding parts, and by the lymph or blood-stream to distant parts. The actual tuberculous tissue is incapable of higher development; its natural tendency is to fatty degeneration, after which it may dry up and remain unchanged; it may calcify or it may soften. Its presence causes irritation of the surrounding tissue beyond the actual tuberculous area. This is accompanied by hyperemia and various other changes according to the intensity of the local process and the resisting power of the tissues. Thus around the tubercle we may have chronic overgrowth of fibroid tissue, rapid formation of vascular granulation tissue, acute inflammation with exudation as in tuberculous meningitis, and even suppuration. Tubercle may be fatal by its local effects on vital organs, as in pulmonary phthisis, by the exhaustion following suppuration round local centres as in tuberculous diseases of bones or joints, or by general acute infection or acute tuberculosis. It may be recovered from by degeneration and by being encapsuled in fibrous tissue, by caseation and calcification and subsequent encapsulation, or by softening and suppuration and elimination from the body. Whether the organism is completely destroyed, or whether its spores remain encapsuled in the healed tissues, we do not know.

We are now in a position to consider the clinical features and the morbid anatomy of tuberculous affections.

Naked-Eye Appearances of Tubercle.—In the description of these, we must here confine our attention to tubercle as it comes under the care of the Surgeon, omitting all mention of the lungs. A single tubercle follicle forms a minute dot just visible to the naked eye: it is semi-transparent and grey in colour, and of cartilaginous hardness, and it has received the name of the *semi-transparent grey granulation*. By an increase in the zone of lymphoid cells, or by the close approximation of two or more separate nodules, the grey granulations frequently reach the size of a millet-seed, and have consequently received the name of miliary tubercle (*miliarius*—millet). The grey granulation has long been considered the most characteristic feature of tubercle. It is commonly surrounded by a zone of hyperemia, and often by distinct evidence of inflammation. Thus on a serous membrane it may be covered by a thin layer of lymph, and the cavity lined by the membrane may contain an excess of fluid. In joints it may be surrounded by a zone of granulation tissue before which the normal structures are disappearing. In some cases, instead of forming distinct nodules, tubercle infiltrates the tissues in a single mass. This is often seen in the testicle when the disease is advancing from the epididymis into the body. Here there may be a hard semi-transparent zone more than an eighth

of an inch in breadth, which on microscopic examination is found to be composed of tubercle nodules, so closely packed as to be practically continuous. (See Figure of Tuberculous Testicle, Vol. II.) This is termed *grey infiltration*. Beyond this dotted grey granulations may be seen in the otherwise healthy tissues.

Before it reaches any considerable size the grey granulation undergoes fatty degeneration. It becomes opaque in its centre, yellowish-white in colour, and more friable in structure, and is then termed *Yellow Tubercle*. By the process of invasion of the surrounding tissues by the tuberculous growth, followed by fatty degeneration and caseation, large cheesy masses may be formed. These commonly reach the size of a pigeon's egg, and are often larger. Thus a lymphatic gland by gradual tuberculous invasion and destruction of its normal tissue, followed by fatty degeneration, may be converted into a yellow cheesy mass, closely surrounded by the stretched capsule. The kidney in like manner may be converted into a huge cheesy mass bigger than a fetal head. Caseated tubercle is soft and brittle, so that it can easily be removed from the cavity in which it is lying, by means of a sharp spoon. This, as will be subsequently seen, distinguishes it from a softening syphilitic gumma, which is leathery and tough.

The fate of these large caseous masses varies. They may either dry up and become firm and be encapsuled, or they may calcify or soften. The particular change that a mass of yellow tubercle undergoes seems to depend in part at least on the situation of the disease. Thus calcification is common in the bones and lymphatic glands, but is rarely, if ever, met with in the skin, testicle, kidney, or synovial membranes. Encapsulation by fibroid tissue is common in the lymphatic glands, and is occasionally met with in the kidney. Softening is the rule in the skin, testicle, kidney, and synovial membranes, and is very common in the lymphatic glands.

By the progressive development of tuberculous tissue with the inflammatory changes around it, the normal appearance of the affected part becomes entirely lost, and it is converted into a soft pulpy mass of **Tuberculous Granulation Tissue**. In this the grey or yellow tubercles can often be recognized with the naked eye.

When tubercle softens it breaks down into a thick curdy fluid. The process is always accompanied by more or less inflammation of the surrounding parts, accompanied in most cases by the formation of pus, and we have thus formed the **Tuberculous Abscess**. This is the most common form of chronic abscess. It may form a large collection of fluid—sometimes, as in the psoas abscess, reaching an enormous size. The fluid it contains is commonly thin and curdy, and contains much granular matter and but few recognizable pus cells. In more acute cases the pus may more closely resemble that of an acute abscess. The wall of the abscess may be composed of a thin layer of caseating tubercle. This is the case in tuberculous abscesses of the kidney, testicle, or skin. In the larger abscesses, such as a psoas abscess, it may be in part formed merely by condensed fibrous tissue not actually tuberculous. Bacilli can scarcely ever be demonstrated in the pus of these abscesses by microscopic examination or direct cultivation, but that their spores are present can be shown by inoculation experiments.

In superficial tuberculous diseases, after softening of the tubercle and discharge of the softened cheesy matter, an ulcer is often left.

The **Tuberculous Ulcer** is usually characterized by the following features: The floor of the ulcer is yellow and granular, the base is slightly indurated, and the edges raised and often undermined. It tends to spread slowly by progressive infection of surrounding tissues. In surgical practice we meet with such ulcers in the skin, bladder, rectum, tongue, and larynx. In these the progress of the disease is often hastened by the decomposition of the discharges from the sore.

Constitutional Symptoms of Tuberculous Diseases.—Local tuberculous diseases are not necessarily accompanied by any recognizable constitutional symptoms, even though many different local centres of tubercle exist. When, however, tubercle exists in a considerable local mass, as in the kidney or testicle, or in a diseased joint, and more especially when it is commencing to soften, careful thermometric observations will almost always show some elevation of temperature, especially at night. This may not be great, perhaps not up to 100° F., but if it is persistent, it is very grave evidence of softening tubercle. The consideration of the symptoms of general tuberculosis belongs rather to Medicine than to Surgery. When visceral tuberculosis occurs as a secondary consequence of a local tuberculous disease it most commonly appears in the form of ordinary pulmonary phthisis, and runs the usual chronic course. Progressive emaciation, evening elevation of temperature and night sweats, which cannot be accounted for by prolonged suppuration from the local seat of disease, always lead to a grave apprehension that general tuberculosis is taking place.

In cases of acute general tuberculosis following a local tuberculous disease, such as are occasionally met with in joint disease and more often in tuberculous testicle, there is marked febrile disturbance, the thermometer reaching often 103° F. or 104° F., without, at first, definite affection of any organ. The symptoms may then closely resemble typhoid fever, or if there is an open wound, may be mistaken for septicæmia. Before long, usually not later than the second week, symptoms either of acute pulmonary phthisis, tuberculous meningitis, or some other definite tuberculous affection, make their appearance.

SPECIAL TUBERCULOUS DISEASES.—The only certain evidence that a disease is tuberculous is the presence of the bacillus tuberculosis in the diseased tissues, proved either by direct microscopic observation, by cultivation, or by inoculation. The general course of the disease, the invasion of the tissues by a chronic inflammatory new growth, incapable of higher development, and tending always to caseation, and the occasional termination in general or pulmonary tuberculosis, are secondary proofs, but cannot be considered conclusive in the absence of the demonstration of the bacillus.

The following surgical diseases have been proved more or less conclusively to be tuberculous:

(a.) Skin and subcutaneous tissue: lupus, and subcutaneous scrofulous abscess; (b.) Mucous membranes: tuberculous ulceration of tongue, pharynx, palate, and larynx; some cases of scrofulous ozæna and fistula in ano; (c.) Lymphatic glands: many cases of strumous enlargement and scrofulous abscess; (d.) Genito-urinary organs: scrofulous kidney, strumous testicle, and some forms of ulceration of the bladder, and scrofulous disease of the prostate and vesiculae seminales; (e.) Bones and joints: all cases of white swelling, or fungous disease; many of chronic synovitis; almost all, if not all, cases of caries, not evidently traumatic, septic, or syphilitic; chronic abscess of bone,

and some forms of chronic osteomyelitis; fungous disease of sheaths of tendons, and some forms of chronic teno-synovitis. This long list shows the truth of Volkmann's remark that since the true nature of these diseases has been recognized, the Surgeon may almost be said to have more to do with tubercle than the Physician.

Predisposing Causes of Tuberculous Disease.—Tubercle being a specific infective disease it follows, as in the case of the infective diseases generally, that the predisposing causes are of two kinds: first, those which favour the entrance of the specific virus into the body; and secondly, those which lessen the resistance of the tissues, either locally or generally, to the growth of the virus.

The path by which the virus originally enters the body is somewhat doubtful. The bacillus can be cultivated out of the body only with considerable difficulty, requiring a temperature of from 80° to 105° F., and growing only on blood-serum. It is probable, therefore, that it is a genuine parasite, and exists out of the body only in the form of spores. These spores are contained in the sputa of phthisical patients, in the fæces of those suffering from tuberculous diseases of the bowels, and in the urine of those affected with genito-urinary tuberculosis. Many of the lower animals are also liable to tubercle, and may disseminate the virus. Thus the milk of cows suffering from tuberculous disease of the udder is undoubtedly a most important source of infection; tubercle bacilli have been demonstrated in the milk, and tuberculosis has been produced by inoculation. The risk of infection by meat from tuberculous animals is probably small. Judging from the analogy of the bacillus anthracis, the spores in all probability retain their vitality for years when dried, and may be diffused everywhere where dust is carried, and there can be little doubt that they are abundant in the dust wherever human beings are crowded together. In all probability we have all frequently taken them into our bodies, but fortunately they can develop only where they find favouring general and local conditions.

A considerable number of cases have now been recorded in which *direct inoculation* of wounds by the tuberculous virus has occurred. Elsenberg has collected thirteen cases in which tubercle appeared to have been directly inoculated during the rite of circumcision. Eve has recorded a remarkable case of the same kind. A child aged five months was admitted into the London Hospital with a large abscess containing caseous pus in each groin, and a small sore on the frænum which had remained unhealed since circumcision had been performed on the eighth day after birth. Inoculation of a guinea-pig with pus from one of the abscesses produced tuberculosis. The individual who had performed the circumcision had died of phthisis a week before the child was admitted to the hospital, and another child whom he had circumcised a year previously had died of tubercle.

A striking case of direct inoculation is recorded by Tscherning of Copenhagen. A healthy woman aged twenty-four cut her finger with a broken glass vessel containing the sputum of a man dying of phthisis. A small fungating mass of granulation tissue formed, and was scraped with a sharp spoon. The disease recurred, and subsequently the finger was amputated, and swollen glands at the elbow and in the axilla excised. The sputum which was the source of inoculation was rich in tubercle bacilli, and the granulation tissue from the finger and the enlarged glands contained tubercle nodules and bacilli.

The occasional transmission of tuberculosis by *contagion* is of interest chiefly in connection with tuberculous affections of the lungs.

Constitutional Predisposing Causes.—Under this heading must be included the various conditions, mostly little understood, which diminish the resisting power of the tissues to the invasion of the tubercle bacillus. Of these the most important is undoubtedly the constitutional condition known as **Scrofula** or **Struma**. Scrofula is characterized, as Virchow expresses it, by an "abnormal vulnerability" of the tissues, or, in other words, by a subnormal resistance to external injurious influences, amongst which must be included the invasion of pathogenic organisms of all kinds. Scrofula is not a disease; it is merely a constitutional predisposition to disease, and not to one disease only, but to many. If we study the diseases of those patients who present the characters to be presently described as those of the scrofulous diathesis, we shall find that it is not to tubercle alone that they show an abnormal susceptibility. Scrofulous patients as a rule suffer more severely from syphilis, should they contract that disease; gonorrhœa with them is difficult to cure; and buboes commonly follow a soft chancre. Scrofulous children are more likely than others to die of scarlet fever or measles; and it is a generally received opinion, though there is no very good evidence for it, that they are more liable than others to acute infective periostitis and necrosis of bone.

The scrofulous diathesis is characterized chiefly by a tendency to various forms of inflammation, resulting from slight causes which would be innocuous to healthy subjects. Catarrhal inflammations of mucous membranes are especially common. Micro-organisms multiply in the discharges, and the further irritation of the products of their growth causes the discharge to become purulent; and, owing to the feeble resisting power of the tissues, the condition may be very chronic. Scrofulous catarrhal inflammation in children is especially likely to attack the eye, nose, throat, and ears. The *conjunctiva* becomes chronically inflamed, and the discharge becomes muco-purulent. As a sequela of this the condition known as "granular lids" is not uncommonly set up. The papillæ become excessively vascular and hypertrophied, till the whole surface of the membrane appears to be covered with genuine granulation tissue. The affection specially known as strumous or phlyctenular ophthalmia often leads to the formation of a small, intractable ulcer on the cornea, with intense injection of the surrounding conjunctiva.

The *mucous membrane lining the nostrils* becomes chronically congested, red and swollen, giving rise to habitual sniffling and to a sensation as of a constant cold. The discharge, at first merely mucous, frequently becomes purulent, and lodging in the irregularities of the nasal fossæ, decomposes, giving rise to the most offensive smell. This condition, known as *strumous ozæna*, may sooner or later cause ulceration of the membrane and subsequent necrosis of the bones. Occasionally the lining membrane of the antrum becomes irritated, and this may be followed by enlargement of the cavity and discharge of unhealthy pus into the nostrils.

The *mucous membrane of the throat* is chronically congested, and the adenoid tissue of the naso-pharynx is often hypertrophied; the tonsils may be enlarged.

Chronic purulent discharge from the ear, *scrofulous otorrhœa*, is another very common affection. The disease most frequently commences in the middle ear, the discharge finding its way out by perforating the membrana

tympani. It frequently leads to destruction of the ossicles and permanent deafness. The mucous membrane of the *genito-urinary organs* also is readily affected with purulent catarrh, often arising from very slight causes and very permanent. Such discharges are of common occurrence in female children, and have frequently given rise to unfounded charges of criminal assault.

The *lymphatic glands* are peculiarly prone to be affected, and the enlargement can almost always be traced to some irritation of the part from which they receive their lymph supply.

These various strumous inflammations undoubtedly render the part affected peculiarly liable to become tuberculous. As an instance may be mentioned the very common cases of tuberculous disease of the lymphatic glands of the neck occurring in strumous children. Here it may fairly be supposed that the unhealthy condition of the mucous membrane of the throat favours the entrance of the bacillus tuberculosis, which, reaching the already inflamed lymphatic gland, finds the soil ready prepared for its growth.

A reference to the list of surgical tuberculous diseases given on p. 1093, will show that many affections previously spoken of as strumous or scrofulous have been definitively proved to be actually tuberculous. The terms "scrofulous" and "tuberculous" are not indeed synonymous. A patient may be scrofulous and yet suffer from no actual disease; he cannot be tuberculous, unless his body is actually invaded by the bacillus.

Signs of the Scrofulous Diathesis.—The existence of the scrofulous diathesis is often marked by the presence of a peculiar temperament.

The **Scrofulous Temperament** assumes two distinct forms, the fair and the dark; and each of these presents two varieties, the fine and the coarse. The most common is that which occurs in persons with fair, soft, and transparent skin, having clear blue eyes with large pupils, light hair, tapering fingers, and fine white teeth; whose beauty indeed is often great, especially in early life, being dependent rather on roundness of outline than on grace of form; and whose growth is rapid and precocious. In these individuals the affections are strong, and the procreative power considerable; the mental activity is also great, and is usually characterized by much delicacy and softness of feeling, and vivacity of intellect. Indeed, it would appear that, in such persons as these, the nutritive, procreative, and mental powers are rapidly and energetically developed in early life, but become proportionately early exhausted. In another variety of the fair scrofulous temperament, we find a coarse skin, short and rounded features, light grey eyes, crisp and curling sandy hair, a short and somewhat ungainly stature, and clubbed fingers; but not uncommonly, as in the former variety, great and early mental activity, and occasionally much muscular strength.

In the dark form of the scrofulous temperament, we usually find a somewhat heavy, sullen, and forbidding appearance; a dark, coarse, sallow, or greasy-looking skin; short, thick, and harsh curly hair; a small stature, but often a powerful and strong-limbed frame; with a certain degree of torpor or languor of the mental faculties, though the powers of the intellect are sometimes remarkably developed. The other dark strumous temperament is characterized by clear dark eyes, fine hair, a sallow skin, and by a mental and physical organization that closely resembles the first described variety of the fair strumous diathesis.

In all these varieties of temperament, the digestive organs will be found to

be weak and irritable. This condition, which I believe to be invariably associated with the scrofulous diathesis, and the importance of which was pointed out by Sir James Clark, must be regarded as one of the most essential conditions connected with scrofula, and as tending greatly to that impairment of nutrition which is so frequent in this state. This gastric irritability is especially characterized by the tongue, even in young children, being habitually coated towards the root with a thick white fur, through which elongated papillæ project, constituting the "pipped" or "strawberry" tongue; the edges and tip, as well as the lips, being usually of a bright red colour. This state of the tongue is aggravated by stimulants, high living, and the habitual use of purgatives. In the fair varieties the bowels are usually somewhat loose, but in the dark forms of struma there is a torpid condition of the intestinal canal. In all cases the action of the heart is feeble, and there is a tendency to coldness, and often to clamminess of the extremities.

The *Hereditary Nature* of tuberculosis is well known to the public and to the profession; for although the scrofulous diathesis is not commonly congenital, yet the tendency to it is, and it often manifests itself at an early period. In other words it seems probable that tuberculosis itself is not inherited, but only that "abnormal vulnerability" of the tissues which renders them peculiarly liable to tuberculous diseases.

A most powerful occasioning cause of the scrofulous diathesis and of tuberculous disease, and that which in most civilized countries is likewise the most frequent, is *malnutrition* arising from an habitual disregard of hygienic laws: either from insufficiency of nourishment, or the administration of improper food, in the poorer classes; or from overfeeding, and overstimulation of the digestive organs, amongst the children of the wealthier orders of society, inducing chronic irritation of the mucous membrane of the stomach and interference with the digestive powers, and consequently with nutrition. The influence of food that is innutritious in quality or insufficient in quantity, was shown by Phillips, in his excellent *Treatise on Scrofula*, to be the most immediate cause of the diathesis; and, when conjoined with the injurious effects of a confined and impure atmosphere, it may be considered as sufficient to occasion it in those cases in which no predisposition to it exists, and greatly to develop any hereditary tendency to it in the system. It is to the conjoined influence of agencies such as these that we must attribute the prevalence of tuberculous diseases amongst the lower orders both of town and of rural populations.

Tuberculous affections of various kinds are often called into activity by the *debility induced by previous diseases*, such as measles, scarlatina, whooping-cough, &c.

Excluding affections of the lungs, tuberculous diseases usually develop at an *early age*, though seldom before the child has reached its second year. They are most common about the period of the second dentition, and it is comparatively rare to meet with them for the first time after the ages of twenty-five or thirty-five. *Sex* does not appear materially to influence the disease.

Local Predisposing Causes.—Although certain constitutional conditions are of great importance as predisposing causes of tuberculosis, yet cases of tuberculous disease are very frequently met with in patients who present none of them. Under these conditions the diminished resisting power of the tissues is local and not general, and as common causes of such local diminished

resistance may be mentioned previous simple inflammation and damage by slight external injury. Thus in many cases of tuberculous joint disease the history clearly points to a sprain or other injury as the starting-point of the disease.

The local effect produced by tuberculous infection varies very greatly under different circumstances. It has been pointed out in the Chapter on Inflammation that the effect of an irritant varies, first, with the intensity of the irritant itself; secondly, with the resisting power of the tissues, and thirdly, with the presence or absence of accessory sources of irritation.

The variation in the local effect of the virus is, perhaps, best illustrated by tuberculous disease of the synovial membrane of the knee. In tolerably healthy adults a few tubercle nodules may form in a limited part of the membrane and there give rise to a chronic inflammatory growth of fibrous tissue around them, the mischief remaining strictly limited and its nature being ascertainable only by the microscopic evidence of a few atrophied nodules in the mass of fibroid tissue. In children we more commonly find the disease extending rapidly; implicating the whole membrane and giving rise to the formation of a mass of soft, pulpy, vascular granulation tissue, scattered through which are numerous non-vascular tubercle nodules which are the centres of irritation which have caused the growth. If such a joint be now put at rest and every accessory source of irritation removed, and the child be well fed and removed to pure air so that the resisting power of the tissues is increased, we find the vascular granulation tissue developing into firm fibroid tissue which encloses the tubercle nodules, and thus recovery takes place. If, on the other hand, the child be neglected and the joint moved, we find the tubercle invading the granulation tissue and replacing it and finally degenerating and softening and thus giving rise to a chronic abscess. If such a joint be opened and decomposition follows, it is possible that the irritation of the septic matter may cause rapid sloughing of all the tuberculous tissue and thus bring the specific disease to an end; but the reverse may occur. The resistance of the tissues may be still further impaired by the irritation of the septic products, and the invasion of the bones by the bacillus may be hastened. If these facts be borne in mind it is not difficult to understand how the presence of tubercle may be associated with all varieties of the inflammatory process, chronic fibroid growth, exuberant formation of granulation tissue, suppuration, ulceration, or even sloughing.

The part played by the constitutional and local predisposing causes varies in different cases. In some diseased joints rest alone is quickly followed by cure; in others local treatment has no effect and the invasion of the bacillus continues unchecked.

Senile Tuberculosis.—Middle-aged and elderly people are occasionally attacked by tuberculous diseases. The individuals so affected have usually suffered from similar disease in their youth, or have come of scrofulous families. But the disease has apparently been cured, and they may have enjoyed good health and led active lives for a long series of years. Under the influence of depressing physical or mental causes, or as the result of debility consequent on some serious illness, typical symptoms of tubercle will manifest themselves in the soft parts, the joints, and the bones. The disease may run an acute course, and the patient will die of tuberculosis of some of the organs.

TREATMENT.—**Preventive Treatment** is that intended to prevent the

development of tuberculous disease in those who present the external signs of the scrofulous diathesis, or who have an hereditary tendency to it. It is of the utmost consequence, and by proper attention to it, I have no hesitation in saying, the development of local disease, even when there is hereditary predisposition, may be stopped; and the child of strumous parents, presenting perhaps the features indicative of the diathesis, may pass through life without the disease having an opportunity of declaring itself. In order to accomplish this, however, the preventive plan of treatment must be commenced early, and continued uninterruptedly for a considerable time, even for years.

The preventive treatment of scrofula and tubercle may be said in general terms to consist in close and continuous attention to hygienic rules. The diet must be specially attended to; nourishing food, but of the lightest quality, being given. A great error is often committed in overloading the stomach with more or with heavier food than it can digest, under the impression that strong food is necessary to give the patient strength. In consequence of this error, the irritability of the mucous membrane is kept up, nutrition is imperfectly performed, the surplus food is thrown off in the shape of lithates, or other products of mal-assimilation, and health and strength, which are the results of perfect nutrition, become impaired rather than improved. The use of stimulants, whether wine or beer, should be very sparing, and the milder and weaker should be preferred to the heavier and stronger kinds of malt liquor; the bowels must be kept regular with the simplest aperients; the clothing should be warm, and must cover the whole of the surface; and the patient should live in well-ventilated rooms. He should be allowed sufficient exercise in the open air, not carried to the point of fatigue, and should, if his circumstances permit, have change of air from time to time, alternating a sea with an inland climate. Bathing also, whether in sea or river, with the habitual use of the tepid or cold sponge-bath, and friction of the surface with horse-hair gloves or a rough towel, so as to keep the skin in healthy action, should be regularly practised. In carrying out this general plan of treatment, it must be borne in mind that though the health and strength of a delicate and weakly child can be improved up to a certain point, it can never, by any means, be rendered as robust and vigorous as a child of good congenital stamina who had been equally well cared for.

The **Curative Treatment** is General and Local. The general treatment should, like the preventive, be specially directed to the improvement of the nutrition, and through it to the augmentation of the constitutional vigour of the patient; all those hygienic means that have just been alluded to being continuously carried out.

The more strictly medical treatment of scrofula consists in the administration of tonics and alteratives with the view of improving the patient's constitutional powers. Before they are administered, however, it is always necessary to see that the digestive organs are in a healthy condition. Scrofula is a consequence of malnutrition; and unless we see that digestion, the first stage of the nutritive process, is properly accomplished, all other means will be useless. When the tongue is covered with a white, thick, creamy fur, and has elongated papillæ and red edges, neither purgatives nor tonics can be largely administered. In these circumstances the patient should be confined to the mildest possible diet, which must principally consist of milk, boiled fish, white meats, and light pudding, no stimulant of any kind being allowed except a small

quantity of claret or bitter beer : and, unless the patient have been accustomed to the use of stimulants, even these had better be dispensed with. Small doses of mercury with chalk, of soda and rhubarb, should be occasionally administered at bed-time, with some of the compound decoction of aloes on the following morning : and a few grains of the carbonate of soda or of potash may be given twice or thrice a day in some light bitter infusion, as of cascarrilla or calumba. In many cases of tuberculous disease, more especially that affecting the joints and bones, the liver will be found to be enlarged and sluggish in action, the patient every now and then becoming bilious, sallow, and jaundiced : in these circumstances, small doses of blue pill, carried off with the compound decoction of aloes or a rhubarb draught, will be found necessary from time to time. When all gastric irritation has been removed in this way, or if it have not existed in the usual marked degree from the first, the patient being pale and flabby, with a weakened condition of the pulse, of the skin, and of the mucous surface, then tonics may be administered, and the more specific treatment adopted.

The great remedies which are employed in the constitutional treatment of scrofula are iron, iodine, the preparations of potash, and cod-liver oil. These are all extremely useful, either singly or conjoined, as they serve to carry out distinct indications in the management of this affection.

Iron is most useful in improving the nutrition of pale, flabby, anæmic subjects. The best preparations for children are, I think, the vinum ferri and the syrup of the iodide of iron. In older persons the tincture of the perchloride and some of the forms of the citrate or the phosphate of iron, appear to be most serviceable ; in other cases, again, the natural chalybeate waters will be found to agree best.

Iodine is universally believed to promote the absorption of the chronic inflammatory products which so commonly form in scrofulous affections. The preparation usually employed is the iodide of potassium. In order that it may produce its full effects, it should be given as freely as the patient can bear it, continued for a considerable length of time, and especially administered in combinations with other preparations of potash. With the view of preventing it from irritating the stomach, it should be given in a considerable quantity of some bland fluid. Its combination with the other salts often renders it more efficacious. For this purpose I have found the following form extremely useful for adults, the dose being proportionately diminished in the case of children :—R Potassii iodidi, Potassæ chloratis, aa ʒj ; Potassæ bicarbonatis, ʒiij. Divide into twelve powders, of which one is to be taken night and morning in half a pint of warm milk. In other cases, the aqueous potassæ, Brandish's alkaline solution, or lime-water given freely in milk, are serviceable ; but I prefer the above prescription.

Cod-liver oil, which may be looked upon rather as an article of diet than as a medicine, is of essential utility in improving the nutrition of the body in cachectic and emaciated states of the system, more particularly in growing children, or in individuals who are suffering from the wasting effects of chronic suppuration ; it not only fattens but strengthens the system, increasing decidedly the muscular power and the quantity of red corpuscles in the blood. It may often very advantageously be administered in combination with the iodides of potassium or iron, and given after meals.

Of the other tonic remedies which may be employed in this affection, such

as the preparations of *bark* and of *sarsaparilla*, I need say nothing further than that they may often be usefully administered in fulfilling ordinary therapeutic indications. Ringer recommends the *sulphide of calcium* as extremely valuable in scrofulous and tuberculous glands, and in chronic strumous sores and abscesses. He uses it in a solution which has much the strength of Harrogate Waters. Thus, he directs a grain of the sulphide of calcium to be dissolved in a half pint of water, and of this a teaspoonful is taken every hour. As this mode of administration is seldom practicable, the drug may be given in small doses from three to six times a day. The best form is in pilules containing from one quarter to half a grain. If these cannot be obtained, the finely powdered sulphide may be kept in a closely stoppered bottle, and enough just to cover the point of a pen-knife taken in a wine-glass of water. It cannot be made up in any mixture, as it rapidly decomposes in contact with water, giving off sulphuretted hydrogen. Under its influence, the glands, it is said, either return to the normal state or hasten on to suppuration, and chronic abscesses either dry up or are speedily brought forward and their contents discharged, a healthy healing sore being left.

Tuberculin.—In 1890, Robert Koch published certain results which he had obtained as the outcome of a long series of investigations made with the object of conferring immunity against inoculation with the tubercle bacillus and of arresting tuberculous disease. It will be possible here only very briefly to describe the chief steps by which Koch arrived at the discovery of a treatment of tuberculosis which, although it has so far been disappointing in practical utility, must be looked upon as a triumph of experimental research. If a guinea-pig be inoculated subcutaneously with a pure cultivation of the bacillus tuberculosis, a hard nodule forms at the seat of inoculation in about ten or fourteen days; this caseates, softens, and forms an ulcer which does not heal. If in such a guinea-pig a second inoculation be made about six weeks after the first, when tuberculosis is fully developed, the local phenomena are different: in a few days a small slough forms and separates, leaving a sore which quickly heals, without infecting the lymphatic glands. Koch next found that inoculation of a pure cultivation, in which the bacilli themselves had been destroyed by prolonged cold or heat, acted in a similar manner. Pure cultivations killed in this way caused little or no general disturbance in healthy guinea-pigs, but only local suppurations. Tuberculous guinea-pigs were, however, killed by very small quantities; whilst, on the other hand, if extremely minute quantities were used, the ulcers at the primary seat of inoculation could be made to heal, the glands to diminish in size, and the disease, if not too far advanced, to become arrested. The next step in the series of experiments consisted in completely separating the dead bacilli from the cultivation, and thus preventing the suppuration which was otherwise produced at the seat of inoculation. Finally, Koch found that the active principle, whatever be its nature, by which these effects are produced could be obtained by making a glycerine extract of pure cultivations of the bacillus. The glycerine extract, which is known as "tuberculin," is a brownish, slightly viscid fluid which contains about one per cent. of the active principle; it is usually diluted with 100 parts of distilled water, to which a $\frac{1}{2}$ per cent. of phenol is added to preserve the fluid. The injections are made beneath the skin of the back by means of a modified Pravaz's hypodermic syringe, which is best rendered aseptic by absolute alcohol. In a healthy adult, or one free from tuberculous disease, the injection of 0.01 cubic centimetre (1 c.c. of the

diluted solution) causes slight pains in the limbs and transient fatigue, with occasionally a slight elevation of temperature. The same dose administered to an adult suffering from any tuberculous disease causes a marked general and local reaction. The general reaction, which usually begins four or five hours after the injection, consists usually of a rigor with a rapid rise of temperature, sometimes reaching 105° — 106° F., with pain in the limbs, coughing, great fatigue and often vomiting. The local reaction, which has been most closely studied in cases of lupus, consists in swelling and redness of the affected area with serous exudation which dries, forming scabs; the neighbouring lymphatic glands often become swollen and tender. These changes, which only affect the living tuberculous tissue, slowly subside, and repeated injections are usually required before the tuberculous tissue is destroyed and no further local reaction is produced. The first dose should be small, such as 0.006 c.c., and the strength may be gradually increased to the maximum (0.01 c.c.); the dose must also be regulated according to the probable amount of tuberculous tissue and its situation. As to the probable mode of action of tuberculin, one fact alone seems certain—that it destroys the living tuberculous tissue and not the tubercle bacilli themselves. It has been suggested by Koch that the fluid contains some extremely irritating substance, which, added to that already produced by the bacilli in the diseased tissues, is sufficient to cause their destruction by a process of coagulation necrosis. The eagerness with which this remedy has been put to the test in every form of tuberculous tissue is altogether without parallel in the history of medical science, but it must be allowed that the experience thus gained does not lead us to hope that the remedy in its present form is likely to be of more than very limited utility. As a means of diagnosing tuberculin may be of service in cases the tuberculous nature of which is suspected; the question being decided by the occurrence of reaction if tubercle be present.

Watson Cheyne has especially studied the effects of the treatment in surgical cases. In the treatment of tuberculous diseases of bones and joints he thinks tuberculin may be of use after operation as a means of aiding the prompt healing of the wound, whilst it may enable the Surgeon to perform less severe and radical operations than he might otherwise do. The best results have been obtained in severe cases of lupus by combining tuberculin with other methods of treatment. Lastly, it may be mentioned that William Hunter has separated three active ingredients from tuberculin—albumoses, alkaloidal substances, and extractives. Hunter has further shown that it is possible by dialysis to separate the albumoses, which exert the remedial action, from the non-albuminous bodies, which possess the fever-producing properties.

It is interesting to note that Liebreich has recorded certain beneficial results in tuberculous cases by the injection of a salt of cantharidin, the active principle of cantharides. In the small doses employed marked serous exudation occurred in the tuberculous tissue, but not from the capillaries of healthy tissues.

The **Local Treatment** of scrofulous affections is generally that of chronic inflammation (p. 229 *et seq.*). Should chronic suppuration occur it must be treated as already described (p. 263). Chronic thickenings left after scrofulous inflammations may be removed by means of lotions containing the iodine of potassium, or the carbonate of potash, applied by means of lint covered with oiled silk: a drachm of each of the salts, with an ounce of spirits of wine to eleven ounces of water, makes an excellent application, which appears often to

be very efficacious. In many cases, frictions with the iodide of lead ointment, or pressure by means of strapping and bandages, will be found the most serviceable means that the Surgeon can adopt.

In the treatment of local tuberculous disease it should be borne in mind that no external application can have any direct influence upon the bacillus. If the organism is to be destroyed it must be by the living cells surrounding it. It is all important, therefore, to remove every possible source of accessory irritation to the affected part. It should be put at perfect rest, protected from external injury and from cold. If the process is very chronic, counter-irritation may probably be of use in external diseases by causing an afflux of blood to the part. Painting with iodine may occasionally be useful in the same way. Under this treatment a large proportion of tuberculous diseases of bones and joints will undergo spontaneous cure by the processes already described (p. 1090). If, in spite of this treatment, the disease continues to advance, the morbid growth should be removed as early and as completely as possible; thus a joint may be excised, or its synovial membrane dissected away, a carious bone scraped, gouged or removed, or a diseased testicle taken away by castration. One object in this is, by removing the local centre, to diminish the risk of general infection. If the disease cannot be removed, as is often the case in lymphatic glands, the caseous mass should be exposed and scraped away as thoroughly as possible with a sharp spoon. The cavity left may often with advantage be forcibly scrubbed with a sponge moistened with some powerful antiseptic. Even if every trace of the disease be not removed, recovery often follows the operation. Every operation on tuberculous tissues should be performed with the strictest antiseptic precautions, as there is every reason to believe that the presence of septic organisms and their products favours rather than hinders the further growth and invasion of the tubercle bacillus. In the treatment of tuberculous ulceration or abscesses, iodoform has been said to exert a specific curative influence, but this is not definitively proved. It cannot be denied, however, that its free use in the wound and externally is attended with very satisfactory results.

The hypodermic injection of carbolic acid, perchloride of mercury, emulsion of iodoform and iodine, has been tried in various forms of local tuberculosis, but not with any uniform success.

The further details of treatment of local tuberculous diseases will be given with the affections of special systems and organs.

Operations in Scrofulous and Tuberculous Cases.—In cases of tuberculous diseases of bones and joints, if the disease is chronic and advancing very slowly, operative interference may be delayed till the effects of simpler measures have been tried. In young children especially we find that very extensive disease may be recovered from under proper constitutional and local treatment without operative interference. If the disease is actively spreading in spite of rest and milder means operative measures become necessary, and with proper antiseptic precautions there need be no fear of unhealthy suppuration occurring in the neighbourhood of the disease. Infection of the operation wound with tubercle is not a common complication, but occasionally a lupoid condition of the scar is met with. After excision of the elbow, the knee, or the bones of the foot and wrist, the disease will sometimes return in the contiguous soft parts to such an extent as to render a second operation necessary; the tissues in the neighbourhood of the cicatrix becoming swollen,

spongy, and infiltrated with a quantity of gelatinous semi-transparent granulation tissue, running into unhealthy suppuration, with fistulous tracts leading through it that cannot be brought to heal. If the disease be but partially removed, local recurrence is naturally not uncommon.

If the patient is suffering from pulmonary phthisis as well as local tuberculous disease of a bone or joint an operation should not be undertaken if it can be avoided, but even in advanced phthisis the patient may survive an amputation for a diseased joint, and even be benefited by it if he previously were suffering much from pain and discharge. If the patient is being exhausted by prolonged suppuration from a tuberculous bone or joint, removal of the source of the mischief, if possible, is the only chance of relief.

ACTINOMYCOSIS.

ACTINOMYCOSIS is a chronic infective disease caused by the invasion of the tissues by a microscopic fungus to which the name of *actinomyces* or *ray fungus* has been given. It was first recognised as a specific disease in cattle by Bollinger in 1877, and in the same year Israel first described its occurrence in man. It was further investigated in 1879 by Ponfick, and subsequently by Moosbrugger, Boström, Crookshank, M'Fadyean and many others.

Pathology.—The disease is characterised both in animals and in man by the formation of tumour-like masses of granulation tissue invading the tissues in which they lie. The fungus can be seen with the naked eye as small yellowish bodies about the size of hemp-seeds, scattered through the granulation tissue. It is the presence of this fungus that sets up the inflammation and causes the formation of the granulation tissue; the large tumour-like masses being formed by the coalescence of numbers of small nodules. In some of these nodules a zone of epithelioid or giant cells may be seen surrounding the fungus, and in others a varying amount of fibrous tissue may be found apparently developed in the granulation tissue furthest removed from the fungus; the changes, indeed, closely resembling those produced by the growth of the tubercle bacillus. After a time, varying from a few weeks to a few months, the granulation tissue round the fungus softens and breaks down into pus. According to Moosbrugger, this occurs only when the diseased tissue becomes infected with the micrococci of suppuration. The abscess thus formed reaches the surface and discharges pus in which the yellow bodies above mentioned can be recognised. As the disease advances new masses of granulation tissue spring up in the neighbourhood of the first, apparently by invasion through the lymphatics.

If one of the small yellow bodies found in the pus or granulation tissue be subjected to microscopic examination, it will be found to consist of a central mass of interwoven threads, and an outer part made up of club-shaped bodies radiating from the centre, giving the whole the appearance of a rosette. In the cases of actinomyces recorded in man, the club-shaped bodies have usually been little developed: there is, however, every reason for supposing that the fungus is identical with that found in cattle. Opinions differ as to the true significance of the clubs, and accordingly as to the real nature of the fungus. According to the older view, which is also supported by the more recent researches of Crookshank, the clubs are reproductive bodies in which spores are formed, the general plan of the fungus being, indeed, that of the higher mould fungi. Boström, however, regards the clubs as evidence of

degeneration and the result of thickening of the outer sheath by which the threads are surrounded. If this view be correct, as indeed seems probable, the organism is more correctly classed with the Schizomycetes or fission fungi.

Boström was the first observer who succeeded in cultivating the organism on artificial culture media, and it is interesting that he used the central network of the fungus and not the clubs, from which to obtain his cultivations. Nutrient agar-agar, blood-serum, and white of egg have been successfully used as culture media, and the disease has been reproduced in calves and rabbits by inoculation with the pure cultivation of the fungus obtained from a case of actinomycosis in man.

Although the disease is common in cattle there is little evidence from recorded cases in man to show that infection occurs directly from them. There is, however, some reason for believing that cereals, and more especially barley, form the usual habitat of the fungus outside the body, and it seems likely that this may be the source from which infection usually occurs.

The mode of entrance of the actinomyces into the body is variable; it probably occurs usually through some breach of continuity of the mucous membrane of the gum or mouth, or by some diseased point such as a carious tooth, or possibly, in some cases, an inflamed tonsil. More rarely, infection occurs through the respiratory tract, or through accidental wounds.

Symptoms in Animals.—In cattle the disease most commonly manifests itself as a local affection of the jaws or tongue. In the lower jaw it attacks first the cancellous tissue, destroying the bone, and reaching the surface in such a way that it was formerly mistaken for some form of sarcoma; this form of the disease is popularly known as a "wen" or "osteo-sarcoma." The affection of the tongue has received the name "wooden tongue;" whilst the so-called "scirrhus cord" in the ox or horse may be the result of inoculation of the spermatic cord at the time of castration. Generalization of the disease may occur.

Symptoms in Man.—The cases that come under the care of the Surgeon commence most commonly as a hard swelling, often painless, attached either to the lower jaw or near it in the submaxillary region. The tumour slowly increases and new centres may appear near it. After some weeks or months it becomes adherent to the skin, softens and bursts, discharging unhealthy curdy pus, in which the yellowish fungoid masses may be recognised. A sinus is then left leading to an unhealthy cavity. When it commences in the upper jaw the sinuses may perforate the cheek. If it spreads backwards towards the spine and pharynx a deep prevertebral abscess may form which may reach down to the mediastinum, and openings may form at the side of the neck leading to deep sinuses. There may be severe fever after the abscesses have opened. The disease has been known to invade the spine, causing caries of the vertebrae.

Other forms of actinomycosis in man have been recorded. Thus in several cases the lung or pleura has been primarily affected, the disease sometimes coming to the surface through the chest-wall, and in other instances extending through the diaphragm into the liver. In a case under the care of Douglas Powell and Godlee at the Brompton Hospital, the disease presented the physical signs and symptoms of an empyema. Exploration, however, showed that the right pleura contained a degenerated semi-solid material containing the

ray fungus in abundance. The boy, who was nine years of age, died after about nine months' illness. At the *post-mortem* examination the most extensive disease was found in the right pleura, from which it had extended through the diaphragm. The right lung was extensively diseased: the left contained scattered nodules, varying in size and having, on section, the "characteristic canary-coloured appearance."

Actinomycosis may occur primarily in the abdominal viscera: thus in at least two cases the first symptoms were those of perityphlitis. In one of these, recorded by W. H. Ransom, it seems probable that the disease began in the vermiform appendix; the case terminated fatally, and in addition to extensive disease in the region of the cæcum, there was a large secondary deposit in the liver. W. B. Ransom was able to diagnose a case by the detection of the spherules of actinomyces in the urine and in the fæces: here it was thought probable that the primary deposit was in the anterior wall of the rectum, and that the prostate and prostatic urethra were secondarily involved. The liver also may be the seat of the primary deposit, and in cases in which the disease becomes generalised, secondary foci may be found in the brain, kidneys, subcutaneous tissue, and other parts.

Diagnosis.—The chief interest of this rare disease to the practical Surgeon consists in the fact that clinically it may closely resemble other more common affections. Thus actinomycosis occurring in the neighbourhood of the jaw may closely simulate a sarcomatous or other malignant growth, or possibly a breaking down syphilitic gumma. We have already seen how, in the chest, the disease may be mistaken for an empyema, whilst the resemblance in its course to a new growth or tuberculous affection of the lung may be very close. Actinomycosis occurring in the abdominal viscera is likely to be confounded with different varieties of new growth and other causes of chronic suppuration. The remarkable tendency of the disease to spread beyond the limits of the organ or structure in which it commences, as, for instance, from the lung through the diaphragm into the liver, has been especially insisted upon by several observers. The only certain means of diagnosis consists in the detection of the fungus with the naked eye or microscope in the discharge or other material obtained from the seat of disease. The careful routine examination of these in all doubtful cases will indeed often materially assist the Surgeon in arriving at a correct opinion.

Treatment.—If the disease is superficial, as when it commences in or near the lower jaw, the tumour must be freely incised, and the unhealthy granulation tissue scraped away with a sharp spoon. This operation is often successful in effecting a cure. In cases of deep-seated disease no surgical interference is likely to be indicated until the disease has gradually worked its way to the surface; free incision, with scraping and drainage, should then be resorted to. The administration of iodide of potassium in full doses has been thought to be beneficial.

CHAPTER XXXVI.

VENEREAL DISEASES.

THE term *Veneral Disease* is used to denote those affections which arise primarily from sexual intercourse, viz., the Local Contagious Chancre, Syphilis, and Gonorrhœa. Hunter believed that all these arose from one poison; but the experiments of Ricord and others conclusively proved that gonorrhœal pus when inoculated never produces a chancre, and the pus of a chancre cannot cause gonorrhœa. Syphilis and the local contagious chancre, were, therefore, clearly separated from gonorrhœa; but for a considerable time these two were still included under the common name of syphilis. Ricord, however, by inoculation showed that the two diseases are not identical. The inoculation of the virus of syphilis infects the whole system, while that of the local contagious chancre is never followed by constitutional symptoms. Each of the diseases—Local Contagious Chancre, Syphilis, and Gonorrhœa—propagates itself, and no other. All these diseases may, however, co-exist in the same person. Thus, we shall have occasion to notice the coincidence, in some cases, of the local chancre with the phenomena of constitutional syphilis. Again, Ricord has pointed out, that a woman may at the same time be affected by gonorrhœa and by chancres on the uterus; and this probably explains those cases in which, after connexion with the same woman, different men have contracted different forms of disease, or even both affections.

It is impossible here to discuss the various views which were formerly held with regard to the supposed relation of the virus of the local contagious sore or soft chancre to that of true syphilis. For this I must refer the reader to special works on venereal diseases. In this chapter will be described—1, the Local Contagious Ulcer or Chancre; and 2, Syphilis; the consideration of Gonorrhœa being reserved till we speak of Diseases of the Urinary Organs.

1. LOCAL CONTAGIOUS ULCER OR CHANCRE.

The **Local Contagious Ulcer, Simple Non-infecting Sore or Soft Chancre**, is a local infective inflammation, produced by the action of a virus which increases in quantity in the affected area. The increase of the poison is supposed to take place by a process analogous to fermentation occurring in the inflammatory exudations. Thus the inoculation of an infinitesimal dose of the poison may result in the formation of a sore from which many drachms of infective pus may be discharged before the process ceases. The intensity of the local action of the poison is such as to cause a progressive destruction of the tissues by ulceration. As a rule it shows but little tendency to diffuse itself amongst the tissues, the area of inflammation beneath and around the ulcerating surface being usually very limited. Occasionally, however, from

causes which are not fully understood, the intensity of the virus is greater : it then extends more deeply, causing more rapid destruction, the dead tissues not being removed by ulceration, but remaining as an adherent pulpy slough. This form is described as the phagedænic or sloughing chancre. The virus of a simple chancre may be taken up by the lymphatics and carried to the nearest lymphatic glands, where it may set up an inflammation of the same character as that at the primary seat of disease. Beyond this it never goes, and although we must suppose that it is possible that it may enter the blood-stream, it certainly produces no general infection under any circumstances. Of the exact nature of the virus we know but little. Chancrous pus is said to lose its activity after drying, or after being kept for some time in capillary tubes. Its infectivity is readily destroyed by alcohol, corrosive sublimate, and many other chemical substances. No specific organism has as yet been shown to be constantly present in the discharges from a chancre.

Ricord and numerous other observers have shown clearly by experiment that pus from a chancre, during its first period, if inoculated into any part of the surface of the body, will produce a specific sore of the same character. After the inoculation has been repeated a certain number of times the individual seems to become insusceptible to the poison, and no chancre follows the introduction of the pus. Boeck states that this occurs usually after three or four months of repeated inoculation, but the time varies in different individuals ; some never acquire an immunity, and in all it is only temporary. No pus that is not chancrous can occasion the specific venereal ulcer.

Whatever the appearances presented by a chancre, there can no longer be any doubt that the disease arises from one kind of virus only : the modifications in the sore depending on its situation, on the constitution of the patient, and occasionally on that of the individual who communicates the infection. That this is so, is evident from the facts that every chancre, when inoculated, reverts to one typical form ; and that, however much chancres may ultimately differ, they all present the same characters during their early stages.

ORIGIN AND PROGRESS.—A chancre is necessarily contracted in most cases during sexual intercourse with a person already contaminated by the disease. It is almost invariably met with on the genital organs, being much more rare on other parts, such as the fingers or face, than the primary sore of syphilis. The reason of this is that in the simple chancre the discharge from the sore is the only source of infection, while in syphilis, the secretions from the mouth, the discharges from secondary syphilitic sores, and even the blood, possess infective properties. In some cases, the disorder is contracted from the contact of filthy clothes or dirty utensils with the person ; and not uncommonly, it is said, chancres are contracted in public water-closets. Although the latter mode of infection is not impossible, it should be received with doubt, as it is an explanation not uncommonly adopted by those who desire to account for the consequences of an act of immorality, in a way that does not expose them to reproof. In speaking of the mode of propagation of syphilis, Wiseman says : " It is frequent to mention other secondary ways of the propagation of it : as lying in the same bed with an infected person, lying in the same sheets after them, or wearing their cloaths. . . . Drinking with one so diseased, or sitting on the close-stool after them, are likewise numbered among the causes of infection. These are all such convenient excuses for the more shie and coy patients, who will not otherwise be brought to confess their

distempers, that it is pity to discountenance them" (Wiseman: "Several Chirurgical Treatises. Of Lues Venerea," London, 1676).

The soft chancre usually commences with a small excoriation, which appears to have been directly inoculated with the specific poison. In other cases, though more rarely, it may be seen at first in the shape of a small vesicle or pustule, which speedily breaks, leaving an ulcer of a specific character in its site. Very generally, however, this pustule escapes observation, and the disease is presented in the first instance as an ulcer. The chancreous ulcer seldom makes its appearance until three to five days after connexion. In some cases, however, I have observed it, evidently from the infection of a fissure or crack, on the day following impure intercourse; and in rare instances, its appearance may be delayed a few days longer than the time which has been mentioned.

The progress of a chancre that has been artificially inoculated on any part of the cutaneous surface is as follows, and its study will serve to elucidate what takes place in other circumstances. During the first twenty-four hours after the introduction of the specific pus into the skin on the point of a lancet, we find that some inflammation is set up around the puncture, which becomes hot, red, and itchy. About the third or fourth day, a pointed pustule is produced, which is at first deep-set, but becomes on the following day more superficial, with some depression in the centre, resembling rather closely a small-pox pustule. On the fifth day the pustule bursts; and on the sixth it has usually dried, forming a small round scab, which comes off, leaving an ulcer which presents the typical characters of a true chancre, being circular and depressed, with an irregular "worm-eaten" surface of a foul greyish colour, which cannot be cleansed, sharp-cut edges, a base slightly indurated by inflammation, and an angry-looking red areola around it. Such induration as may be present is not sharply defined, but fades away into the surrounding healthy tissues. This is the typical chancre, and these are the appearances that every true venereal non-syphilitic sore on the skin will present about the fifth or sixth day after inoculation; from this time it may diverge more or less completely from these characters, but will yet, if inoculated at any time during the poisonous stage, produce an ulcer that will run the specific course up to the same period, after which it may in its turn again deviate into one or other of the unusual forms that chancres occasionally assume.

VARIETIES.—These have been described under various denominations by the numerous writers on these affections. The following classification will include them all:—1, the Simple or Soft Chancre, or Chancreous Excoriation; 2, the Sloughing Chancre; and 3, the Phagedænic Chancre. The particular form of the sore is in each case determined by its situation, and the constitution of the patient or that of the individual furnishing the contagion.

1. **Simple or Soft Chancre, or Chancreous Excoriation**, is the most common form of the disease. It consists of one or more small sores, somewhat circular in shape, of a very shallow character, resembling rather an abrasion, with sharp-cut edges, sometimes slightly undermined, and having an irregular, spongy surface, of a tawny greyish or yellowish colour, with a narrow red areola around the edge; it is in many cases attended with much heat and itching. These sores are usually seated on the cleft under the corona glandis, or about the glans, the whole of which may be studded with them. In fact, one peculiarity of this chancre is its tendency to multiplication on the con-

tigious structures. In other cases, the sores invade the frænum, which may be perforated; or they may occupy the mucous surface of the prepuce. The absence of induration is a marked feature of these sores; the only exception being that the base of an inflamed sore, especially on the frænum, may be slightly hardened.

The excoriated chancres not unfrequently present somewhat varying appearances. In some cases their surface becomes covered with large fungous granulations; hence these are termed *fungating sores*. In other instances they are very irritable, becoming exceedingly sensitive, with a tendency to spread, and having a dusky red areola around them. These chancres are very frequently attended by much general inflammation of the penis; the organ being red and swollen from subcutaneous œdema, and usually in a state of phimosis, with much purulent discharge from between the prepuce and the glans.

2. Sloughing Chancre.—This may be looked upon as a gangrenous inflammation of a non-infecting sore. It is usually the result of want of cleanliness, and of the confinement of the specific pus under a long foreskin. It is most likely to occur in weak and debilitated subjects, but it is also met with in healthy young men. The penis becomes red, greatly swollen, and somewhat brawny, the prepuce cannot be retracted, and very offensive pus, often stained with blood, escapes from beneath it. If it be not relieved, a dusky spot soon makes its appearance on one side of the prepuce; this rapidly extends, thick black pultaceous sloughs appear, and thus one side of the foreskin may be destroyed, or a round aperture may form in it, through which the glans projects, whilst the swollen and inflamed extremity of the prepuce hangs down behind it, giving the organ a very remarkable, and, at first sight, somewhat puzzling appearance. As soon as the pent-up discharges find exit in this way, the intensity of the inflammation is somewhat relieved. In other cases the whole foreskin may slough, and the glans be deeply implicated, and even the corpora cavernosa denuded. Severe hæmorrhage from the dorsal artery or the artery of the frænum may take place. Not uncommonly the pus, being unable to find exit from the orifice of the swollen prepuce, bursts through the reflection of the foreskin at the corona, and burrows beneath the skin of the penis for some distance superficial to the corpora cavernosa. I have seen it extending in this way for a distance equal to the two first joints of the finger. In other cases, abscesses may form on the penis along the line of the dorsal lymphatics. Lastly, when the sore is near the frænum, it may perforate the urethra, leaving a fistulous opening which it may be impossible to close. After the separation of the sloughs, healthy granulations spring up, the sore loses its specific character, and cicatrization advances rapidly.

3. The Phagedænic Chancre.—This differs from the sloughing chancre in not being evidently due to want of cleanliness. It attacks sores that can be freely exposed, as well as those that are concealed beneath a long foreskin, and if occurring in the latter condition does not show the same tendency to cease extending as soon as the retention of the discharges and inflammatory tension are relieved by slitting up the foreskin. The sore may assume the phagedænic character from the very first, or this may be set up at some period of its course. Phagedæna affects both the simple chancre and the true syphilitic sore. In fact some Surgeons, especially Jonathan Hutchinson, believe that it is invariably syphilitic, either attacking a primary syphilitic sore or a

soft sore in a person already suffering from syphilis, and Berkeley Hill states that a considerable proportion of cases are followed by secondary symptoms. As soon as the phagedænic ulceration sets in, the characteristic appearances of the sore are lost, so that it is not possible to say what form it had originally assumed.

The phagedænic chancre is characterized by a tendency to erosion, with extensive destruction of the parts that it invades. The progress of the sore varies greatly in its rapidity. In some cases it advances slowly and irregularly, healing at one part while spreading at another; thus forming the *serpiginous sore*. In other cases the advance is extremely rapid. In men the whole thickness of the penis may be destroyed for some distance, and in women the recto-vaginal septum may be perforated. Between these forms every variety may be met with. Wallace has divided phagedænic sores into three varieties: those *without slough*, those *with white slough*, and those *with black slough*. This classification appears to me to be a useful and practical one.

The *phagedænic chancre without slough* is a truly eroding ulcer, spreading with sharply-cut edges, attended with slight inflammation, and with moderate activity of progress; it is commonly observed about the frenum and under part of the glans, and very frequently hollows out and destroys the organ in this situation to a considerable extent. When reaching the skin, it often assumes the *serpiginous* form.

In the *phagedænic chancre with white slough*, we find an irregular eroding ulcer, with a thin margin of white slough situated at the junction of the dead and living structures; that which covers the surface of the sore having usually become darkened by exposure to air, to dressings, and to secretions.

The *phagedænic chancre with black slough* differs but little from the last, except in the colour of the slough, which may be in a great measure accidental, and in its tendency to somewhat rapid extension.

Phagedænic sores are most commonly met with in persons suffering from debility from want of food, or after exhausting diseases, and in scrofulous subjects. Chronic Bright's disease and chronic alcoholism may also be mentioned as predisposing causes. Chancres are also very apt to assume this form amongst troops exhausted by the hardships of a campaign. Phagedænic sores when spreading rapidly are often accompanied by much pain and constitutional disturbance.

SITUATION.—As simple chancres almost invariably result from connexion with persons suffering from sores of similar nature, they commonly occur on the genital organs. Berkeley Hill states that 99 per cent. are in this situation. Accidental inoculations on the fingers of medical men or on the face are extremely rare, in fact almost unknown. On the genital organs in the **male** they may be met with in various situations. They are by far most commonly seated in the angle formed between the glans and the prepuce; the situation next in order of frequency is the orifice or the inner surface of the prepuce, next the frenum, then the glans, more rarely the orifice of the urethra in some cases extending a short way down the canal, and lastly the skin of the body of the penis. Those about the frenum are often sloughy and irritable, have a great tendency to perforate or destroy this membrane, and are more frequently followed by hæmorrhage or bubo than any of the other varieties of the disease.

In **women**, chancres are most commonly situated on the external organs of generation, usually just inside the fourchette or labia minora, very rarely indeed on the lining membrane of the vagina, but sometimes on the cervix or os uteri; hence it is impossible ever to pronounce a woman free from chancre without examining these parts by means of the speculum. When situated upon the external organs, they are not unfrequently concealed between the rugæ of the mucous membrane. In these cases, their presence may sometimes be detected by the labia being swollen and œdematous from the irritation they produce; œdema of one labium only is especially suggestive of the existence of a sore.

Chancres may also form on other parts where they have been accidentally or purposely inoculated. Thus in 1839 I saw in Ricord's wards, a man, labouring under *eczema of the legs*, in whom the cutaneous disease had been converted into a series of immense chancres by accidental inoculation from a sore on the penis.

DIAGNOSIS.—The diagnosis of chancre is usually not difficult, the peculiar character of the sore enabling the Surgeon to recognize it in all its forms. In some instances, however, it is by no means easy to say positively whether an ulcer on the penis be chancrous or not. It is especially difficult to distinguish some forms of excoriated chancre from herpes on the prepuce or glans, or from those slight excoriations that many men habitually contract after a somewhat impure connexion; so, also, the wound resulting from a ruptured frænum often presents a suspicious appearance.

Herpes of the prepuce is recognized by the closely-set crop of small vesicles with some redness round them. Herpes may become inoculated with the poison of a chancre. Pustules then quickly form in the place of the vesicles, and burst, leaving a number of small sores which soon coalesce. A simple excoriation, or the wound from a ruptured frænum, can only be distinguished from a chancre by watching the sore for a few days; it is better, however, not to wait till the characteristic appearances show themselves, but to treat every doubtful case as a soft chancre. When the prepuce is in a state of inflammatory phimosis, it is always extremely difficult to determine without slitting up the foreskin whether there be chancres under it, or whether the discharge be due to simple balanoposthitis or gonorrhœa. Sometimes, however, the inflammatory induration round the sores can be felt through the swollen foreskin. The diagnosis of the simple non-infecting chancre from the primary syphilitic sore will be described with the latter affection.

TREATMENT OF NON-INFECTING OR SOFT CHANCRES.—Until the simple non-infecting chancre was clearly distinguished from the true syphilitic sore much difference of opinion and practice prevailed. It is now, however, fully recognized that the simple chancre, being a local disease, and occurring in the great majority of cases in persons otherwise in perfect health, requires no special constitutional treatment. The gangrenous and phagedenic forms, on the other hand, being often accompanied by serious constitutional disturbance, or depending partly on a debilitated state of health, require constitutional treatment as well as local.

Local Treatment.—This has for its object the destruction of the specific character of the sore.

With a view of modifying the specific character of the sore, there is no application so efficacious as *iodoform*. It will usually cure a simple soft

chancre in a week or ten days. The crystalline, and not the precipitated, iodoform should be used, as the latter sometimes causes irritation. It is applied by simply dusting a small quantity of the powder on the sore twice a day, and afterwards covering it with a piece of cotton-wool, either simple or impregnated with iodoform. At each dressing the sore must be carefully washed with tepid water. The only objection to this treatment is the powerful smell of the drug. If the pure iodoform is used, it is better to apply it before dressing in the morning and after undressing at night, to avoid any chance of its falling upon the clothes. Berkeley Hill recommended the use of "iodo-carbon paste," composed of iodoform in fine powder, 3j; wood charcoal, 3ij; glycerine of starch, 3ij; glycerine, 5j; oil of lavender, ℥xx; or a solution of iodoform in eucalyptus oil: iodoform, ʒiss; oil of eucalyptus, 3j; olive oil, ʒv. The smell of iodoform may also be lessened by the addition of coumarine, obtained from the Tonquin bean in the proportion of 1 in 50, or of finely-ground coffee 1 in 3. Iodol, which has no unpleasant smell, may be used instead of iodoform, but it is very expensive; it should be lightly dusted over the sore, and then a piece of thin lint soaked in lead lotion applied. If however the odour of iodoform is not a very great objection, there is nothing so efficient as the pure crystals.

The treatment of simple soft sores with strong caustics is not to be recommended. In some cases, however, in which the sore begins to spread rapidly, with a tendency to become phagedænic, Ricord's paste may be very useful. This consists of sulphuric acid and powdered charcoal mixed so as to form a thick paste. The sore should be washed and a layer of the paste applied with a match. The serous discharge should be absorbed by a dry wool dressing, and on about the third day the slough will usually separate in a hot bath, a healthy surface being left. This treatment is, however, very rarely required.

If the healing sore be weak and fungating, an astringent lotion, such as the following, will be found most useful: R Tannin, gr. xx; Tinct. lavandulæ comp. ʒij; Vini rubri, ʒiv. Or a solution of sulphate of copper may be applied, and the sore touched from time to time with nitrate of silver.

In using lotions to any form of chancre, care should always be taken to keep a piece of lint soaked in the fluid constantly applied between the prepuce and the glans, and, in women, between the labia: for, unless this be done, the contact of the inflamed mucous surfaces with one another will tend to keep up the ulceration.

These are the means that are generally most useful in *Simple Chancres*. In some cases, however, inflammation of the sore, or peculiarities in its situation, demand modifications of the treatment.

If there be much inflammation about the sore and the prepuce, this must first be subdued by the application of wet dressing, or of lead and spirit lotion. When this is removed, if the sore have not lost its specific character, iodoform should be applied in the usual way.

Should there be phimosis with discharge of pus from under the tightened prepuce, this must be slit up, so as to expose the subjacent chancre. It is better at the same time to complete the operation of circumcision by removing the foreskin with the knife or scissors after it has been slit up along its dorsal aspect. Otherwise when it heals an inconvenient pendulous flap of skin will be left, requiring subsequent removal. In order to avoid infection of the raw surface from the chancre, the operation may be thus performed. The fore-

skin is first slit up along its dorsum; the surface of the glans and the prepuce are then thoroughly cleaned with carbolic lotion (1 in 20), and the sore wiped out with chloride of zinc solution (40 grs. to ʒj). The surface of the sore may be rubbed forcibly with a dossil of lint soaked in this solution, to remove any adherent slough. Everything being thus thoroughly cleaned the circumcision may be completed; after ligaturing any bleeding vessels, the parts must be thoroughly sprinkled with iodoform and wrapped in iodoform wool. By these means infection of the wound can generally be avoided. There should be no delay in performing the operation. When pus comes from under a long foreskin and its source cannot be seen the patient should always be advised to submit to circumcision, unless there is some very marked improvement, following the application of fomentations and the injection of antiseptic solutions, by the third day at the latest. If the pus is offensive the operation should be performed at once, as it probably arises from a sloughing chancre.

If the chancres be situated round the orifice of an elongated and tight prepuce, circumcision is the best means of removing the disease and the inconvenience at the same time. The precautions just described must be adopted to prevent infection of the cut surface.

In the **Sloughing Chancre**, when the prepuce is greatly swollen, in a state of inflammatory phimosis, and of a deep red or purplish colour, with threatening of extensive gangrene, a director should be passed between it and the glans penis, and the swollen prepuce slit up. In this way tension is removed, and the sloughing arrested. The chancre when exposed will be found to be covered with a pulpy grey tenacious slough. This is best removed by forcibly rubbing the surface with a piece of sponge or lint soaked in a solution of chloride of zinc (gr. 40 to ʒj), after which iodoform must be applied. The application of nitric acid is seldom necessary. If the state of the parts is such as to admit of it, the operation of circumcision may be at once completed. If there be much sloughing of the prepuce it is better to delay the completion of the operation till the sloughs have separated, when perhaps it may be found unnecessary. During the separation of the sloughs the penis should be wrapped in lint soaked in some warm antiseptic solution, as boric acid or permanganate of potash. The patient should sit in a hot hip-bath (98° F.), to which some solution of permanganate of potash (Condy's fluid), or some boric acid, may be added, for half an hour or more twice a day. A little hæmorrhage need cause no anxiety, and is usually easily arrested by dry cotton-wool and pressure, but if it be profuse, the patient should be put under chloroform, and the actual cantery freely applied. This not only stops the bleeding, but arrests the progress of the sloughing. When once the chancre is healthily granulating, it must be dressed in the same way as any common ulcer.

The local treatment of the **Phagedænic Chancre** depends on the form it assumes. If it be the eroding ulcer without slough, iodoform will often arrest it, but its action is by no means certain. If it fails, perchloride of mercury (gr. ij to ʒj), diluted if it is too painful, is often of great service. Should this fail, the strong nitric acid may be applied, after which it may be dressed with a dilute nitric acid and opium lotion. If the phagedænic process be spreading rapidly with a white or black slough, the sore must be treated like hospital gangrene. The slough must be scraped away, and fuming nitric acid, or an

bad cases the actual canter, applied freely, after which iodoform and boric acid fomentations, or lint soaked in the nitric acid and opium lotion, may be used, the caustic being applied again whenever there is any tendency to extension of the disease. In obstinate cases of phagedænic chancre Hebra in Germany and Hutchinson in this country have recommended that the patient should be immersed for ten hours daily in a bath of hot water, maintained constantly at a temperature of 98° F. The bath must be repeated daily till healing is distinctly taking place.

Constitutional Treatment.—The **Simple, Soft, or Excoriated** sore requires no constitutional treatment beyond attention to the ordinary rules of health.

In the **Sloughing Chancre** it frequently happens that the mischief is entirely due to local causes, such as the accumulation of discharge under a long foreskin. In these cases the constitutional disturbance, which may be severe, will subside as soon as the local condition is relieved. In other cases the sloughing is due partly to local causes and partly to a depressed state of health. In these ammonia and bark, good nourishment and abundant stimulants, will be required. Opium may be necessary to relieve pain and irritability, and eventually the patient's strength may be supported by iron and quinine. In a sloughing chancre mercury is never required.

In the constitutional treatment of **Phagedænic Chancre** it must be borne in mind that the patient is usually in a debilitated condition before the invasion of the disease: consequently tonics, such as bark or iron, with good food and stimulants, are frequently required, together with opiates to allay pain and procure rest. The preparations of iron, especially the ammonio-citrate and the tartrate, either alone or in combination with sarsaparilla, are especially useful in these cases. It has before been stated that phagedænic ulceration may start from a true syphilitic sore or occur in a patient suffering from constitutional syphilis. Mercury is, however, often inadmissible, and if given indiscriminately may do much harm in many cases by further debilitating the patient. On the other hand, some sores which have resisted treatment for a long time may rapidly improve if mercury be carefully administered in small doses. Wallace stated that its beneficial effects are most marked in those cases which are characterized by the presence of a white slough. It is best given as the perchloride, in doses of $\frac{1}{2}$ to $\frac{1}{4}$ of a grain with rincture and decoction of cinchona. It is in these cases also that the local application of perchloride, in the strength of from one to two grains to the ounce of water, is so frequently useful.

CONSECUTIVE SYMPTOMS OF THE LOCAL CONTAGIOUS ULCER.—Chancres are not unfrequently followed by a series of affections which may be termed *consecutive*, depending as they do upon the primary disease, but being local in their character, and presenting no evidence of constitutional infection. These consecutive symptoms are three in number: viz., Contraction of the Cicatrix of the Chancre, Bubo, and Warts.

Contracted Cicatrices.—Most excoriated chancres are healed without any marked cicatrix being left; but, in the phagedænic and the sloughing chancres, there is always loss of substance, often to a considerable extent, and consequently a depressed scar. If the ulceration happens to have involved the orifice of the urethra a very intractable stricture may result, which may subsequently necessitate division of the scar for its relief. The situations of all venereal ulcers should be watched for some time, however readily the sore

may have healed; for the virus of syphilis may have been introduced with that of the simple chancre, and if this have happened, induration will commence at the point of contagion, when the time of incubation has elapsed. Thus a month or six weeks should pass away after the suspicious connexion, before the Surgeon pronounces the patient safe from syphilis.

Bubo.—By bubo is meant an inflammatory enlargement, frequently terminating in suppuration of the lymphatic glands which receive the lymph-stream from the inoculated surface. A bubo, though generally produced in the groin by absorption of irritating matter from chancres on the penis, may occur elsewhere—as for instance, in the axilla, in cases of chancre on the finger; in the submaxillary region, if the disease occur on the lip. The enlargements of the inguinal or other lymphatic glands that occur in cases of venereal chancre, may be either simple or specific. In the former the irritating material may be derived from concomitant inflammation about the sore, as when balanoposthitis or phimosis is present, without the specific virus of the soft chancre reaching the gland. In serofulous subjects this readily takes place. In these cases the bubo is termed *sympathetic*, and the affection must be considered as simple inflammation. It may speedily subside without the formation of pus, but should suppuration take place the pus possesses no specific properties, and is not inoculable. It constitutes in fact a simple glandular abscess and presents nothing in any way peculiar. Indeed, in a very large proportion of cases of simple chancre, there is some slight enlargement with tenderness of the glands above Poupart's ligament, accompanied by some degree of stiffness and dragging pain. The liability to irritation and inflammation of the glands in the groin is greatly increased by the patient walking about or otherwise exerting himself. But I do not think that causes such as these influence the occurrence of the other and more troublesome affection of the lymphatic glands, namely the *virulent bubo*, which appears to originate from direct absorption of the specific poison of the chancre; so that we may consider with Ricord that a virulent bubo is, properly speaking, a chancre of a lymphatic gland, differing only in seat from that which is situated on the surface of the body. Ricord has observed, and I have often had an opportunity of testing the correctness of this observation, that the pus of a virulent bubo is as readily inoculable as that of an ordinary chancre. This kind of bubo, then, may be considered as a *specific abscess*, at first limited to the gland, but subsequently infecting the surrounding tissues. Ricord also pointed out that in some cases suppuration takes place round the affected gland without infection of the tissues by the specific pus. Thus if a virulent bubo be carefully opened a cavity is sometimes exposed in which the gland can be seen partially separated by pus from the surrounding tissues. Inoculations made with the pus surrounding the gland may fail, but if the incision be carried further into the gland itself a second cavity is found containing inoculable pus. If this condition be met with, infection may be prevented by scooping the gland out entire without opening into it. When once a gland has become virulently infected, it is probable that no treatment can prevent suppuration.

Usually only one or two glands suppurate, although several may be enlarged; and very commonly the disease is confined to one groin though both may be affected, more particularly if the chancre be situated on the *frænum*.

In the early stages it is impossible to distinguish a sympathetic from a virulent bubo. The glands become swollen and tender; at first they are not adherent to the skin, and their form and outline can be clearly recognized. As soon as the inflammation extends to the tissue outside the capsule, the glands become lost in the surrounding inflammatory exudation. The swelling is at first brawny and hard, but it soon becomes softer and boggy, after which distinct fluctuation becomes perceptible. The skin, at first red, becomes dusky and purple, and if the case be left to nature, it is frequently extensively undermined before the bubo bursts. If the bubo be simple, the cavity presents nothing differing from that of an ordinary abscess. If it be virulent, its walls are ragged and sloughy-looking, and instead of healing, the sore may spread, with all the characteristics of a chancre.

Bubo most commonly occurs during the second or third week after the first appearance of the chancre, but may happen at an earlier or at a later period, even after the chancre itself has healed.

A rare form of bubo is that which forms within the abdomen in the lymphatic glands in this situation. It is a very dangerous variety, and may prove fatal by rupture into the peritoneum and consequent peritonitis.

Primary Bubo.—The French Surgeons have described a form of bubo which they call *bubon d'emblée* or *primary bubo*; this is said to occur from the direct absorption of the specific poison, without the previous formation of a chancre.

Only one case apparently of this kind has fallen under my observation, but I am not yet fully convinced that this suggested mode of origin is the true one. A young man was admitted into the Hospital with a rather large abscess in the groin. He denied ever having had any venereal disease, though he admitted having had intercourse with a woman of the town. On examining the penis, no chancre, abrasion, or cicatrix could be discerned. The abscess was opened, and two ounces of rather bloody and very thick pus were let out: no enlarged glands could be seen. For the sake of experiment the pus was inoculated into the left thigh, and two distinct and well-marked pustules were produced. That such an effect can be obtained by matter of very irritating character without any venereal origin, is shown by the experiments of several Surgeons who have succeeded in inoculating matter from itch and impetigo contagiosa; hence it must not be concluded that in this case the bubo was consequent on the direct absorption of venereal matter along the lymphatics. In fact, the proof of the existence of this form of bubo is far from satisfactory. It frequently happens that small excoriated chancres heal in a few days, before which time, however, the inguinal glands have become irritated and enlarged; and, as the enlargement of the glands goes on after the healing of the chancre, a bubo may be formed when all trace of its primary source has entirely disappeared.

Creeping Bubo.—In some cases a virulent bubo, as has been well shown by Solly, assumes a tendency to creep or spread over the neighbouring integument, extending in this way a considerable distance down the thigh, upon the abdomen, or over the ilium. This *creeping bubo* is characterized by the peculiar semicircular or horse-shoe shape that the sore assumes, and by its tendency to cicatrize at one margin, whilst it slowly extends at the other; the cicatrix always being thin, blue, and weak, closely resembling that of a burn.

After a bubo has disappeared, a good deal of induration may be left in the

may have healed; for the virus of syphilis may have been introduced with that of the simple chancre, and if this have happened, induration will commence at the point of contagion, when the time of incubation has elapsed. Thus a month or six weeks should pass away after the suspicious connexion, before the Surgeon pronounces the patient safe from syphilis.

Bubo.—By bubo is meant an inflammatory enlargement, frequently terminating in suppuration of the lymphatic glands which receive the lymph-stream from the inoculated surface. A bubo, though generally produced in the groin by absorption of irritating matter from chancres on the penis, may occur elsewhere—as for instance, in the axilla, in cases of chancre on the finger; in the submaxillary region, if the disease occur on the lip. The enlargements of the inguinal or other lymphatic glands that occur in cases of venereal chancre may be either simple or specific. In the former the irritating material may be derived from concomitant inflammation about the sore, as when balanoposthitis or phimosis is present, without the specific virus of the soft chancre reaching the gland. In scrofulous subjects this readily takes place. In these cases the bubo is termed *sympathetic*, and the affection must be considered as simple inflammation. It may speedily subside without the formation of pus, but should suppuration take place the pus possesses no specific properties, and is not inoculable. It constitutes in fact a simple glandular abscess and presents nothing in any way peculiar. Indeed, in a very large proportion of cases of simple chancre, there is some slight enlargement with tenderness of the glands above Poupart's ligament, accompanied by some degree of stiffness and dragging pain. The liability to irritation and inflammation of the glands in the groin is greatly increased by the patient walking about or otherwise exerting himself. But I do not think that causes such as these influence the occurrence of the other and more troublesome affection of the lymphatic glands, namely the *virulent bubo*, which appears to originate from direct absorption of the specific poison of the chancre; so that we may consider with Ricord that a virulent bubo is, properly speaking, a chancre of a lymphatic gland, differing only in seat from that which is situated on the surface of the body. Ricord has observed, and I have often had an opportunity of testing the correctness of this observation, that the pus of a virulent bubo is as readily inoculable as that of an ordinary chancre. This kind of bubo, then, may be considered as a *specific abscess*, at first limited to the gland, but subsequently infecting the surrounding tissues. Ricord also pointed out that in some cases suppuration takes place round the affected gland without infection of the tissues by the specific pus. Thus if a virulent bubo be carefully opened a cavity is sometimes exposed in which the gland can be seen partially separated by pus from the surrounding tissues. Inoculations made with the pus surrounding the gland may fail, but if the incision be carried further into the gland itself a second cavity is found containing inoculable pus. If this condition be met with, infection may be prevented by scooping the gland out entire without opening into it. When once a gland has become virulently infected, it is probable that no treatment can prevent suppuration.

Usually only one or two glands suppurate, although several may be enlarged; and very commonly the disease is confined to one groin though both may be affected, more particularly if the chancre be situated on the *frænum*.

In the early stages it is impossible to distinguish a sympathetic from a virulent bubo. The glands become swollen and tender; at first they are not adherent to the skin, and their form and outline can be clearly recognized. As soon as the inflammation extends to the tissue outside the capsule, the glands become lost in the surrounding inflammatory exudation. The swelling is at first brawny and hard, but it soon becomes softer and boggy, after which distinct fluctuation becomes perceptible. The skin, at first red, becomes dusky and purple, and if the case be left to nature, it is frequently extensively undermined before the bubo bursts. If the bubo be simple, the cavity presents nothing differing from that of an ordinary abscess. If it be virulent, its walls are ragged and sloughy-looking, and instead of healing, the sore may spread, with all the characteristics of a chancre.

Bubo most commonly occurs during the second or third week after the first appearance of the chancre, but may happen at an earlier or at a later period, even after the chancre itself has healed.

A rare form of bubo is that which forms within the abdomen in the lymphatic glands in this situation. It is a very dangerous variety, and may prove fatal by rupture into the peritoneum and consequent peritonitis.

Primary Bubo.—The French Surgeons have described a form of bubo which they call *bubon d'emblée* or *primary bubo*; this is said to occur from the direct absorption of the specific poison, without the previous formation of a chancre.

Only one case apparently of this kind has fallen under my observation, but I am not yet fully convinced that this suggested mode of origin is the true one. A young man was admitted into the Hospital with a rather large abscess in the groin. He denied ever having had any venereal disease, though he admitted having had intercourse with a woman of the town. On examining the penis, no chancre, abrasion, or cicatrix could be discerned. The abscess was opened, and two ounces of rather bloody and very thick pus were let out: no enlarged glands could be seen. For the sake of experiment the pus was inoculated into the left thigh, and two distinct and well-marked pustules were produced. That such an effect can be obtained by matter of very irritating character without any venereal origin, is shown by the experiments of several Surgeons who have succeeded in inoculating matter from itch and impetigo contagiosa; hence it must not be concluded that in this case the bubo was consequent on the direct absorption of venereal matter along the lymphatics. In fact, the proof of the existence of this form of bubo is far from satisfactory. It frequently happens that small excoriated chancres heal in a few days, before which time, however, the inguinal glands have become irritated and enlarged; and, as the enlargement of the glands goes on after the healing of the chancre, a bubo may be formed when all trace of its primary source has entirely disappeared.

Creeping Bubo.—In some cases a virulent bubo, as has been well shown by Solly, assumes a tendency to creep or spread over the neighbouring integument, extending in this way a considerable distance down the thigh, upon the abdomen, or over the ilium. This *creeping bubo* is characterized by the peculiar semicircular or horse-shoe shape that the sore assumes, and by its tendency to cicatrize at one margin, whilst it slowly extends at the other; the cicatrix always being thin, blue, and weak, closely resembling that of a burn.

After a bubo has disappeared, a good deal of induration may be left in the

glands of the groin, perhaps with matting together of the surrounding areolar tissue; and this induration may continue for years, or even for the remainder of life.

The **Treatment** of bubo consists, in the first instance, in endeavouring to prevent the occurrence of suppuration; and should pus form, in letting it out.

The *Preventive Treatment* of bubo consists in perfect rest of the part, and the application of leeches and of cold lead lotions. In reference to the application of leeches, there is a practical point that requires attention—viz., that the leech-bites may become infected by the chancreous pus, and thus converted into a number of new chancres. This accident is best guarded against by covering the bites with collodion and plaster.

If there be much pain, and if the skin be already reddened, hot fomentations, and the application of equal parts of extract of belladonna and glycerine, will offer the best chance of arresting the progress of the inflammation.

If the bubo be indolent, with but little tendency to suppuration, the application of blisters or tincture of iodine may be of service. Berkeley Hill states that steady pressure by means of a pad of cotton-wool and an elastic bandage may sometimes produce absorption. The application of lint soaked in a lead lotion containing about two drachms of the solution of the subacetate and one ounce of spirit to half a pint of water has been said to promote resolution.

If, notwithstanding our endeavours to prevent suppuration, matter form within or around the gland, as evinced by the swelling becoming soft, boggy, and inflamed, a free opening should be made. This should, as a rule, be parallel to Poupart's ligament, but if a vertical incision would lay the cavity open more perfectly, there is no objection to adopting it. The incision should be made early, before the surrounding skin has been undermined and thinned. If this should have happened it may be necessary to cut it away with scissors, before healing will take place.

After the bubo has been opened it should be dressed from the bottom, either with salicylic or iodoform wool or lint soaked in carbolic oil (1 in 100), or some such simple application.

If the cavity presents a chancreous appearance, being irregular and sloughy, with elevated and angry red edges, it should be treated by the free application of iodoform in the same way as for the original sore. If on opening the bubo a gland can be seen projecting into the cavity, attached only by one side to the wall of the abscess, this is best scooped out either with the finger-nail or the handle of the scalpel, otherwise it is apt to keep up the suppuration and delay healing. Sometimes, even after the bubo has been opened, the pus may burrow in various directions. Such cases are best treated by laying open the sinuses freely to the very end with a probe-pointed bistoury.

Zeissl opens the bubo by a number of small punctures with a tenotomy knife, after which lint soaked in lead lotion (*Liquor Plumb. Subacetatis*, 3ss., Rectified Spirit, 3 j, water, to O j), may be kept constantly applied. By this means he says that scarring can often be avoided.

Should sloughing or phagedenic ulceration commence in an open bubo, extensive destruction of tissue may ensue, and even fatal hæmorrhage from the femoral artery has been known to occur. The sore must be treated in the same way as the sloughing or phagedenic chancre. The application of nitro

acid is occasionally necessary. If there be any signs of syphilis the cautious administration of mercury may be required.

During the treatment of a suppurating bubo the patient should, if possible, be kept at rest till the sore is superficial. Movement greatly delays healing, and in some cases a splint is required to fix the thigh.

Venereal Warts.—Warts occur frequently round or on the scar of a chancre, independently of any constitutional affection, but merely from simple continued irritation of the muco-cutaneous surfaces. They differ in no respect from those which frequently follow gonorrhoea. They commonly occur on the prepuce or glans, and are especially apt to be situated in the angle between these parts: they are of a red colour, very vascular, and, if left without interference, may increase immensely in size and number, distending the prepuce, and giving a clubbed appearance to the penis; there is then always phimosis, and the tension of the prepuce may be such that ulceration may take place in it, allowing a protrusion of these growths through an aperture in its side. These warts are occasionally met with on the labia, forming large, irregular, cauliflower-looking masses. The *Treatment* consists in the early stage when the warts are small, in the application of salicylic collodion (p. 1033), under which they usually quickly disappear; or they may be carefully painted with the strong liquor plumbi, or with liquor sodii ethylatis. When they have reached a larger size the prepuce must be laid open unless the warts are so small that the glans can be readily exposed by drawing the foreskin back. The warts may then be pared off with scissors, and the part from which they grow touched with nitrate of silver. Even after this they are very apt to recur, especially under a long, moist foreskin. In such a case careful attention to cleanliness and the use of a powder of oxide of zinc and starch or the application of an ointment composed of vaseline, with about one-tenth part of extract of belladonna added to it, will usually cure the tendency to recurrence. If these measures fail, circumcision may be necessary. In women, warts must be treated in the same way; but if they are of great size, Paquelin's cautery or the galvano-cautery should be used in removing them, to avoid loss of blood.

II.—SYPHILIS.

Syphilis is a specific disease, or general infective process, resulting from the inoculation of a virus, which multiplies in the system till the whole body is infected. It is communicated by the direct contact of the blood, secretions, or discharges of a person suffering from syphilis with an abraded surface of a healthy individual, and under certain circumstances it is also transmitted from syphilitic parents to their offspring. It is therefore contagious, but not infectious.

The exact nature of the virus is not known. Klebs, Birch-Hirschfeld, and some others, have described a special microscopic organism of an oval form, or nearly approaching a short rod in shape, which they believe to be in some way connected with syphilis. Birch-Hirschfeld observed it in gummata, and in a flat condyloma, but failed to detect it in the blood of a patient suffering from active syphilis. Lustgarten has described a bacillus somewhat resembling that of tubercle as being constantly present in the primary and secondary lesion of syphilis, but his observations have not yet been fully confirmed. More evidence

is required before any conclusions for or against the fungoid origin of syphilis can be drawn from these observations.

Syphilis is divided into *acquired* and *hereditary or congenital*, and there is sufficient difference between these two forms to justify their being described separately.

Syphilis runs a course tolerably definite in its main phenomena, but varying in duration and detail. It is divided into various stages, which, although perhaps not capable in all cases of being sharply separated from each other, are sufficiently distinct to be used as a means of classifying the manifestations of the disease.

The *first* stage is the **period of incubation**, extending from the inoculation to the appearance of the local signs of the disease at the seat of infection.

The *second*, or **Primary Stage**, includes the appearance of the characteristic initial manifestation, the indurated sore, accompanied by indolent enlargement of the nearest group of lymphatic glands.

The *third* includes the period during which the so-called **Secondary Symptoms** make their appearance. These consist of more or less symmetrical eruptions on the skin and mucous membranes, ulceration of the tonsils, condylomata, periostitis, iritis, loss of hair, &c.

The *fourth* stage, or **Tertiary Syphilis**, includes the more remote effects of the disease, such as the formation of gummata, deep unsymmetrical ulceration of the skin or mucous membranes, and various deep-seated visceral affections. Only a comparatively small proportion of those infected suffer from tertiary symptoms.

Between the secondary and tertiary stages an interval of perfect health may intervene, perhaps interrupted by occasional recurrences of the secondary symptoms. During the intervals of health, the syphilis is said to be "*latent*."

The **duration of these various stages** is uncertain. According to Berkeley Hill, the period of incubation in thirty-seven trustworthy cases of experimental inoculation collected from various sources, varied from ten to forty-six days, the average being twenty-four. The most common periods were twenty-five and twenty-eight days. The duration of the primary symptoms depends very much on treatment, but it seldom extends beyond a month or six weeks. The secondary symptoms commence from two to three months after inoculation, and last from a few weeks to a year. The period of development, and the duration of the tertiary symptoms, are too indefinite to be stated with any approach to accuracy. Symptoms classed as tertiary may appear immediately after the secondary signs, or may prove fatal after many years of apparent health.

One attack of syphilis, as a rule, confers upon the patient subsequent **immunity** from the primary or secondary forms of the disease. Second attacks are, however, not unknown, but they are not more frequent than in small-pox or measles. When the patient has the misfortune to suffer a second time, the symptoms are never so severe as in the first attack.

From a consideration of the course of the disease as above described, with its periods of incubation, and of invasion, its sequelæ, and the immunity it confers from a second attack, Jonathan Hutchinson long ago pointed out its analogy to the specific fevers. He regarded the disease as a specific fever of a very *chronic* nature and irregular course. As at the present time the acute specific

diseases and syphilis are equally included in the group of general infective processes. Hutchinson's views may be said to be generally accepted.

Origin of Syphilis.—It would be altogether foreign to the scope of this work were I to enter into the very curious and interesting question as to the origin of syphilis, a subject that admits of much dispute, and which has been keenly argued. The disease first attracted public attention in Europe towards the end of the fifteenth century, in consequence of a virulent outbreak which occurred amongst the troops of Charles VIII. of France, during the siege of Naples in 1494. At the time it was undoubtedly considered a new disease, and many of the writers of the period believed it to have been introduced from the newly-discovered continent of America. There is, however, no trustworthy evidence to support this theory. A careful study of the ancient medical writers has led many authorities to the belief that syphilis existed in their time, though the definite relation of the various secondary and tertiary phenomena to the primary sore was not recognized. If it existed previously to the great outbreak in Europe in 1493 and 1494, it is probable that it was in a mild or modified form, different from what we now observe, and that about that time it suddenly assumed greater intensity, all its symptoms being aggravated in a remarkable manner, and presenting characters which had not previously been alluded to, but which have often been reproduced in modern times; as, for instance, in those severe forms that were observed in the British armies during the Peninsular war, and, according to Lurrey, among the French troops during Napoleon's German campaigns.

CONTAGION OF SYPHILIS.—Syphilis is communicable, 1st, by the direct inoculation of any fluid containing the specific virus; and 2ndly, from parents to their offspring.

1. **Direct Inoculation.**—In discussing this question, it is necessary to consider first what fluids or secretions of a syphilitic subject contain the virus, and secondly, the various ways in which the virus may be communicated from one individual to another.

That the discharge from the primary sore, whether it be thick and purulent, or simply serous, is inoculable, is too well known to require further notice.

The contagiousness of the discharges from secondary syphilitic sores has also been demonstrated by numerous experiments. The thin secretion from mucous tubercles of the vagina, anus, and mouth has frequently been shown to be capable of causing infection. The blood itself, in more than one instance, has been inoculated with success. Professor Pellizzari, of Florence, inoculated a young Surgeon, Dr. Bargioni, on the 6th of February, 1860, with blood taken from the vein of a woman suffering from syphilitic eruptions. The site of the inoculation, which was carefully protected by a watch-glass cover, remained quiet for twenty-five days; then a papule developed, which in forty-four days became an ulcer with hard base. On the sixty-fifth day after inoculation, a roseola broke out on the trunk.

Some uncertainty still exists as to whether the natural secretions of syphilitic persons are contagious of themselves, or become so by admixture with the blood or the discharge of local syphilitic affections. The saliva, the milk, and the semen have been inoculated on healthy individuals with almost invariably negative results. So far, therefore, it may be said to be proved beyond a doubt that the discharges from all secondary syphilitic affections, and the blood of patients suffering from active syphilis, contain the specific virus, &c.

there is no definite evidence to show that the secretions of apparently healthy mucous surfaces or glands in a syphilitic subject are capable of transmitting the disease.

The actual inoculation of the virus may take place in many ways. There is no reason to believe that it can enter the system through an unbroken epithelial surface. On the other hand, it readily infects any surface from which the epithelium has been removed by abrasion, vesication, or ulceration. Wounds or punctures are also readily inoculated.

Infection naturally takes place in most cases during coitus, and the primary manifestation is usually situated in those parts most likely to suffer from abrasion during the act. Whether the vaginal mucus of a syphilitic woman is capable of conveying the poison, if she be not at the same time suffering from primary sores or mucous tubercles, is uncertain.

The next most common source of infection is the secretion of the mouth. As before stated, the saliva alone has not been proved to be capable of conveying the poison, but if mingled with the secretion from mucous tubercles or the discharges from secondary ulcerations of the tongue or tonsils, it is undoubtedly infectious. The disease is then most commonly communicated by kissing, and the primary sore appears on the lip or cheek. Authentic cases are also on record in which the infection has been carried by drinking vessels, spoons, or pipes, and in one case the primary sore appeared on the knuckle of a cut received whilst striking the affected person on the mouth. Infants suffering from inherited syphilis have infected their wet-nurses, the primary manifestation appearing at the nipple. This point is one of very great importance, inasmuch as actions for damages have been brought by women who have stated that they have become diseased from the child they have nursed. There are so many cases of the kind recorded, that there can be no doubt as to the possibility of the occurrence. Hunter and Lawrence related cases in which an infected child communicated the disease to several nurses in succession; in Hunter's cases three wet nurses were successively infected, two of whom gave the disease again to their own children. The disease is especially apt to be communicated in this way, if the nurse have any crack or abrasion upon her nipple, and the infant sores in the mouth. Colles, however, who had great experience in syphilis, states that the disease may be communicated to the nurse from an infected child by mere contact, without excoriation; but when we consider that a period of three weeks or more may intervene between inoculation and the appearance of any sign of the disease, the statement must be accepted with considerable caution.

Whether a wet-nurse can infect the child she suckles through the medium of the milk is a more doubtful question, and cannot be said to be finally determined. Ricord and many others of equal authority believe it to be possible, and my own opinion is that syphilis has been transmitted in this way, though very rarely. In *Ranking's Abstract*, vol. iv., a number of cases are recorded in proof of its occurrence.

Primary sores on the finger are unfortunately by no means uncommon amongst Surgeons and accoucheurs, who become infected whilst dressing syphilitic sores or attending diseased women in labour. Washerwomen are said to have been infected in the hands by washing linen soiled by the discharges from venereal sores.

The transmission of the disease by vaccination with lymph taken from a

child suffering from congenital syphilis was until comparatively recently denied by most authorities. It has now, however, been placed beyond a doubt that the disease can be thus communicated. One of the most unquestionable of these accidents is that which occurred in the sub-Apennine valley of Rivalta in Piedmont, in 1861. Dr. Pacchiotti, of Turin, who was employed by the Italian Government to report on the attack, published an account of it. The facts are shortly as follows :—In May, 1861, an apparently healthy child, named Chiabrera, was vaccinated at Rivalta with lymph sent from Acqui for the purpose. Ten days after this vaccination—on June 7th—forty-six healthy children were vaccinated at one sitting from this child. Again, on the 12th June, seventeen other healthy children were vaccinated from one of the forty-six. Thirty-nine of the first series of forty-six, and seven of the second series of seventeen, received syphilis with the vaccine disease, making a total of forty-six out of sixty-three children simultaneously inoculated with syphilis in a mountain village. Some months elapsed before the vaccination was suspected to have been the source of the children's bad health. By the 7th October, when attention was drawn to this spreading disease, six of the forty-six syphilized children had died without receiving any treatment, fourteen were recovering, and three were in a precarious condition. Twenty-three were dispersed through the country, and their condition was unknown until further researches traced them out. In addition to the children, twenty women suckling them were inoculated with syphilis from the children; through the mothers, the disease had reached some of the husbands and even the elder children of the different families. The history of this outbreak of vaccino-syphilis shows that the disease appears in only a certain proportion of those inoculated with the lymph. It has been attempted to explain this by supposing that syphilis is spread only when blood is mixed with the lymph, and that pure lymph will not convey syphilis even when taken from a syphilitic child. The evidence, however, at the present time is not sufficient to prove this definitively, but it is enough to impress upon every vaccinator the necessity of not only carefully examining every vaccinifer for syphilis, but also of obtaining the lymph free from contamination with blood, even when taken from an apparently healthy child.

Syphilis has been transmitted in one well-authenticated case (see p. 277) by *skin-grafting*. In this operation the grafts are cut of sufficient thickness just to draw blood, so that there is no difficulty in understanding how the poison may be conveyed from one person to another.

2. Transmission of Syphilis from Parent to Offspring.—The mode of communication of syphilis to the ovum, or to the fetus in utero, is an investigation that has much occupied the attention of Surgeons, and is of considerable practical interest. It has been considered probable that the poison may be communicated to the embryo in at least four ways: *viz.*, 1, the father may have a constitutional taint of which he has been imperfectly cured, and, without communicating any syphilitic disease to his wife, may be the parent of an offspring that exhibits indications of being infected; or, 2, the mother, having a similar constitutional disease, may in like manner taint her own offspring; or, 3, the diseased child may be born of parents, both of whom are constitutionally infected; or, 4, the mother may become pregnant with a healthy embryo, but, afterwards contracting syphilis, may transmit it to her offspring.

There are very good reasons for believing that the disease does not pass from the father to the child without also implicating the mother. In the first place, this faculty is shared by no other contagious disease. No father can give his offspring small-pox, though the mother frequently communicates that disease to her fetus. In the next place, it is well known, as Colles of Dublin long ago pointed out, that a congenitally syphilitic child never locally infects its mother, though it will transmit its disease readily to a wet-nurse; this apparent exemption of the mother being due to the fact that she has been already infected. Again, the symptoms of syphilis are often exceedingly mild in women, and are constantly overlooked. Hence, in the present state of our knowledge, it is safer to conclude that the father infects the mother, and that she transmits her disease to the offspring.

Ricord, however, states that a mother, pregnant with a syphilitic fetus, the offspring of a father labouring under constitutional disease, can be infected through it without herself having had primary syphilis; and Jonathan Hutchinson has advanced a considerable amount of evidence in support of this doctrine, which, nevertheless, fails to carry conviction to my mind that such communication ever takes place.

Duration of Transmissive Power in the Parents.—This question is one of great importance as bearing on the question of marriage of persons who have suffered from syphilis. There can be no doubt that the power to transmit the disease lasts during the whole time that the secondary manifestations are present. There is equally strong evidence for believing that during the tertiary stage the parent does *not* infect his offspring. I know instances of men who had contracted syphilis before marriage, and had been imperfectly cured, and had for many years (ten, fifteen, or even twenty) occasionally suffered from outbreaks of cutaneous syphilides, gummata, and other varieties of the advanced form of the disease, and yet have been the parents of perfectly healthy children, and have never infected their wives. Cases have, however, been recorded in which the wife and her offspring have been affected after very long periods, extending even to ten or twelve years, even when no evident signs of the disease were present in the parents: and, on the other hand, marriage two years after infection has frequently been followed by the production of healthy children. When, therefore, the question is put to the Surgeon, When may a patient marry who has suffered from constitutional syphilis? it is by no means always easy to give a direct and immediate answer. In answering, the Surgeon must be very cautious; he must bear in mind that the health and happiness of a woman and the future of a family are often dependent on his reply; and that, should he give his consent to the union and evil consequences follow, the whole responsibility will be thrown upon him. It may be stated generally in the first place, that if any of the local symptoms of syphilis are developing themselves, the affected person should not marry, whatever time has elapsed since the commencement of the attack. As a general rule, even if all local symptoms have disappeared, it is advisable not to marry till three years after the commencement of the disease. It, however, there are reasons which make it difficult to delay so long, the Surgeon may give his consent to the patient's marrying two years after the time of infection, provided he have shown no distinct symptoms of active syphilis in the preceding twelve months. Marriage under two years is most frequently followed by the production of diseased children, and should never

be consented to unless the attack has been of a very slight character and no symptoms have been observed for a year.

PROGRESS OF ACQUIRED SYPHILIS. First Stage. Period of Incubation.—The effects of contagion are not immediately manifested. The time that intervenes between inoculation and activity of the poison is called the *incubation period*. It may be occupied in three ways. If the vehicle containing the virus be of a non-irritating character, the broken surface heals, and all trace of the inoculation disappears until the incubation is completed: or, as the vehicle of the virus is often pus or discharge of an irritating kind, it may cause immediate inflammation at the point of inoculation. This irritation subsides in a short time, and the part then remains quiet until the incubation is complete, when the syphilitic poison betrays its presence by characteristic phenomena. An experiment of Vidal's illustrates this. He inoculated the matter of a pustular syphilitic eruption on the arm of a medical student, which produced a pustule in a couple of days; this healed over in about a fortnight, and the experiment was supposed to have failed until the thirty-fifth day: a papule then developed, which subsequently ulcerated, and general syphilis followed in due course. If the syphilitic virus be carried in the pus of a local contagious chancre, the time of incubation is often occupied by the course of a chancre, which may or may not have healed over when the syphilitic poison produces its characteristic effect. This series of events—first a suppurating contagious sore, and then induration forming in the base of the sore, or in its scar if the sore have already healed—is perhaps almost as common as the inoculation of syphilis unaccompanied by immediate local irritation: but the two morbid processes have no connection with each other, and are only accidentally co-existent.

The length of this time of inactivity varies in different persons: it is commonly twenty-five days. The shortest known period before the poison began to reveal its presence has been ten days, and the longest forty-six days. The most important question with regard to this stage of the disease is, how long does the poison remain localized at the seat of inoculation before entering the circulation? No certain answer can be given to this question, but it is probable that the period between inoculation and general infection is very short. Berkeley Hill records a case in which he freely destroyed the surface of the wound left by a rupture of the frenum about twelve hours after infection, but in spite of this general syphilis followed. Ricord, who at one time believed that destruction of the seat of inoculation within five days would prevent the general disease, afterwards completely abandoned this view, and came to the conclusion that destruction of the seat of infection is useless. Experiments on the inoculation of vaccine lymph on the human subject, and the virus of glanders on horses, have shown that the time that elapses between the local introduction of the virus and its entrance into the circulation is very short. In glanders, the excision of the seat of inoculation one minute after the poison was inserted failed to arrest the development of the disease. Those cases, therefore, in which general syphilis is reported to have been cured by excision of the primary sore, cannot be accepted without further evidence.

Second Stage. Appearance of the Initial Manifestation or Primary Sore.—When the period of incubation is past, a peculiar chronic inflammatory process, accompanied by the growth of new tissue, takes place in the seat of inoculation beneath the epithelium, if that be intact, or in the

tissues forming the base of the ulcer, if the inoculation has been immediately followed by the formation of a sore consequent upon the simultaneous introduction of the poison of the non-infecting chancre or other irritating matter. Should such a sore have healed, the new growth commences in the scar. The new tissue may be of almost cartilaginous hardness. Microscopic examination shows it to be formed by an infiltration of the connective tissue with small round cells. With these larger cells containing a single nucleus are found, and not uncommonly multinuclear cells of considerable size are met with. These differ from the giant cells of tubercle in being smaller and more regular in outline. It is the formation of this growth that forms the most distinctive features of the true syphilitic sore. The simple chancre is formed by a true process of ulceration. There is destruction of tissue from the first, and such apparent increase as there may be results merely from inflammatory exudation, and the cells infiltrating the tissues are apparently all migrated white corpuscles, and show no signs of higher development. In the initial manifestation of syphilis, in addition to the small round cells, larger cells evidently undergoing development are met with. In the simple chancre there is from the first evident loss of substance: in the hard sore there may be distinct increase of tissue even when ulceration is taking place. The new growth in the initial manifestation of syphilis is imperfectly vascularized. The walls of the small arteries and veins in the infected tissue are sometimes found to be thickened, and the lumen obstructed by a growth from the endothelium. Consequently the indurated tissue tends readily to degenerate and break down.

Clinically, the initial manifestation assumes two forms,—the desquamating papule, and the indurated chancre.

The **desquamating papule** appears at the point of inoculation as an elevated hard dark-red or copper-coloured spot distinctly elevated above the surface, with slight desquamation of the epithelium covering it. At first it is very small, but it may gradually extend till it reaches half an inch in diameter. It is dense and hard, its edges are sharply defined; it is practically painless, causing at most a slight itching. It occurs most frequently where it is little exposed to friction or to the irritation of accumulated secretions. If irritated in any way it readily ulcerates and then becomes an indurated chancre. In fact it rarely remains as a papule to the end. From its painless nature, if ulceration does not occur, it may run its course and subside without attracting the attention of the patient.

The **Indurated or Hunterian Chancre** commences as a papule, or may begin as an apparently simple sore which becomes indurated when the period of incubation is past. It assumes two forms dependent on the amount of the surrounding induration. In one form the sore is superficial, and the hardness, which is clearly defined, extends but little beyond it. In this variety, the sore is the most prominent feature, and the induration may even be difficult to detect, sometimes assuming the form described by Ricord as "parchment induration." The discharge, if the sore be kept clean and free from irritation, is merely serous, and under the microscope shows granular *débris* with a few epithelium scales. If the surface be irritated by dirt, or the friction of clothing, or by any substance used as a dressing, it rapidly becomes purulent. The extension of the ulceration is slow and painless. The superficial sore forms the most common variety of the initial manifestation. It occurs

usually on moist surfaces as the glans or inside of the prepuce in the male, or the labia in the female.

The second form of indurated sore is that most properly described as the "true Hunterian chancre." It is surrounded by a dense mass of induration extending deeply into the tissues. It is considerably elevated above the surrounding parts, and the surface is often slightly cup-shaped. Grasped between the fingers it feels almost like a piece of cartilage, the limits of the induration being clearly and sharply defined, and the surrounding tissues free from inflammation. It is usually painless, and its surface is often almost dry, there being merely a very slight serous discharge. It is most common on the glans or on the corona. Every modification may be met with between these two forms of the indurated sore. It has been maintained by Surgeons of great authority that induration at the site of inoculation may occasionally be absent. It is certainly in some rare cases so slight that it is detected with difficulty, but it is doubtful if it is ever wholly wanting.

As soon as the primary sore makes its appearance, the patient acquires an immunity from re-inoculation of the poison, the discharge from an indurated sore not being inoculable on the patient himself under ordinary circumstances. If, however, the surface be irritated mechanically, by the application of irritating dressings or from want of cleanliness, to such an extent that the discharge becomes purulent, it will then as a rule become auto-inoculable, the resulting sore resembling a soft chancre in appearance, and not presenting the characteristic features of the hard chancre. The non-inoculability of the discharge from an inflamed hard sore has been used as a means of diagnosis between the hard and the soft chancre, but in cases in which doubt existed the sore would probably be suppurating from irritation, and consequently an error might easily arise.

Number.—The primary syphilitic sore is almost invariably single. This fact is readily explained by its non-inoculability on the patient himself. Arthur Cooper states that of 103 cases of early syphilis admitted into the Male Lock Hospital, in 91 there was only one initial lesion, 7 had two sores, and 5 had more than two.

Situation.—The indurated primary ulcers of syphilis are most frequent on the *genitals*, but not so exclusively limited to these parts as are local venereal sores, because syphilis is communicated in various ways besides sexual intercourse. They may appear on any part of the body. Fournier found that, of 472 cases of inoculation in men, 314 were on the prepuce and glans penis, 109 on other parts of the male organ, 12 only in the mouth, 6 on the hands and fingers, and a few on the eyelids, tonsil, and navel.

The **Urethral Chancre** is usually situated just within the orifice of the canal, and may be seen on pressing open its lips, in the form of a small sore, which occasionally creeps out upon the glans. Sometimes it is more deeply seated, so as to be out of sight; when this is the case, a discharge, occasionally tinged with blood, appears in small quantities from the urethra; at a little distance up the canal there will usually be felt, on grasping the organ, a circumscribed indurated spot, which is somewhat painful on pressure and after micturition. It is the presence of chancres in this canal that formerly led to the supposition of the identity of syphilis and gonorrhoea, an error which was disproved by the test of inoculation; the discharge from urethral chancre producing the typical sore, that from gonorrhoea giving no result when in-

roduced into the skin. The existence of chancre within the urethra may be suspected if the urethral discharge be small in quantity, serous in character, and tinged with blood. The chancre may be detected by evertng the edges of the urethra, or, if situated too high up the canal to be seen without the help of the endoscope, by being felt, hard and nodulated, through its coats. Care must be taken not to mistake the inflammatory induration sometimes occurring around the urethra in gonorrhoea for that of a hard sore.

In some cases of unnatural depravity chancres are met with at the margin of the **anus**. In this situation they present nothing peculiar.

In **women** chancres are very rare on the vaginal wall; about four per cent. are said to occur on the cervix uteri, and the remainder on the external organs of generation.

Labial and Facial Chancres are by no means uncommon, being usually the result of the inoculation of a small crack on the lip or excoriation of the skin of the face with the discharge from mucous tubercles in the mouth of an infected person. Chancres on the lip may possibly result also from drinking or using a spoon after a syphilized person, or smoking the same pipe. These sores are often very deceptive, the raised and indurated base causing them closely to resemble epithelioma. They frequently show a tendency to the formation of a soft fungating growth, all induration being absent. In a case of chancre of the cheek lately admitted into University College Hospital, the sore was as large as half-a-crown, and raised abruptly above the surrounding skin for about a quarter of an inch. It was scarcely indurated, and the discharge was serous and bloody, mixed with a little pus. The surface had a great tendency to become covered with scab. In other cases the induration may be of the same character as in the Hunterian sore on the penis. The diagnosis can usually be made by attention to the foul surface, hard base, and persistent character of the sore, and by the invariable presence of indolent enlargement of the nearest lymphatic glands commencing at the same time as the appearance of the sore or at most a few days later. Later on, the appearance of skin eruptions will make the nature of the case evident. From cancer, chancre of the lip can usually be distinguished by the age and sex of the patient, as it is most commonly met with in girls and young women who have not reached the age for cancer; indeed, in women at any period of life cancer of the lip is extremely rare. Chancres have been met with even on the **tongue** and **tonsil**.

I would especially caution the Surgeon not to be misled in his diagnosis by the modest look or the respectable station in life of the infected woman. In this, as in all other cases of venereal disease, he must make an independent diagnosis without regard to social considerations or to the statements, often purposely misleading, made by the patient.

Syphilis not unfrequently occurs amongst Surgeons and accoucheurs as a consequence of inoculation on the **fingers**, during the dressing of a venereal sore, or the delivery of a diseased woman; and is occasionally met with also among non-professional persons. It usually appears as a small sore by the side of the nail and under its matrix, with much swelling, redness, and pain in the finger, which becomes bulbous; indolent swelling of the glands at the elbow and in the axilla soon follows. If the nature of the disease be not recognized, the ulceration will creep round the tip of the finger, will have a foul and sloughy look, with exquisite tenderness, and, resisting all ordinary treatment, may be

set down as malignant; on which supposition amputation of the finger has been proposed and practised. I have seen at least four cases in which this extreme measure has been proposed, but in which, by a timely discovery of the true nature of the affection, the finger was saved. In the earlier stages a chancre on the finger is likely to be mistaken for a whitlow.

Variations in the Sore as the result of Irritation.—As the result of irritation, the normal serous discharge of a hard chancre becomes purulent. If the irritation be more severe, and especially if inefficient caustics, as nitrate of silver, have been applied, the surrounding tissues become infiltrated and swollen so as to obscure the characteristic sharply defined edge of the induration. In such cases it is often impossible to make a diagnosis until the inflammation has been subdued by proper treatment.

Hard sores rarely if ever assume a sloughing form. Phagedænic ulceration is, however, not uncommon (see p. 1110).

Prognosis from the Appearance of the Primary Sore.—Every patient who has the initial manifestation is already suffering from constitutional syphilis, and nothing can prevent the development of secondary symptoms. These may be so slight as to be scarcely noticeable, or so severe as to endanger life. Much induration is often thought to precede a severe course of syphilis, and possibly this may be true; but the most severe symptoms have also followed small superficial sores, so that it is not safe to draw any conclusion from the appearance of the initial manifestation.

Course of the Indurated Sore.—If unmodified by treatment, the initial manifestation tends slowly to disappear, the surrounding induration melting away and the sore healing, a scar being left behind, which is more or less marked, according to the extent and depth of the ulceration that has accompanied the process. The simple desquamating papule may leave no recognizable scar. The length of time which may elapse before spontaneous disappearance of the induration takes place is uncertain, but it is rarely, if ever, under two months.

Indolent Enlargement of the Lymphatic Glands.—The so-called *indolent bubo* is the next change to follow induration at the seat of inoculation. The time at which this follows the appearance of the initial manifestation is variously stated at from seven to eleven days. Most commonly the glands are found already enlarged when the patient first presents himself, and form a most important element in the diagnosis. One gland enlarges first and several follow; the glands are painless, or only very slightly tender, and the hardness is such that they are often described as feeling like bullets. The skin over them is unaltered, and the individual glands can be clearly distinguished, even when they form together a considerable mass, there being no doughy swelling about them as in the acute suppurating bubo. In rare cases, if the sore be irritated so that it is suppurating freely, or if the patient have unwisely taken violent exercise, as dancing, riding, and the like, suppuration may follow, and an abscess form around the glands. The pus from such an abscess, however, is never auto-inoculable like that from the virulent bubo following a soft chancre. If the point of contagion be situated near the middle line, at the frenum for instance, the glands in both groins are often enlarged.

Enlargement of Dorsal Lymphatics of Penis.—Simultaneously with the occurrence of glandular enlargement some induration and thickening of

the lymphatics which pass along the dorsum of the penis can often be detected, and must be looked upon as good evidence of the syphilitic nature of a doubtful sore. The lymphatic is usually felt as a fine hard cord, but occasionally it may reach the size of a cedar pencil.

SECONDARY AND TERTIARY CONSTITUTIONAL MANIFESTATIONS OF SYPHILIS.

In describing the constitutional manifestations of syphilis it will be most convenient to give first an outline of the general pathology and the ordinary course of the disease and its treatment, and subsequently to consider in detail the special syphilitic affections of the various textures and organs.

GENERAL PATHOLOGY AND PROGRESS OF SYPHILIS.—After the appearance of the initial manifestation there is usually an interval of from five to seven weeks before any further characteristic symptoms are developed. This has been termed "the period of second incubation." During this time there is in most cases some disturbance of health: the patient becomes pale, and suffers from malaise or a general sense of indisposition, often with some loss of flesh. Neuralgic pains in the head and other parts of the body are common. Sometimes there is distinct but slight febrile disturbance just before the cutaneous eruptions make their appearance. This is seldom sufficiently marked to attract attention, but in very rare instances the fever may be high and accompanied by delirium.

At the end of this period, often before the primary sore is healed, the secondary manifestations of the disease make their appearance. These consist of various superficial affections of the skin and mucous membranes, usually appearing more or less symmetrically. In the skin the early syphilitic eruptions or syphilides present the following gradations. In the simplest form there is hyperæmia of the papillæ in localized spots with some retardation of the blood-stream. We consequently get a red patch of a somewhat dusky colour not perceptibly elevated above the surface. On pressing on the discoloured area the red tint disappears, and a faint brownish or copper coloured stain is left behind. This is presumably due to staining of the tissues by the pigment from a few corpuscles which have escaped from the distended vessels. This form of eruption is described as *macular syphilide* or *syphilitic rosolia*. It is the most common and the earliest of all the cutaneous affections. It occurs also on mucous membranes, and is usually of short duration.

If the hyperæmia continues for a longer time, the papillæ become swollen and an increased growth of epithelium takes place on their surface. There is thus formed a red patch, slightly elevated and covered with a branny or scaly layer of desquamating epithelium. This is the *squamous syphilide* or *syphilitic psoriasis*, a common early syphilitic eruption. If the eruption occurs in a moist place, as in the neighbourhood of the anus or on a mucous membrane, the hypertrophy of the papillæ is usually more marked, and the new epithelium instead of forming dry scales separates early or forms a sodden white mass on the surface of the patch. Occasionally the papillary aspect of the growth is very distinct. This is the *mucous tubercle* or *flat condyloma*, and when the eruption is general every gradation may be traced between it and the squamous syphilide, according to the degree of moisture of the part in which the patch is situated.

The next degree of the process is the *syphilitic papule* or *papular syphilide*.

This is the result of a congluable inflammatory exudation into the papillae of the skin. It forms a hard, red, elevated patch, usually of small size and covered by a bran-like desquamation of the epithelium. It merges insensibly into the squamous syphilide, or, if in a moist part, into the mucous tubercle.

If the process be more acute, the serum from the exudation raises the cuticle and a vesicle is formed. *Vesicular syphilide* is a rare form of eruption. Should it be still more acute, migrating corpuscles penetrate the Malpighian layer of the epithelium, and mixing with the serum in the vesicle, convert it into a pustule, and there is then developed the *pustular syphilide*. When the pustules occur in the early stages of syphilis, they dry up and form scabs, beneath which no ulceration takes place, and no scars are left when they are healed. On mucous membranes, from the thinness and softness of the epithelium, the superficial layer is very early cast off, and there is thus formed the small superficial ulcer commonly met with on the tongue and lip.

All the early syphilitic eruptions are merely modifications of one pathological process, differing in degree but not in nature. They occur in all parts of the body, and often in situations which are not affected by simple eruptions of the same character: thus, for instance, the squamous syphilide is common on the palms of the hands, the soles of the feet, and the flexure of joints. They present also the great peculiarity of causing little or no itching or irritation. More than one form of eruption may be present at the same time, and in this again they differ from simple skin diseases.

With the skin eruptions there is, in the majority of cases, some affection of the *throat*. With the roseola of the skin there is usually some redness and dryness of the fauces, as if a similar eruption was taking place there also. Later on ulceration of the *tonsils* very commonly takes place. The ulcers are, as a rule, symmetrical: they have sharply-cut edges and a grey floor, and the mucous membrane round is reddened. They cause singularly little pain in most cases, and have no tendency in this stage of the disease to extend far beyond the surface of the tonsil, or to cause extensive destruction of the *pillars of the fauces* or soft palate.

The remaining symptoms belonging to the secondary stage of the disease are, *loss of hair*, pains in the *bones*, periostitis without any tendency to terminate in suppuration, and *inflammation of the iris*.

The most common of the foregoing symptoms is roseola followed by papular and squamous syphilide, with ulceration of the throat; mucous tubercles, loss of hair, and periostitis are common but by no means constant; iritis is, fortunately, met with only in a small percentage of cases.

During the time the eruptions are making their appearance chronic enlargement, with induration, of the *lymphatic glands* throughout the body, is not uncommon. The patient is usually anæmic and thin, but not necessarily so.

The secondary stage may end in two months or extend over a year. Not uncommonly after complete disappearance of all symptoms and an interval of some months of apparent health, a relapse takes place, indicated by a return of some of the secondary eruptions. When the secondary stage has come to an end the patient may never suffer again from any signs of the disease, or he may pass on directly to the development of those symptoms which are classed as tertiary. In many cases an interval of months or years intervenes between the secondary and the tertiary stages, during which occasional relapses of the secondary symptoms may occur. In other cases, again, the tertiary affections

may appear before the secondary signs have subsided. Thus there is no distinct line of demarcation between secondary and tertiary syphilis.

The **Tertiary Stage of Syphilis** is characterized by the appearance of ulcers on the skin and mucous membranes, usually unsymmetrical, and having a tendency to spread widely, and to cause considerable destruction of tissue: by certain chronic degenerative changes in the blood-vessels; by chronic fibroid induration and hyperplasia of organs and tissues, and by the development of masses of new tissue forming definite tumours prone to early degeneration—*syphilitic gummata* or *syphilomata*.

The *ulcers on the skin* begin in various ways. First, they may arise in much the same way as the secondary eruptions. A localized patch of the skin, a quarter of an inch or more in diameter, becomes inflamed, usually vesication takes place, the fluid in the bleb becomes rapidly purulent and then dries up, leaving a dry adherent scab which gradually increases in thickness and diameter. If this be removed, a circular ulceration of the cutis is found beneath, which may slowly spread with the formation of a fresh scab. This form of eruption, known as *rupia*, occurs scattered over the whole body, and in this resembles a secondary eruption. In fact, it forms an intermediate link between secondary and tertiary affections.

Secondly, small gummata form in the cutis vera, forming flat dusky-red or copper-coloured elevations, known as *tubercular syphilide*, or *syphilitic tubercles*. These soften in the centre, and an ulcer forms which may spread slowly.

Thirdly, a gumma may form in the subcutaneous tissue; which softens, becomes adherent to the skin, and opens on the surface by ulceration, leaving a deep excavated cavity, with an adherent yellow slough.

Lastly, in syphilitic subjects, a simple injury to the skin may lead to a spreading ulcer. This form is most common on the leg. All tertiary ulcers tend to spread slowly, often extending on one side while healing on the other. They thus are often crescentic or serpiginous in form.

The *changes observed in the smaller arteries* consist of a gradual narrowing of the lumen by a growth apparently originating by proliferation of the endothelium. The external coat is also thickened, but in a slighter degree. These changes have been observed in the cerebral and renal arteries of medium size, and in the smaller vessels in the neighbourhood of gummata. In the larger arteries no distinctive changes are met with, but it is a well-known fact that the great majority of aneurisms of the larger vessels in young subjects occur in those who have suffered from constitutional syphilis.

Overgrowth of the connective tissue is met with in the lung, liver, spleen, testicle, and other organs, and with it must be classed the diffuse hypertrophy of bone, which is not an uncommon consequence of syphilis. An organ affected in this way is tougher and harder than natural, and at first increased in bulk. If it is enclosed in a fibrous capsule, as the liver or testicle, this is thickened and opaque, sometimes uniformly, sometimes in patches. When the organ is covered with a serous membrane this also shows signs of chronic inflammation: thus a syphilitic testicle is almost invariably surrounded by a hydrocele often divided into separate sacs by adhesions between the visceral and parietal layers of the tunica vaginalis. In a later stage the affected organ may shrink and become puckered on the surface. A section shows, in the early stage of enlargement, that the proper structure is infiltrated by a whitish or semi-

transparent material of considerable firmness lying in the natural situations of the connective tissue and following the lines of the vessels. In the testicle the septa may thus be increased to half a line or more in thickness. In the later stages, when the active process has ceased, dense cicatricial bands of fibrous tissue may pass through the organ in various directions leading to puckered scars on the surface. The process is painless, and the performance of the natural function of the organ is diminished in proportion to the destruction of its proper structure by the pressure of the new growth.

The microscopic appearances presented by organs thus affected are those of chronic interstitial inflammation. The interstitial connective tissue, sometimes throughout the affected organ, sometimes in bands or patches, is found to be infiltrated with small round cells, between which is a delicate stroma, usually finely fibrillated. Vessels of new formation are abundantly present in the new tissue. The growth seems to commence round the vessels and to infiltrate along their course. At a later stage it becomes developed into dense fibroid tissue, and at the same time undergoes considerable contraction, which may lead to deformity and puckering of the affected organ. The normal structures of the part are pressed upon by the growth, and may degenerate and be completely absorbed in parts. The original vessels show the changes just described, and are frequently obliterated.

This process manifests itself in bone by a gradual enlargement extending over a considerable area, and accompanied by a great increase in density of the structure (sclerosis of bone). The Haversian canals are narrowed, and in many are completely obliterated, and thus from want of blood-supply death of a portion of bone may take place (syphilitic necrosis). The bones of the skull furnish some of the best specimens of this change.

The most characteristic pathological product of tertiary syphilis is the **Gumma**, or, as it is sometimes called, the *sypuloma* or *sypilitic granuloma*. A gumma commences by a localized process essentially similar to the diffuse form just described, namely, an infiltration of the connective tissue of the affected part with small round cells. These cells may be in part migrated white corpuscles, and in part formed by proliferation of the original connective tissue corpuscles. It is impossible to say to what extent they owe their origin to these two sources. Small multinucleated cells are often present. New vessels are formed amongst the cells, and thus a tissue is developed having the characters of granulation tissue. This continues to increase in quantity till the special structure of the part, such as epithelium in a gland, striated fibres in muscle, fat cells in adipose tissue, or the compact tissue of bone, disappear in the affected area, being destroyed and absorbed in consequence of the pressure of the invading growth. Thus a nodule is formed, composed of small round cells, between which is an intercellular substance, small in amount and usually distinctly fibrillated, so as to give the new tissue considerable toughness. The gumma in this stage is abundantly vascular. The new tissue exceeds in bulk that which it has replaced, and thus forms a distinct tumour. It increases by a progressive infiltration of the surrounding structures, and not, as in tubercle, by the formation of new nodules which coalesce with that first formed. The growth continues till the gumma may reach the size of a walnut; but long before this—in fact, soon after the gumma becomes recognizable—degenerative changes have taken place in its structure. These arise, not, as in tubercle, from the absence of vessels in the new tissue, but, as

has been pointed out by Greenfield, from a gradual obliteration of the small arteries entering the mass by the process, already described, of proliferation of the endothelium and thickening of the external coat. Probably also the pressure of the new cells, closely packed together, obstructs the circulation through the capillaries. As a result of the starving of the new tissue thus brought about, fatty degeneration takes place. The cells wither and become filled with fat granules, and finally are represented merely by fatty *debris*, amongst which the individual elements are not recognizable. The intercellular tissue, when fibrillated, undergoes but little change, and thus the caseous mass retains a considerable degree of toughness, very different from that of yellow

Fig. 407. Syphilitic Gumma, showing a large vessel becoming obliterated by proliferation of the endothelium.

tubercle. The caseation may follow very closely on the growth; but while growing, a gumma is always surrounded by a zone of cell-infiltration of the neighbouring connective tissue, with vessels of new formation amongst the cells. The caseated centre of an old gumma often contains crystals of cholesteroline. Gummata vary somewhat in consistence according to the degree of fibrillation of the intercellular substance. In some cases mucous softening seems to take place and the gumma may be almost gelatinous in consistence.

The ultimate fate of a gumma varies in different parts and under different circumstances. Even after caseation and partial softening it may, under proper treatment, be completely absorbed, leaving a depressed fibrous cicatrix behind it. In other cases, especially in gummata of the subcutaneous tissue, bone and muscle,

softening takes place, followed by suppuration round the softened mass. The pus finally reaches the surface, and the tissue of the gumma is cast off as a slough. The slough is tenacious and slow to separate even after the pus has been discharged. It has been very aptly compared to a piece of wet wash-leather. In this it differs entirely from caseated tubercle, which, under similar circumstances, forms a granular mass which can readily be scraped away with a sharp spoon. In the liver, testicle and brain growth may cease, and the surrounding zone of cell-infiltration, instead of degenerating, may be developed into a fibrous capsule, which may enclose the caseated mass and completely encyst it. In this condition it may remain permanently without causing further mischief. Calcification occasionally takes place, but is far from common.

A fully developed gumma, free from softening, presents to the naked eye on section the following appearances. The cut surface is smooth, of a pale cream-yellow colour, of tough consistence, and on scraping yields but a small amount of granular *debris*, sometimes scarcely any. Though its outline is tolerably well defined, it can always be seen that the growth is not circumscribed, but is surrounded by a greyish semi-transparent or opaque zone infiltrating

the surrounding tissues, and often sending processes in various directions along the lines of the vessels for some distance. The organ in which it is situated is also, in many cases, the seat of general interstitial fibroid induration.

From the above description it will be seen that a gumma resembles tubercle in being a new growth of the type of granulation tissue, prone to early fatty degeneration, followed often by softening and elimination by suppuration. It differs from tubercle in being vascular during the whole stage of evolution, in its capability of being absorbed or of undergoing a development in part into fibrous tissue, in the toughness of its tissue, and in the absence of the characteristic tubercle nodule, with its giant cell, epithelioid cells and lymphoid corpuscles. Moreover, it is not inoculable on animals, nor has it been proved to contain any specific organism. Lustgarten has described a bacillus, but the observation requires confirmation.

Clinically in those parts in which a gumma comes under the observation of the Surgeon, it forms an indolent tumour of slow growth, often accompanied by a good deal of aching pain. If superficial, it slowly approaches the cutaneous surface, the skin becomes adherent, and then dusky red. The mass softens and fluctuates distinctly, and an opening forms from which some thin unhealthy pus escapes. This gradually increases in size by ulceration in many cases, till the whole reddened skin is destroyed. The tissue of the gumma is seen as an adherent, tough slough, like a piece of wet wash-leather, which slowly separates; the cavity becomes lined with healthy granulations, and heals without difficulty, leaving a deep cicatrix. If a bone be affected, a carious patch is left, sometimes complicated by the presence of sequestra of varying size. Small gummata, not more than one-quarter of an inch in diameter, may form in the cutis vera, and afterwards soften and run the same course as deeper and larger growths of the same kind. In this situation they form the skin disease known as *tubercular syphilide*. Gummata do not necessarily cause any enlargement of the neighbouring lymphatic glands, though this may occur when softening and suppuration are taking place.

Gummata will be further referred to in connexion with the organs in which they are found.

Gummata have occasionally been met with in an early stage of syphilis, and some authorities have maintained that the processes concerned in the formation of a gumma differ in no essential respect from those occurring in the induration round the primary sore and in the lymphatic glands. There is, however, one essential difference—the discharges from softening gummata are, so far as is known, not infective, consequently it seems probable that the specific virus of syphilis is not present in them. It has therefore been suggested that the changes in the vessels, the diffuse overgrowth of interstitial tissue of organs, and the formation of gummata, are not the direct effects of the virus, but are due to some modification of the mode of growth and nutrition of the tissues, impressed upon them by the poison while it was active in the system. The unsymmetrical character of the later eruptions would indicate that they are not dependent on an active virus circulating in the blood-stream. At present we have not sufficient knowledge of the nature of the virus of syphilis, or of its mode of action, to render these speculations of any real value.

PROGNOSIS.—The severity and form of the manifestations which follow contagion vary greatly. Diday states that in 93 cases treated by him without

specifics, 7 suffered only from a single eruption on the skin, and after that showed no further signs of the disease; in 53 the disease lasted from ten to eleven months, with eruption on the skin and mucous membranes, occurring irregularly with repeated relapses; 29 suffered from severe cutaneous eruptions, periostitis, iritis, &c., the average duration of the disease being twenty months; and in 4 only did the disease assume a grave form with early appearance of tertiary symptoms. Berkeley Hill considers that these statistics form a valuable index of the natural course of syphilis.

The **Circumstances influencing the Progress** of the disease are chiefly the following:—

Age.—Other things being equal, the disease runs the mildest course in young adults. Infants suffer more severely, and after middle life syphilis is very apt to prove intractable. According to some authorities, it is practically incurable if contracted after forty, the patient being constantly troubled by relapses for the remainder of his life.

Sex.—Females are apt to suffer severely, because, owing to the more concealed situation of the primary sore, they often do not come under treatment till the secondary symptoms are fully developed. Pregnancy usually aggravates the course of the disease.

Personal Habits and Surroundings have a considerable influence on the course of syphilis. The disease is seen in its worst forms amongst those who suffer from insufficient food, clothing and washing, and are addicted to alcoholic excesses. In a young adult of sound constitution, who leads a healthy and steady life, with plenty of out-door exercise, syphilis is very rarely followed by any of its graver consequences, and usually ceases to give rise to any symptoms in about one year.

The *state of the patient's health* also determines to a great extent the kind of attack he will undergo. In scrofulous subjects the disease usually runs a severe course, and tertiary ulcerations are very prone to occur. In gouty subjects the skin eruptions are very apt to relapse, and periostitis is common. Rheumatism also is said to render the patient prone to inflammations of bones and to iritis during the progress of syphilis. Chronic renal disease is always a most serious complication, partly no doubt because patients so affected do not bear the mercurial treatment well.

After the symptoms of the disease have subsided, they may again be called into activity by any cause which seriously impairs the general health. It is remarkable for how long a time the syphilitic poison will lie dormant in the constitution without producing any local manifestation of its existence, until this is developed under the influence of a broken state of health. I have had under my care an extremely severe case of constitutional syphilis, in which twelve years elapsed after the occurrence of the primary disease, during the whole of which time no secondary affection was observed until the patient's health gave way from other causes. I have also had under my care an officer, in whom a very severe form of constitutional syphilis occurred, for the first time, after salivation for hepatic disease, five years after the primary sore had been contracted—no constitutional manifestation having attracted the patient's attention in the meanwhile. Not only does a state of ill-health hasten the occurrence of secondary syphilis, but neglect or indifference to its existence may keep it up indefinitely.

That the *treatment of the primary sore* exercises considerable influence on

not be doubted. The severity of the course of syphilis is, I believe, materially lessened by a mercurial course, if that course be properly conducted.

The question as to there being any connexion between the *nature of the primary sore* and the character of the consecutive constitutional affection has been much discussed, and very different opinions have been expressed. The generally received opinion at the present time is, that no safe conclusions as to the future course of the disease can be drawn from the appearance of the primary sore. Tertiary symptoms are, in fact, frequently met with in patients who have not a trace of a scar left by the primary sore, and sometimes even in those in whom the initial manifestation has been so slight as to escape notice.

The *character of the secondary symptoms* seems to give a much more valuable indication of the probable course of the disease. A copious early squamous or papular eruption is believed to indicate a quick course, terminating at an early period. Those cases in which the skin disease persists long and frequently relapses have been observed to suffer but rarely from visceral affections. It is a remarkable fact, noted by Lancereaux, Berkeley Hill, and Wilks, that a large proportion of those who suffer from visceral syphilis have passed through a very mild secondary stage, often so wanting in symptoms as to be scarcely recognizable. This fact is particularly noticeable in tertiary syphiloma of the nervous system. It must not be concluded, however, from these facts that severe tertiary symptoms must necessarily follow a mild secondary stage. In the great majority of cases a mild secondary stage, when it occurs, forms the end of the disease. Berkeley Hill states, that marked general glandular enlargement is a bad sign, being usually accompanied by anæmia and debility.

As a probable explanation of at least some cases in which severe tertiary symptoms follow a slightly marked primary and secondary stage, it must be remembered that such cases are very likely to have been imperfectly treated. This explanation is undoubtedly true of some cases in which a patient with tertiary symptoms is altogether unaware of ever having had a primary sore.

Death from syphilis, directly, during its secondary stage, is practically unknown. The disease kills more often by its tertiary manifestations, such as the development of gummata in the central nervous system or liver. Gowers is of the opinion that locomotor ataxy is most common in patients who have suffered from constitutional syphilis. Many aneurisms are believed to be due to syphilitic changes in the vessels. The proportion of cases, however, in which syphilis even indirectly shortens life is so small that it is not considered necessary to make any addition to the premium charged for life insurance because a patient has passed through an attack of syphilis, unless some definite tertiary symptoms are present.

Duration of Syphilis.—It is extremely difficult to say when syphilis can be eradicated from the system; and indeed it is a question whether it may not impress the constitution in a peculiar way, modifying certain processes during the rest of life, as we know to be the case in other specific diseases, such as cow-pox or scarlet fever. Certain it is that, if neglected or improperly treated, it may affect the system for an indefinite time, declaring its existence by exciting and modifying various local inflammations years after the original absorption of the poison. It is tolerably clear that a person who has once had the usual course of syphilis very rarely has it a second time, though he contract a fresh chancre. Exceptions to this rule are, however, occasionally

met with. But such cases are exceedingly rare, and occur only after an interval of some years has elapsed between the two attacks. Hutchinson has related a very interesting example of this kind in a medical student, who also suffered from two attacks of small-pox. Daily experience shows that in many constitutions syphilis cannot be eradicated, and that in most others, when once it has occurred, it is apt, even when apparently cured, to modify certain cutaneous and other affections in a remarkable manner, after a lapse of many years; showing clearly that, if the poison no longer exists in the system, the constitution has received a peculiar impress from it, which it is long in losing.

TREATMENT.—The **treatment of the primary stage** of the disease is local and constitutional.

Local Treatment, which is all that is required in the simple chancre, is of comparatively little importance in the true syphilitic sore, the causes of the local manifestation being beyond the reach of any direct application. If the initial manifestation assumes the form of the desquamating papule every effort must be made to prevent its ulcerating by the application of some simple non-irritating substance, such as vaseline, to protect it from irritating secretions and friction. Attention to cleanliness by frequent washing is also essential. If an indurated sore forms, iodoform, which is of such singular benefit in the simple chancre, will be found of little use. Attention to cleanliness, the avoidance of irritating dressings, and the application of a piece of lint soaked in black wash will be found in most cases to be all that is necessary. Black wash sometimes proves irritating; a weak lead lotion, made by adding 5 minims of liquor plumbi diacetatis to an ounce of water, may then be used. Caustics are always injurious. It has been recommended by Auspitz and others to excise the sore—on the theory that the virus may be still localized at the seat of infection, and that by removing the initial manifestation the further progress of the disease may be arrested. Experience has shown that excision does not produce the desired effect, a fact which confirms the view that the induration of the sore is in fact the first sign of constitutional infection. Should the sore assume a phagedænic form, it must be treated as already described.

The **Constitutional Treatment** of primary syphilis need not be separated from that of the secondary stage, as the same remedies that favour the healing of the initial manifestation exercise a beneficial influence on the secondary affections. The constitutional treatment of syphilis has undergone various changes according to the prevailing doctrine of the day. It had been decided by the Surgeons of the last and the early part of this century, that mercury acted as a specific against the syphilitic poison. This doctrine was so firmly established, that Hunter, and many of the great Surgeons of his school, looked on the curability of a sore without mercury as a proof that it was not syphilitic.

About the commencement of this century, however, it was found by observations of the Army Surgeons, amongst whom Rose took a principal share in the inquiry, that many forms of venereal ulcer (no distinction being then drawn between the local non-infecting sores and the ulcers which resulted from the contagion of the constitutional disease) were curable without the necessity of administering mercury, or indeed of having recourse to any specific treatment whatever. These observations, which were chiefly made in Spain and Portugal during the Peninsular War, led to the introduction of

the *non-mercurial* or *simple* treatment, as it is termed—a mode of practice that obtained great favour and was extensively tried. On the definite separation of the simple non-infecting chancre from the true syphilitic sore, however, a reaction took place in the minds of most Surgeons, and mercury is now almost invariably employed in the treatment of the latter, and is administered more moderately and scientifically, and consequently more successfully, than before.

The arguments in favour of the non-mercurial plan of treatment were briefly these: that the constitution of the patient is saved the introduction of a mineral which occasionally acts injuriously, and which, as the disease can be cured without it, may at all events be looked upon as unnecessary; that secondary affections less frequently follow this plan than they do the administration of mercury; and, lastly, that those distressing cases of constitutional syphilis which are common after mercurial courses, and which are said to depend upon a peculiar combination of the syphilitic poison with the mineral in the system, are never met with in persons who have undergone the simple treatment. These arguments, however, on closer examination and further experience, have been proved to be not quite so conclusive as the supporters of the simple treatment appear to believe. Before the simple sore was clearly distinguished from the initial manifestation of syphilis, the early healing of the chancre and the absence of secondary symptoms after it were taken as evidence of the efficacy of the non-mercurial treatment of syphilis. Now that the two forms of sore are clearly separated from each other this fact has of course no bearing on the question, and experience has undoubtedly shown that although the true indurated sore will heal in time without the administration of mercury, yet the process of cicatrization is slow and often imperfect, the scar readily breaking down again for some time after apparent healing; whereas if mercury be given the healing is rapid and permanent. This is, however, but a small part of the question. It is a most serious error to confound the healing of the primary sore with the cure of syphilis. The test of the relative value of the two plans of treatment must depend rather on the influence they have over the course of syphilis, and on the character that the symptoms assume under one or other of these methods, than on the mere skinning over of the ulcer. I cannot agree with the statement that secondary symptoms are less frequent after the simple than after the mercurial treatment. In fact, since the separation of the simple chancre from the true syphilitic sore the fact has become clearly recognised that no mode of treatment can prevent the appearance of secondary symptoms; mercury may diminish their severity or delay their appearance, but constitutional syphilis must unavoidably follow the indurated sore, though sometimes the symptoms may be so slight as almost to escape detection.

I have seen the non-mercurial plan of treatment very extensively employed at University College Hospital; indeed, it was formerly almost invariably practised there, more particularly in the syphilitic cases occurring among the out-patients under Morton, who strongly advocated it; and I have had repeated occasion to observe the frequency with which it was followed by secondary symptoms. In private practice, also, I have had considerable opportunities of comparing the two methods, and I can safely say that I have seen the simple treatment more frequently followed by severe secondary symptoms than the mercurial plan has been when properly and judiciously employed. The supporters of the non-mercurial treatment, when obliged to

admit the great frequency with which it is followed by secondary symptoms, argue that these are less severe after the simple than after the mercurial plan; and they state—as it appears to me, without one atom of evidence to support their statement—that mercury and syphilis together form a sort of poisonous compound in the system, which produces the most destructive forms of constitutional syphilis. It is doubtless true that, after an ill-regulated mercurial course, constitutional syphilis of a very severe character may occasionally appear; but this seems to me to be rather owing to mercury having been improperly administered in constitutions that will not bear it, and in which, by the induction of a cachectic condition of the system, it favours the occurrence of some of the more severe forms of secondary syphilis, in the same way that any other lowering plan of treatment, or simple debility, might occasion them, but without the exercise of any specifically injurious influence. Some of the worst forms of constitutional syphilis that I have seen occurred in patients to whom no mercury had been administered, but in whom the syphilitic virus had been allowed to exercise its influence unchecked, save by the so-called simple treatment. Thus I have seen the body covered with immense ecchymatous crusts and sores in one case, rupial ulcers with destruction of the nose and palate in another, the worst kind of syphilitic cachexy with the tuberculo-pustular syphilide in a third, and extensive disease of the cranial bones and the clavicle in a fourth.

But, though I cannot admit that the supporters of the non-mercurial treatment of syphilis have brought forward any proof of its superiority over the mercurial plan, and though my own experience has taught me that secondary symptoms occur after it with no less severity than they do when mercury is judiciously administered, yet I am quite ready to allow that there are certain conditions of syphilis in which the non-mercurial treatment alone is admissible, the state of the constitution or the disease being such that mercury cannot be given in any form. In these cases such a treatment must be adopted, in accordance with ordinary medical principles, as will tend to improve the general condition. It is, indeed, especially in individuals who are suffering from visceral disease of some kind, especially Bright's disease, or whose powers have been broken by habitual dissipation, that this plan of treatment should be adopted. So also in those who, from the nature of their occupations, are subjected to much exposure to wet and cold, a mercurial course cannot be properly or safely administered, and the simple treatment is most advisable. In all other cases I am certainly of opinion that mercury ought to be administered; and this opinion appears to be entertained by the most experienced Surgeons of the day in this country and abroad.

The first question in connexion with the employment of mercury in syphilis has reference to the principle on which this remedy is administered. Whether mercury exercises a specific action over the poison of syphilis or not, has been much discussed, and is difficult of proof. I certainly think that it does act as a specific in syphilis, but that this action is much influenced by the condition of the system, the habits of the patient, and the mode of administering the remedy; these conditions under certain circumstances tending to counteract or otherwise to interfere with its operation. That mercury is antagonistic to the syphilitic poison, appears evident from the fact that in some instances hard sores will not heal unless it be given internally; from its influence in speedily curing infantile syphilis and preventing after-

manifestations: and from the fact that, when properly administered in healthy constitutions, it may almost to a certainty be expected to dissipate the various symptoms of constitutional syphilis. When it fails, as it doubtless does in many cases, to prevent severe constitutional symptoms, the failure may usually be traced either to want of care in the administration of the medicine, or to the existence of an impaired state of the patient's health. The essential practical point in the treatment of primary syphilis by mercury is to keep the patient under a prolonged and mild course, rather than a short and active one.

Administration of Mercury in Syphilis.—In discussing this question the following points require consideration:—1. The cases in which mercury is inadmissible. 2. Cases in which it is required. 3. The effects of mercury and the degree to which its use should be pushed in treatment. 4. Its effect in different stages of the disease. 5. The time during which its use should be continued. 6. The mode of administration. 7. The general management of the patient during the time he is taking the drug.

1. *Cases in which mercury is inadmissible.*—Mercury is especially dangerous in all forms of Bright's disease, so that it is well, if there be any suspicion of an unhealthy state of the kidneys, to examine the urine for albumen before commencing to give the drug. It is not well borne by those also who are exhausted by habits of dissipation, by insufficient food, or by bad hygienic surroundings. Lastly, some patients are peculiarly intolerant of mercury, apparently from some idiosyncrasy, and in these it may be impossible to give it with safety.

2. *Cases in which mercury is required.*—There is no doubt that the natural tendency of syphilis is to spontaneous recovery; this has been clearly proved by the effects of the non-mercurial treatment. It is equally certain, however, that mercury shortens the stages and lessens the severity of the disease, and that if carefully administered, it cannot do any harm. The administration of mercury is therefore advisable in every case of syphilis in which its use is not contra-indicated by one of the conditions above mentioned. As age increases, its use becomes more essential, for, as before stated, the disease becomes more obstinate in proportion to the age of the patient at the time of infection. In patients of the scrofulous diathesis, or in those suffering from active tuberculous disease, mercury must be administered with great caution, but its use is not contra-indicated.

3. *The general effects of mercury, and the degree to which it should be pushed in treatment.*—The observations of Liegeois, Hughes Bennett, and Keyes, show that mercury administered to a healthy subject in very small doses acts as a tonic. Under its influence the red corpuscles increase in number, and in animals a gain in weight has been noted. In larger doses it diminishes the red corpuscles. In syphilis, in which the red corpuscles are diminished in number, it causes an increase if administered in moderate doses. All forms of mercury administered by the mouth tend to act upon the bowels, and unless this tendency be checked, the desired alterative effect is not easily produced. The most marked sign of the action of the mercury is the effect upon the gums and mouth. The first sign that the drug is affecting the constitution is the appearance of a red line along the gums, close to the teeth: there is at the same time a slight sense of tenderness on biting any hard substance. In the present day the administration of mercury is not pushed beyond this point, and in the primary stage of syphilis, it is not even necessary in most cases to carry it so far before its good effects are apparent on the sore. Should the

drug be pushed further, either intentionally or accidentally, the swelling increases; the gums become soft and spongy, and overhang the teeth; the tongue swells, so as to show the impression of the teeth along its sides, and it becomes covered with a thick fur. The breath is offensive, and there is an increased flow of saliva, and a metallic taste in the mouth. This condition of "*mercurial salivation*" was in former times regarded as the proper effect to be obtained by the administration of the drug. In the present day it is regarded as an evil to be carefully avoided. If the drug be pushed still further, the teeth may be loosened, and fall out; the gums and tongue may become ulcerated, and acute inflammation may take place in the salivary glands. Ulceration of the inner surface of the cheek opposite the molar teeth may occur. At the same time there may be considerable febrile disturbance. The effects produced by mercury vary greatly in different individuals, a dose which would salivate one patient producing no effect on another. In the administration it is necessary, therefore, in all cases, to begin with a small quantity which may be gradually increased till the patient's dose is ascertained. Before beginning the treatment it is very advisable that all tartar should be scaled from the teeth. When symptoms of salivation set in, the mercury must immediately be discontinued. A brisk saline purge may be given, and the mouth must be washed with a strong alum or chlorate of potash gargle (10 to 15 grs. to the ounce of water). Ten to twenty grains of chlorate of potash with five minims of tincture of belladonna may be given internally three times daily.

In the treatment of syphilis the effect upon the primary sore is often a useful guide in the administration of mercury. If, under the influence of a certain dose, the sore rapidly assumes a healthy appearance and begins to heal, it may be taken for granted that that quantity is sufficient to act beneficially on the patient, and it may be adhered to during the whole course, unless special circumstances require an increase. It is better in all cases to be guided rather by the effect on the disease than by the effect on the gums. Swollen gums show that the limit of safety has been reached; if the symptoms are relieved without affecting the mouth, so much the better. There is no evidence that any tolerance of the drug is acquired by its prolonged administration.

4. *The effects of mercury in the different stages of syphilis.*—The effect of the drug on the primary sore is almost invariably very distinctly marked. The hardness round the sore becomes less intense and less sharply defined. The smooth pale surface becomes of a healthy red colour, granulations spring up, often of a florid tint, and bleeding readily; the thin serous discharge, characteristic of the typical hard sore, is replaced by pus, and by the end of a week or ten days the indurated chancre has assumed the appearance of a healthy granulating sore. As these changes take place, the sore usually becomes more tender and painful, and the patient may become alarmed at what to him seems a change for the worse. The induration at the base of the sore is often not completely absorbed for many weeks after the surface has been covered by new epithelium. Simultaneously with the softening of the induration, the glands in the groin become smaller, but they do not, as a rule, reach their normal size and consistence till long after the sore is healed.

The influence of mercury is not, in all cases, so unmistakable in the secondary stage; but, in most cases, it is evident enough. The rashes fade or diminish in abundance, or may even be entirely prevented, and the sore throat subsides under the influence of the drug. It may be necessary, however, to push the

administration till the gums are distinctly affected before the effect is produced. In the tertiary stage its effect is far less certain, and the state of the patient's health is frequently such as to contra-indicate its administration. As a rule, it should not be given unless other means have failed, when it will sometimes be found to produce excellent effects if carefully administered.

5. *The time during which mercury should be continued.*—The administration of mercury should commence as soon as the nature of the disease is recognized, and be steadily continued while the secondary symptoms are making their appearance. Even if no secondary signs appear, it is better to continue the administration uninterruptedly for from four to six months, and then with occasional intervals to the end of a year. If no signs of the disease are present, its use may then be abandoned, and not renewed unless some fresh symptoms appear. The patient must be carefully watched, and if any signs of depression from the use of the drug become apparent, its use must at once be suspended. The occurrence of marked febrile disturbance immediately before the outbreak of the secondary symptoms is usually an indication for carefully pushing the drug.

6. *Mode of administration.*—Mercury may be administered in four ways : (a.) by the mouth ; (b.) by inunction ; (c.) by subcutaneous injection ; or (d.) by fumigation.

(a.) *By the mouth.*—This, being the most convenient method, is usually adopted. As mercurial preparations are mostly purgative, it is necessary, in most cases, to add a small quantity of opium, to prevent this action. In the treatment of any given case, it is necessary to ascertain what preparation has least tendency to purge the patient, what amount of opium is required just to neutralize the purgative tendency without causing constipation or headache, and what dose is required to produce the desired effect on the disease. All these points can be ascertained only by observation of the particular case. The form that will be found most generally useful is the following : R, grey powder, gr. j. ; Dover's powder, gr. j. ; extract of gentian, q. s. to make a pill. The patient may begin with three pills a day for three days ; if they give rise to no effects, either beneficial or the reverse, the dose may be increased to four, and after a few days to five, if necessary. Six are very rarely required. If the pill purges, the Dover's powder may be increased ; if it constipates it must be diminished. A few variations usually succeed in hitting the exact proportion and dose suited to the case, and the prescription may then remain unchanged for weeks or even months. The ordinary blue pill is of the same strength as the grey powder, and may be given instead of it, if preferred ; but it is slightly more apt to purge. It may be first tried alone, or with an equal quantity of extract of gentian, in grain doses, three, four, or five times a day. If necessary, powdered opium or Dover's powder is added. By patients very insusceptible to the drug, as much as ten grains a day of blue pill can sometimes be taken. If these preparations do not suit the patient, the green iodide of mercury, in doses commencing at half a grain, and gradually increased to a grain, three times a day, may be employed. It should be made into a pill with extract of gentian, and, if necessary, a sixth to a third of a grain of extract of opium may be added. The only objection to this preparation is that it may decompose, the red iodide and free mercury being formed ; it then acts much more powerfully, and may savigate. The perchloride of mercury, or the bichyanide may sometimes be tried if the foregoing

fail. They are given in doses of from $\frac{1}{16}$ to $\frac{1}{8}$ of a grain, made up into pills with sugar of milk and varnished. Calomel is never to be recommended, being too irritating. Mercury can also be administered in a mixture, if the pills do not suit. In debilitated constitutions, and in the tertiary stage of the disease, the perchloride in doses of from $\frac{1}{16}$ to $\frac{1}{8}$ of a grain may be given, with compound tincture and infusion or decoction of cinchona. To this are sometimes advantageously added a few grains of iodide of potassium, by which the perchloride is converted into the red iodide of mercury, which is held in solution by the excess of the potassic iodide. Plummer's pill, in five grain doses, taken two or three times a day, is very useful in the syphilides.

In many cases iron may advantageously be combined with mercury. For this purpose a pill having the following composition may be given three times a day: Grey powder, gr. j.; reduced iron, gr. j.; sulphate of quinine, gr. j.; powdered opium, gr. $\frac{1}{4}$; extract of gentian, gr. j.

(b.) *Inunction*.—This may conveniently be practised when it is desired to put the patient rapidly under the influence of mercury or when the bowels are so irritable that the drug, if given by the mouth, invariably purges the patient. It is best done by rubbing a scruple to a drachm of mercurial ointment into the inside of each thigh or arm or in the axilla before going to bed. Hill recommended that the ointment should be made up with lanolin and that a drachm of olive oil should be added to each ounce of the ointment. The skin should be well washed before the mercury is rubbed in. After the inunction the patient should put on flannel clothes next his skin to encourage sweating and go to bed. In the morning he should take a hot bath. The inunction must be repeated daily till some effect is produced, and it is best not to rub the ointment into the same part on two consecutive days. It must be borne in mind that the orifices of the sweat-glands and hair-follicles become filled with the ointment; so that, should salivation commence, it is not easy at once to arrest the absorption of the mercury. During the treatment the patient should use an alum mouth-wash. The use of the hot bath every morning diminishes the risk of the absorption of an undue amount.

(c.) *Subcutaneous injection* of mercury has been employed on the Continent by Lewin and other Surgeons, and in this country by Walker of Peterborough, Bloxam, and others. Sigmund of Vienna believed it to be most useful in those forms of the disease affecting the more superficial structures and the osseous, muscular, and fibrous tissues. Hill, who extensively tried this mode of administration, was of opinion that it should be reserved for those rare cases in which mercury cannot be taken in the more ordinary ways.

The best preparation for injection is sal alembroth, the double chloride of mercury and ammonium; one-third of a grain should be dissolved in ten drops of water and injected on every fifth day. The injections should be made into the muscles of the back or buttock. Sal alembroth injections are very rarely followed by abscess, which is not uncommon after the injection of the perchloride, red iodide, and the so-called "grey oil" (composed of mercury, lanolin, and olive oil), which have all been employed. Another preparation which has been recommended for injection is the sosoiodolate of mercury; one-third of a grain is dissolved with two-thirds of a grain of iodide of sodium in ten minims of water. This may be given as an intramuscular injection every fifth or seventh day.

(d.) *Mercurial fumigation*.—In some cases of syphilis in which the patient

cannot tolerate the drug by the mouth, mercury may conveniently be administered by fumigation. This plan of treatment, which has been especially recommended by Langston Parker and H. Lee, consists of a combination of vapour-bathing and of mercurial fumigation. The baths may also be associated with appropriate internal treatment. Fumigation is thus carried out: the patient is seated naked on a wood-bottomed chair and is covered with a cloak made of some thick woollen material reaching to the floor and fastened round the neck. It is fitted with a cane hoop to keep it from touching the body. A lamp consisting of a circular trough to contain about one ounce of water, and a central plate for the mercurial preparation, is used for producing the vapour. The water must be made to boil thoroughly before the mercury is put on the plate. It is then immediately put under the chair, and thus the patient's body will be steamed for a minute or two before the mercury begins to volatilize. The best form of apparatus is that known as Lee's lamp, but in the absence of all special apparatus fumigation can very easily be carried out by means of two spirit lamps and two metal vessels, one for the water and one for the mercury, the patient being covered with a thick blanket. Various forms of mercury have been used, but the two best seem to be the bisulphuret as recommended by Langston Parker, in doses of from one to two drachms at each bath, and calomel, which has been extensively used by Henry Lee in doses of from twenty to thirty grains. Whatever form of apparatus be used, after about twenty minutes, when the whole of the mercury will have been volatilized, the patient gets into bed wearing the cloak or blanket. He must not be left alone during the bath, as he may become faint. If perspiration does not begin at once, a little weak hot tea may be given to encourage it.

7. *General management of a patient during a course of mercury.*—Regular hours, sufficient exercise in the open air, abundant simple food, and the avoidance of alcoholic or other excesses are of equal importance in the management of a case of syphilis as the administration of mercury. While the patient is under the influence of mercury the skin should be kept in a healthy state by baths. In summer there is no objection to a morning cold bath, but in winter some warm water should be added to prevent a chill. The patient should wear flannel next his skin both in summer and winter. A chill during a course of mercury may cause a violent attack of diarrhoea, sometimes accompanied by much griping pain and vomiting. The diet should be plain, and anything likely to irritate the bowels, as excess of fresh fruit, green vegetables, or made dishes, should be avoided. Beer should be prohibited, as it is apt to cause purging. Claret is perhaps the best alcoholic drink that can be taken. All these things must, however, be left, to a certain extent, to the common sense and experience of the patient. Exercise is of the greatest value, but should not be carried to the extent of fatigue.

Other Drugs used in the Treatment of Syphilis.—In the primary and early secondary stages of syphilis no drug but mercury can be said to exert any real influence on the disease; but in the later secondary and tertiary stages the preparations of iodine produce effects not less clearly marked. Iodine is supposed to be a specific in a minor degree to mercury. It has also been proved that in patients who have undergone a course of mercurial treatment iodine liberates the mercury which may have become stored up in the body, the mercury re-appearing in the urine and other secretions on the administration of the drug. The effects of iodine are not, however, due to

this, for they are well marked in patients who have never taken any mercury during the early stages. The preparations of iodine are most useful in the various forms of visceral-syphilis, in syphilitic disease of the nervous centres, and in treatment of gummata wherever they may be situated. Useful as iodide of potassium is, however, I do not believe that syphilis can be eradicated from the system by means of it; indeed, I cannot call to mind a single case presenting marked tertiary symptoms which has been permanently relieved without the administration of mercury.

Iodine is commonly administered, as *iodide of potassium*, in doses of from five to twenty or even thirty grains. It is often combined with some bitter infusion, but there is no advantage in this unless the patient requires a tonic. A most convenient mode of giving iodide of potassium is the following: Put one ounce of the iodide into a two-ounce bottle and fill it up with water; let the patient take eight drops of the solution in a wineglass of water or in milk three times a day, and gradually increase the dose by two drops every two or three days till he finds by the symptoms of iodism that he has reached his limit. An intelligent patient will soon learn to regulate his dose without the necessity of constantly applying to the Surgeon. The addition of a few drops of aromatic spirit of ammonia is said to make the iodide more active. If the patient is anemic it may be taken in conjunction with the iodide of iron.

Iodide of Ammonium can sometimes be taken by patients who cannot tolerate the potassic iodide. It may be given in doses of ten grains and upwards, and two or three grains of carbonate of ammonia must be added to each dose to prevent the decomposition of the iodide. It is probably the least depressing of the iodides.

Iodide of Sodium has also been recommended in doses of five grains and upwards. It is said to be less depressing than the potassium salt.

In whatever way iodine is administered, if pushed beyond a certain point it gives rise to toxic symptoms known as "*iodism*." The amount of the drug required to produce these effects varies with every case. The symptoms resemble a bad cold in the head; there are redness of the eyes, running at the nose, and frontal headache. Every patient who is taking the iodides must be warned of these symptoms, and be told to reduce the dose immediately they appear. In severe cases swelling of the tongue and lips, and even ulceration of the pharynx, may occur. Prolonged administration of iodides not unfrequently gives rise to a pustular eruption resembling acne, or more rarely to large pustules on an indurated base, which dry up, leaving a scab behind them. In other cases an eruption consisting of large papules and plaques may occur about the neck and face. Purpura and albuminuria have also been attributed to its influence. It must be remembered that children do not bear the iodides well.

The *Sulphides of Calcium and Potassium* are said to form most useful adjuvants to mercury, promoting its action and preventing its accumulation in the system. How much real value they possess is still uncertain. The Aix-la-Chapelle treatment, which has obtained great celebrity for the cure of syphilis, consists of the administration of mercury by inunction, combined with the use of the natural hot sulphur waters, both for bathing and drinking. The chief advantage derived in most cases from a visit to Aix-la-Chapelle arises from the fact that the patient, having little else to do, and being carefully looked

after by the physicians and the rubbers, and regularly dieted in his hotel, cannot neglect the treatment as he is too apt to do at home. It is for rich patients who are not taking proper care of themselves that a visit to the baths is to be recommended. A course lasts from six to seven weeks.

Sarsaparilla formerly enjoyed a great reputation in the treatment of syphilis, but at the present time it is little used. It may, however, be given in the late secondary or tertiary stage, especially if the patient have fallen into a cachectic state, having lost flesh, colour, appetite, and spirits. In this condition of the system dilute nitro-hydrochloric acid, in doses of fifteen to twenty minims, with half an ounce of the liquid extract of sarsaparilla in four ounces of water, may be taken three times a day.

Cod-liver Oil is often of great use when there has been considerable loss of flesh. It may be given at the same time as the iodides of potassium or iron.

Bitter Tonics and the *Preparations of Iron* are frequently useful in the tertiary stage. They are given on general principles after or in the intervals of specific treatment.

LOCAL SECONDARY AND TERTIARY MANIFESTATIONS OF SYPHILIS.

LOCAL SECONDARY AFFECTIONS.—We shall next proceed to describe the character and treatment of the different *local forms* in which constitutional syphilis manifests itself, and shall consider them as affecting the skin; the mucous membranes of the mouth, nose, tongue, palate, and larynx; the eye, bones, testes, muscles, viscera, and nervous system.

1. Syphilitic Affections of the Skin.—Syphilo-dermata or Syphilides present various modifications of appearance, corresponding closely to the different groups of simple cutaneous diseases; thus we find exanthematous, papular, squamous, vesicular, pustular, and tubercular syphilitic affections of the skin, with various ulcers and growths. These differ from the corresponding simple cutaneous diseases, in their redness being more dusky or coppery, in leaving stains of a brownish or purplish hue, and in their giving rise to no itching or other painful sensations. The general pathology of these affections has already been described (p. 1130).

Besides this, syphilis may modify materially the general character of the cuticle, causing it to assume a yellow or earthy tint, and to be rough or powdery.

Syphilitic skin diseases arrange themselves under the following groups:—

Syphilitic *Roseola* consists of blotches of a reddish-brown or coppery tint, becoming more distinct as the redness declines; they vary in size from small circular spots to large and diffused patches, and are usually first observed about the abdomen. Syphilitic roseola is the most constant, and the earliest of all the syphilitic eruptions, often appearing before the primary sore is healed. It usually appears about seven or eight weeks after infection, and may last from a few days to two or three weeks. It is very frequently accompanied by an erythematous redness of the throat.

The *Squamous* syphilide, or as it is often called *syphilitic psoriasis*, occurs in small patches of an irregular shape, of a dusky red colour, sometimes assuming a coppery tint, covered with thin filmy scales. In many instances, however, the patches are quite smooth, and have a glazed and almost shining look. They are usually situated on the inside of the arms and thighs,

often on the scrotum and penis, even occurring on the glans. They also frequently appear on the palms and soles, where deep fissures and cracks are met with. In moist parts, as in the folds of the groin in fat people, at the margin of the anus or between the toes, they become more elevated and merge gradually into the "mucous tubercle" or flat condyloma to be described hereafter. About the lips the squamous syphilide gives rise to deep and troublesome fissures. It differs from psoriasis in its showing a preference for the softer and moister parts of the skin, whereas psoriasis is most abundant on the drier parts, as on the back of the elbow or the front of the knee. The scales also are less abundant. Squamous syphilide forms the most common eruption, after the roseola, during the first year of syphilis. It is often associated with ulceration of the tonsils and iritis, and not uncommonly with periostitis.

Papular Syphilide, or *Syphilitic lichen*, consists of small hard elevations, at first red, but afterwards becoming dusky or brownish. There is some slight branny desquamation on the surface. They are most common on the forehead and shoulders, and last about three weeks before fading. A rare eruption is the *Follicular syphilide* in which small papules form around the hairs.

The *Vesicular syphilide* is of very rare occurrence. The vesicles vary in size from a pin's head to a pea. They soon dry, and when the scales so formed separate a coppery red patch is left beneath. In one case which fell under my observation, the rash appeared in the form of clusters of small pointed vesicles, which on drying left grey or brownish crusts and coppery marks. Many varieties have been described and named according to the non-syphilitic skin affections they resemble, as eczematous, herpetiform, varioliform, and varicelliform.

Pustular syphilides occur somewhat rarely in the early stages, but are more common later on. The early pustular syphilide commences as a small vesicle which soon becomes pustular. It then dries into a crust, which falls off, leaving an elevated coppery spot beneath. It is merely an aggravation of the vesicular eruption, and leaves no ulceration or scar behind it. Larger pustules forming slowly with a dusky-red or coppery areola are met with in cachectic subjects, forming the eruption known as *syphilitic ecthyma*. The pustules dry, leaving a dark flat scab, which after a time falls off, leaving an ulcer which heals slowly. Ecchyma is most common on the limbs.

In the late secondary or in the tertiary stage in debilitated subjects, the affection known as *rupia* is not uncommon. It seldom occurs before the end of the first year, and may be met with as long as the syphilitic taint persists. *Rupia* commences as a bleb which rapidly becomes converted into a large pustule, surrounded by a wide brown or coppery areola. It soon dries into a circular dark brown or even black scab. Beneath this ulceration takes place, and the crust increases in thickness from the drying of the discharge, while at the same time it extends at its circumference: it thus comes to assume a conical form, and somewhat resembles a limpet-shell in appearance. After its separation a troublesome ulcer of a circular shape, often with a somewhat foul surface, is left, which may continue to spread slowly. This disease may appear on the face, but is especially common on the extremities. It is always indicative of grave constitutional debility.

Syphilitic Tubercles commonly occur as an advanced or tertiary symptom: they are in fact gummata of the cutis vera. They appear as hard, smooth

flat elevations of a reddish-brown or purplish colour, usually arranged in groups of single tubercles lying closely together. They are seated on the face or extremities, the skin covering the patella and the ala of the nose being common situations. They may be resolved by proper treatment, but have a great tendency to ulcerate and to be followed by slowly spreading serpiginous sores.

Subcutaneous syphilitic gummata, or, as they have been called, deep syphilitic tubercles, arise in the tertiary stage of syphilis as hard indolent masses in the subcutaneous tissue, usually accompanied by some slight aching pain or tenderness. They may vary in size from a pea to a walnut. They are of slow growth, but ultimately become adherent to the skin, which then assumes a dusky-purple tint. If unrelieved by treatment the gumma softens and the skin gives way over it, exposing the characteristic adherent slough resembling wet wash-leather. This slowly separates, leaving a deep cavity. Subcutaneous gummata may occur at any part of the body; common situations are the back of the thigh and the upper part of the arm.

Syphilitic Boils of a somewhat chronic character, but painful, and discharging a thin ichorous pus, with a core of shreddy areolar tissue, and leaving deep, irregular, and foul ulcers, are sometimes met with.

Syphilitic Ulcers are superficial and deep. The superficial ulcers arise from pustules, ecthyma, rupia, superficial tubercles, or boils. In some cases, especially on the leg, they arise like simple ulcers from some slight injury, but assume peculiar features in consequence of the syphilitic taint. Superficial syphilitic ulcers are usually characterized by their multiplicity, by their tendency to spread at one edge while healing at the other, and thus to assume a crescentic or serpiginous form, and by their unhealthy grey surface. They leave bluish or brownish cicatrices, often thin and smooth, and apt to break open again on slight irritation. The deep ulcers arise from softening gummata as above described.

The *Hair* during the first year of syphilis frequently becomes lustreless and dull, and comes out in large quantities, often so as to cause baldness—syphilitic alopecia. Occasionally it may separate in patches. The baldness is not permanent; in fact, it resembles the fall of the hair so often noticed in erysipelas and various fevers.

Diseases of the *Nails* are common. During the early stages the nails frequently become brittle and irregular in growth. A more serious affection is *Syphilitic Onychia*, which consists in a chronic inflammation of the matrix, with foetid discharge from under the nail; the end of the affected digit is swollen, purple in colour, and intensely tender; the nail becomes black, more or less bent, and scales off, leaving a dirty ulcerated surface exposed beneath. One nail only is usually affected.

Ulceration between the Toes with excessively foul discharge and great swelling of the foot is not an uncommon condition in syphilis. It apparently arises from the formation of soft flat growths of the same character as the mucous tubercles at the anus, the ulceration being due to the irritating secretion between the toes and want of cleanliness. It is easily recognized, for it may be taken as a rule that all ulcerations between the toes are due either to syphilis or to scabies. The ordinary soft corn discharges no pus.

The *Treatment of Syphilitic affections of the Skin* must be conducted in accordance with the general principles already laid down. All the symmetrical

eruptions occurring in the early stages of the disease are best treated by the administration of mercury according to the rules already given. The tubercular eruptions and the squamous forms, when occurring after the first year, can often be relieved by iodide of potassium, especially if the patient has been treated with mercury in the earlier period. Donovan's solution is often of the greatest possible value, the disease rapidly disappearing under its use. The same plan is required in the management of syphilitic boils. In the pustular forms, syphilitic rupia and ecthyma, as the constitution is commonly shattered, a tonic plan of treatment is required in the first instance; after which the perchloride of mercury with tincture and decoction of cinchona, or sarsaparilla should be steadily administered. In these cases also much benefit will be derived from mercurial fumigation.

In most cases no local treatment is required for the squamous or papular eruptions, but should they occur on the face the patient is often anxious to hasten their disappearance. For this purpose dilute white precipitate ointment, or calomel made into a cream with olive-oil and lard, may be applied. Marshall recommends the application of a 10 per cent. solution of oleate of mercury with some morphia added. In all *ulcerating syphilides* iodoform, either applied pure or made into an ointment with vaseline, will be found most useful. In deep ulcerations iodide of starch ointment often produces a good effect. If these fail, yellow wash or perchloride of mercury in the strength of two grains to the ounce, diluted with water if it cause too much pain, will often arrest the spread of the ulceration and hasten its healing. If nothing else succeeds it may be necessary to cauterize the surface with fuming nitric acid or the acid nitrate of mercury. In syphilitic *alopecia* the internal administration of mercury has most influence in arresting the loss of hair; at the same time dilute white precipitate ointment may be rubbed into the scalp at night or a stimulating lotion applied. B. Hill recommended the following:—*R.* Tincture of Cantharides, Solution of Ammonia, aa ʒss .; Spirit of Rosemary, ʒi .; Glycerine, ʒss .; Rose water to ʒviij . In *syphilitic onychia* the nail should be removed and iodoform applied. Black wash or yellow wash is sometimes useful. In *ulcerations between the toes* dilute white precipitate ointment, with a small quantity of extract of belladonna added, is useful, or the following dusting powder may be applied:—Calomel, ʒj .; oxide of zinc, ʒj .; starch, ʒij .

2. Mucous Tubercles and Condylomata.—*Mucous tubercles* are flat patches, seldom more than half an inch in diameter, slightly elevated, soft, and papillary on the surface (Fig. 404). They are situated in moist parts of the body, very commonly on muco-cutaneous surfaces, as the anus, labia, and angles of the mouth; they are also frequently met with on mucous surfaces, as on the tongue, tonsils, palate, and larynx, and exactly similar growths are found in any part of the skin that is kept moist by the natural secretions, and not properly cleaned, as between the scrotum and the thigh, in the fold of the groin in fat people, and between the toes. They are moistened by a good deal of mucous secretion when seated on mucous membranes, or by perspiration when on the skin. In the mouth and throat they are usually small and not so distinctly elevated, but rather like a thickened and opaque condition of the mucous membrane in these situations. At the anus they sometimes attain a considerable size, so as to project a quarter to half an inch above the surface, and it is then that they are commonly termed *condylomata*. They are frequently

mistaken by the patient for piles. They consist essentially of an overgrowth of the papillæ stimulated in part by the irritation of dirt or unhealthy secretions. They are common in conjunction with the squamous syphilide on the drier parts of the skin, and every gradation can sometimes be traced between a scaly patch to a mucous tubercle, according to the moisture of the part in which the patch is situated. They are met with most commonly during the first six months of the disease. They differ from the venereal warts already described (p. 1119), not only in their flatter form and less marked papillary structure, but in being dependent on a constitutional disease, and not on local causes solely, such as the irritation of discharges and want of cleanliness. The discharge with which they are moistened is intensely contagious, and it is from them, when situated in the mouth, that the disease is transmitted by kissing, or by means of drinking-vessels, or pipes, and from infants to their nurses. Their *Treatment* must be constitutional and local. The constitutional treatment is merely that of early syphilis. When seated at the anus or on the skin, they are best treated with the dasting power above-mentioned, and the use of boric acid baths. If this does not relieve them they may be rubbed with nitrate of silver or sulphate of copper. In the mouth the application of a solution of perchloride of mercury (gr. ij. to ʒi.), or of the solid nitrate of silver, is the best treatment. Not being pendulous, they do not, like simple venereal warts, require to be cut off.

3. The **mucous membranes** of the *mouth, pharynx, and larynx* are commonly affected with **secondary syphilitic eruptions**, which assume the form of mucous tubercles, and of the exanthematous, squamous, and ulcerating syphilides; and in the later stages of the disease submucous gummata may form.

The *exanthematous* affection, corresponding to the roseolous form of cutaneous syphilis, and arising from the same cause and in the same constitution, principally affects the palate and throat. The *tubercular* variety corresponds to the squamous cutaneous eruptions, and is met with chiefly as flat, hard, and elevated tubercles in the interior of the mouth, nose, and throat. The *ulcerative* affection of the mucous membranes assumes a variety of forms, which will immediately be described, and occurs principally in the throat and nose. The exanthematous affection of the mucous membrane is usually an early sign of constitutional syphilis, frequently showing itself a few weeks after the primary occurrence of the disease. The other varieties belong to the more advanced secondary and tertiary periods. *Contractions* of various mucous canals often occur as the result of syphilitic affections, the narrowing being due to firm, fibrous bands, often excessively dense in structure. These

Fig. 404. — Syphilitic Condyloma, showing enlarged papillæ covered with a thick layer of epithelium.

are often merely cicatricial, formed on the healing of syphilitic ulcerations. In other cases they seem out of all proportion to the extent of the destruction by ulceration, and would appear then to be due to diffuse fibroid induration of the submucous tissue, followed by contraction. They are most frequently met with in the rectum, vagina, and pharynx.

The syphilitic affections of the mucous membranes are most conveniently considered according as they affect distinct organs or parts of the body.

The *Lips* are commonly affected in persons labouring under squamous syphilide, with fissures or cracks usually somewhat indurated, and very painful in the movement of these parts. In the *Treatment*, the application of a pointed piece of nitrate of silver to the bottom of the crack will give the most effectual relief. The insides of the cheeks are not unfrequently affected in a similar manner, or become the seat of mucous tubercles, which must be treated as already described. In tertiary syphilis the lower lip is occasionally the seat of a diffuse gummatous infiltration.

The *Tongue* may be affected in various ways: when severely, its disease usually constitutes one of the tertiary manifestations of syphilis.

In the early period of the secondary stage of syphilis, small papules, similar to those on the skin, may appear. They are of little importance, and cause no inconvenience. During the second half of the first year of syphilis, and often at a later period, small superficial ulcers on the sides of the tongue, having an irregular or oval outline, and a grey surface, are not uncommon. They cause considerable discomfort. They are best treated by being touched twice a day with a solution of perchloride of mercury (gr. ij. to ʒj.). The surface must previously be dried with a handkerchief. Solid nitrate of silver is often as efficacious. Another form of late secondary manifestation on the tongue is a small fissure, or crack, at one side, surrounded by a zone of thickened epithelium, which gives the mucous membrane at the affected spot an opaque blue tint. These ulcers require the same treatment as those just described. Mucous tubercles are not uncommon on the tongue, but are less frequent than on the lips or cheek.

At a later period the dorsal surface of the tongue, usually only in its anterior half, undergoes a chronic change. The epithelium becomes opaque, white, and thickened, sometimes in patches, sometimes uniformly, and if the tongue be dried and then examined, it will be observed that the papillae in the affected area have disappeared, the surface being almost smooth. The disease is a chronic inflammation affecting the corium of the mucous membrane, and the submucous tissue, with overgrowth of the epithelium covering the affected part. It has received various names, according to the appearance produced: when the surface is smooth, and bluish in tint, it is spoken of as the "*smooth tongue*," or *chronic superficial glossitis*; when the opacity is greater it has been called *psoriasis of the tongue*; and when the epithelium is heaped up so as to form scales, the term *ichthyosis linguae* has been applied to it. These conditions most frequently result from syphilis, but cases are often met with in which no history of the disease can be obtained; they are permanent, the normal papillary condition of the tongue never being regained. Simple ulceration is not uncommon in the opaque patches, and in later life epithelioma frequently attacks the diseased mucous membrane. The treatment of this condition is very unsatisfactory. Perchloride of mercury lotions are often of use; they should be used in the strength of gr. ½ to gr. j.

to the ounce, and the patient should be directed to take a small quantity into the mouth and thoroughly pickle the tongue in it. Internally iodide of potassium produces most effect. If it fails, and the patient is in a state to stand it, a course of mercury may be tried.

The tongue is affected also in some cases by *diffuse overgrowth of its connective tissue*, occurring in patches and extending deeply into its substance from the mucous surface. More commonly it is the seat of *gummata*. These form, as a rule, in the muscular substance of the organ, and sometimes in the fibrous septum. They form indolent tumours, gradually reaching the mucous membrane, and implicating it. They run the usual course of *gummata*, and when they soften and open on the surface, leave deep foul ulcers, which may be mistaken for squamous carcinoma. The diagnosis of these affections, and their treatment, will be more fully considered under the diseases of the tongue.

The syphilitic diseases of the *Throat* are amongst the most common manifestations of constitutional syphilis, and frequently occur early. They present three chief forms, occurring in the early secondary, the later secondary, and the tertiary stages of the disease.

The early secondary eruption is a deep red exanthematous efflorescence of the soft palate and pillars of the fauces, either without ulceration or with but superficial abrasion. It occurs about the period of the invasion of the roseola and requires no special treatment. In the later secondary period, corresponding to that at which the squamous and papular eruptions appear on the skin, ulceration of the tonsils is very common. It appears first as white patches and mucous tubercles, in the centre of which the ulceration commences. The ulcers have sharply cut edges, often somewhat undermined. Superficial mucous patches may surround the ulcer, and extend on to the soft palate and pillars of the fauces. These ulcerations give little or no pain in most cases, and never cause any serious destruction of the mucous membrane. They require the ordinary treatment of constitutional syphilis, and locally may be occasionally touched with the perchloride of mercury solution (gr. ij to ʒj), or with nitrate of silver.

The tertiary ulcerations of the pharynx are far more serious. They seldom occur till three or more years after infection, and then only in patients in a debilitated state of health. The ulcers commence by a gummatus infiltration of the mucous membrane, similar in character to the tubercular syphilides of the skin. This breaks down, and a serpiginous ulceration starts from the affected spot, and may spread widely and rapidly. The ulcer has an irregular form and a foul grey surface, and may destroy in a few weeks a great part of the pillars of the fauces or of the soft palate. When the soft palate is destroyed, there is usually considerable difficulty in swallowing, and speech becomes altered. This form of ulceration occurs sometimes simultaneously with rupia on the skin, and requires the same constitutional treatment, the use of tonics being generally indicated. The best local application is a gargle, composed of corrosive sublimate, gr. iv; hydrochloric acid, ℥ viij; and water, ʒx. If the patient cannot gargle, or if the treatment has no effect, corrosive sublimate lotion (gr. ij to ʒj) may be carefully applied with a camel's hair pencil. Dusting the surface with iodotannin often has a most excellent effect. It may be used in conjunction with the perchloride lotion or gargle. It is important to remember that gargles of the perchloride of

mercury cannot safely be used of a greater strength than a quarter to half a grain to the ounce of water; stronger preparations must be applied with a brush. In very obstinate cases cyanide of mercury is often useful; it may be used as a solution of the strength of 5 to 10 grains to the ounce, which must be applied with a brush by the Surgeon himself.

When the ulcers heal, the contraction of the cicatrices may give rise to *stenosis of the pharynx*. This may occur in three situations: 1st, between the top of the palate and the posterior wall of the pharynx, so as to cut off the nasal portion of the latter; 2ndly, between the soft palate, the walls of the pharynx and the tongue, and 3rdly, across between the pharynx and the posterior wall of the larynx. This stenosis is probably the result of ulceration of the opposite mucous surfaces; but it is often out of all proportion to the extent of the ulceration. It may gradually increase until the contraction becomes so great that swallowing is seriously impeded and breathing is carried on with difficulty.

In the second and third forms of the contraction it becomes necessary, in order to enable the patient to swallow and to breathe, to dilate the opening. This, if the stenosis be not too tight, may be done by simple dilatation by means of bougies. If very contracted, its edges should be carefully notched before dilatation. Before doing this it may be well to perform tracheotomy as a prophylactic measure, averting all danger of suffocation and spasmodic irritation during the manipulations in the pharynx.

Syphilitic ulcerations have been described as occurring also in the *trachea*, and leading to stricture of that canal.

The mucous membrane of the *larynx* is frequently affected both in early and in advanced syphilis. The affections are similar to those of the fauces and pharynx. During the early exanthematous eruptions there may be some catarrh causing hoarseness and cough. Later on flat mucous tubercles may appear, but ulceration is rare. They disappear under treatment, leaving no effects behind. In the tertiary stage the most extensive ulceration, leading to destruction of the epiglottis and vocal cords, with necrosis of the cartilages, may take place. There is usually great thickening of the aryteno-epiglottidean folds, not unfrequently complicated by the formation of submucous gummata. If the patient recover, the opening of the glottis may be so far closed as to necessitate tracheotomy, and the use of a tube for the remainder of life. The symptoms and treatment are more fully described with *Diseases of the Larynx*, Vol. II.

The *Nose* is often extensively affected in constitutional syphilis, especially in individuals who are addicted to drink or much exposed to changes of temperature, and who are unable to pay proper attention to their treatment. The mucous membrane becomes chronically thickened, and this is accompanied by discharge of blood and pus, coryza, and habitual snuffling. In other cases ulceration takes place, with a very fetid odour of the breath, and the formation of thick crusts on the septum, or between this and the alæ. This ulceration is very persistent and troublesome, and usually requires mercurial treatment, with the local application of strong nitric acid, or of the acid nitrate of mercury, to arrest its progress. In many cases ulceration will rapidly proceed to destruction and perforation of the septum, or necrosis of the spongy bones, the vomer, and ethmoid: sometimes excavating the whole of the interior of the nose, hollowing it out into one great chasm. When this

happens, the nasal bones are usually flattened, broken down, or destroyed, the alæ and columna ulcerating away, so as to give rise to great disfigurement. In other cases the hard palate is affected, and perforation takes place into the mouth. Occasionally the disease extends to the bones of the base of the skull, and in this way may occasion impairment of vision, epilepsy, or death. Cerebral symptoms, however, do not necessarily occur when the base of the skull is implicated. In 1870 I removed the whole body of the sphenoid from the nasal cavity of a man who had never suffered from any disturbance of the cerebral functions.

The *Treatment* of these nasal affections must be conducted in accordance with general principles. In many cases mercurial fumigation is extremely useful, though as a rule iodide of potassium has more effect. Iodoform sniffed up the nose, either pure, or diluted with nitrate of bismuth or starch powder, is more efficient than any other application in neutralising the intolerable stench caused by syphilitic disease of the bones of the nose. The cavity must also be washed out twice a day by means of a nasal douche. The dead bone must be removed when loose. (See *Diseases of the Nose*, Vol. II.)

The mucous membrane of the *Rectum* is not unfrequently affected in syphilis. In the early stages of the disease mucous tubercles are common at the anus. Small superficial ulcers, similar to those on other mucous membranes, may also be met with. These are not, however, of serious importance. The tertiary affections of the rectum, on the other hand, are always serious and often fatal. They occur most frequently in women. Two conditions are usually met with together—fibroid induration of the coats of the gut and ulceration of the mucous membrane. Submucous gummata are very rare. The induration of the coats of the gut, as a rule, precedes the ulceration; it commences as a fibroid overgrowth in the submucous tissue, starting from the region of the anus and extending upwards. The new tissue, as it develops, contracts like that of a scar, and thus the wall of the gut becomes indurated and the canal narrowed. In the later stages the fibroid growth extends into the muscular coat, and the peritoneal covering may be thickened and opaque. The thickening of the submucous tissue interferes with the proper vascular supply of the mucous membrane, and ulceration follows. The ulcers have a foul grey floor and slightly raised edges. They may slowly perforate the gut into the vagina or peritoneum; but general peritonitis is rare, as from the slowness of the process firm adhesions to surrounding parts have usually formed before perforation takes place. (See *Syphilitic Stricture of the Rectum*, Vol. II.) As the induration of the coats of the gut at first causes but little inconvenience, the patient seldom comes under the care of the Surgeon till some ulceration has taken place. In some cases serpiginous ulceration may be the primary change; but these are certainly the less common.

4. **Syphilitic Iritis** usually occurs during the first year after infection and often in people who are otherwise strong and healthy. The ordinary symptoms of iritis, somewhat modified, characterize the affection. The patient complains of dimness of sight, pain in the eye, and often of very severe circumorbital or hemieranian pains. On examining the eye, the conjunctiva will be found to be slightly injected, and a zone of pink vessels to be seated in the sclerotic, close to the cornea: the aqueous humour has lost its transparency, giving a muddy look to the eye, and the colour of the iris is altered.

The pupil is diminished in size and irregular in shape, usually angular towards the nasal side, and small yellowish or brownish nodules of lymph may be seen on the surface of the iris. If the case be left to itself, or be improperly treated, it may advance to disorganization of the globe, and to permanent loss of sight. The retina often becomes affected, and inevitable blindness results.

The *Treatment* consists in local depletion by means of cupping and leeches to the temples, and the administration of mercury and opium internally, at the same time that atropine drops are put frequently into the eye. Most commonly, as the mouth becomes affected by the mercurial, the eye will clear, the lymph becoming absorbed, and the pupil regaining its normal shape and colour. In some cases, however, a chronic inflammation continues: here the best effects result from the administration of small doses of perchloride of mercury, with repeated blistering to the temples; and, in a later stage, soda and bark may advantageously be given.

Fig. 100. Syphilitic Periostitis of Tibia, resulting in the formation of a Pustiform Nodule.

5. Syphilitic Diseases of the Bones.

—The bones are liable to suffer both in the secondary and the tertiary stages of syphilis.

In the secondary stage aching pains in the bones are not uncommon. They are worse at night, and may be unaccompanied by any recognizable change of structure.

The characteristic bone diseases of syphilis are usually delayed till the tertiary stage, some two years or more after infection. By some Surgeons the graver forms are said to be the result of the administration of mercury, rather than of the syphilis for which the drug is given. This doctrine I believe to be entirely without foundation. That they are met with in syphilitic cases in which no mercury has been given, there can be no doubt. I have had under my care patients with extensive disease of the cranium and of the clavicle, whose syphilis had been treated throughout on the non-mercurial plan. One patient especially, a soldier from whom I removed portions of the

cranium and of the clavicle for necrosis accompanying constitutional syphilis, had been treated in a military hospital without mercury. I have never seen or heard of mercury producing necrosis in any bones, except those of the jaws, when given for diseases other than syphilis. No doubt diseases of the bones are especially apt to occur when the patient's constitution has been broken down by any means; and an improperly conducted mercurial

course may have this result. They occur usually after the patient has passed through the whole course of the less severe syphilitic affections, such as those of the skin, mucous membrane, and throat. The affections of the bones, however, may in some cases declare themselves at the same time as the affections of the skin and mucous membranes. They occur more commonly amongst the poorer classes, especially those who are exposed to atmospheric vicissitudes, and chiefly in strumous constitutions.

The diseases to which the bones are liable as a consequence of syphilis are the following :—

Syphilitic Periostitis or Node.—This consists of a localized inflammation of the periosteum, usually affecting one bone only, but sometimes many. The inflammation is accompanied by exudation into and under the membrane; the exudation may be absorbed, and the part restored to its normal condition, but more commonly it is partly or entirely developed into new bone, and thus a permanent thickening may remain (Fig. 405). In the early stages the new bone is soft and spongy, and is sharply separated from the compact bone beneath, which, beyond some slight superficial rarefaction from enlargement of the Haversian canals, shows no sign of change. As time goes on, however, the new bone becomes more compact till at last it seems merely a part of the compact tissues which at the affected spot may be a little denser than natural. Nodes may occur on almost any of the bones; but they are most commonly met with on the tibia, the clavicle, or the bones of the forearm. They form elongated, uniform, elastic or hard swellings, usually tender on pressure, and generally but little painful during the day; but at night the aggravation of pain is peculiarly marked, and constitutes perhaps the most distressing symptom. They cause no redness of skin and have no tendency to suppurate.

Sclerosis of Bone.—This corresponds to the diffuse overgrowth of fibroid tissue in other parts. It usually affects one of the long bones or the cranium. The bones become increased in size and density. The new osseous tissue is formed on the surface from the periosteum, but does not show the distinct separation from the old so clearly noticed in the ordinary node; the growth is, moreover, not limited as in a node, but widely diffused as through the whole shaft of a long bone or throughout the vault of the skull. At the same time that new bone is formed on the surface a similar change may occur internally till the medullary canal becomes gradually filled with dense new bone (Fig. 406). The symptoms of this affection are merely the steady increase in size, with obscure aching pains, worse at night.

Gumma of Bone.—These never occur alone, but are always associated with the periosteal node or with sclerosis of the surrounding bone. They most commonly form superficially, and are at first indistinguishable from the ordinary node; in fact, as before pointed out, the gumma in its commencement is identical in its nature with the diffuse syphilitic overgrowth of fibroid tissue, differing merely in its localization and intensity and in its tendency to pass

Fig. 406.—Syphilitic Sclerosis of Tibia. Transverse section showing Medullary Canal almost obliterated by dense new bone.

degeneration and softening. A subperiosteal gumma runs the ordinary course of such growths; if unrelieved by treatment it gradually increases in size, approaches the skin superficially, and extends into the bone beneath; finally, it softens, the skin gives way, the slough is discharged, and a deep ulcer is left, at the bottom of which spongy ulcerating bone is exposed. This forms the most common variety of *syphilitic caries*. In the cranium the gumma may completely perforate the bone, but more commonly it is associated with great sclerosis of the vault of the skull, the thickened bone being hollowed out and worm-eaten in parts corresponding to the situation of the gummata. Occasionally the gummata form on the internal aspect of the skull, and may give rise to cerebral symptoms. Gummata of bone form rounded flattened tumours, accompanied with aching pain usually worse at night. After a time they soften, and may then resemble abscesses. However soft they may become, they must on no account be opened, as absorption may take place even after distinct fluctuation is present.

Syphilitic Necrosis may arise in various ways. In the vault of the skull it is

Fig. 407.—*Syphilitic Necrosis of Frontal Bone.* The sequestrum, which has completely separated, has a worm-eaten surface, the result of the inflammation of the bone which preceded its death.

most commonly due to an exaggeration of the process of sclerosis, by which the Haversian canals become obliterated to such an extent that death of the bone follows. The sequestra thus formed are often of considerable size, sometimes reaching that of the palm of the hand (Fig. 407). They are composed of dense hard bone, much thicker than the normal skull, and always more or less worm-eaten on the surface. This appearance is due to the previous existence of subperiosteal gummata which have softened and been thrown off. The skin of the scalp having been implicated in the gummata is destroyed partly by their softening and partly by subsequent ulceration, so that the surface of the sequestrum is usually bare and exposed. The process of separation is very slow, often lasting many years. Cerebral symptoms may be present, but are quite as often absent. Necrosis of the bones of the base of the skull may arise in the same way, or may result from ulceration of the mucous membrane of the nasal cavity or pharynx by which they are in many parts thinly covered. The tertiary ulcerations in the mouth and nose also may be

followed by necrosis of the hard palate, of the turbinate and ethmoid bones ; but it is a remarkable fact that the hard palate is not nearly so frequently affected as the nasal and spongy bones. In consequence of this destruction of bony tissue, the nose may fall in, or a communication may be established between the nose and the mouth through the hard palate. Syphilitic necrosis may also affect the alveolar processes of the jaws. It is very uncommon in the long bones.

Syphilitic Caries, or ulceration of bone, is most commonly the result of the softening of a periosteal gumma, but it may be due to the extension of a superficial ulcer to the bone in thinly covered parts. The caries is rarely uncomplicated ; usually, the surrounding compact bone is sclerosed, or in the neighbourhood of the ulcer there may be a considerable formation of new bone

Fig. 408.—Syphilitic Caries of Frontal Bone. The surface of the bone is extensively wormeaten and eroded. Above the right orbit there is a shallow depression which has resulted from the healing of a carious patch.

from the periosteum. In other cases the process is a combination of necrosis and ulceration ; the sequestra being surrounded by a zone of ulceration extending a considerable distance from the dead bone and not closely limited to its edge, as in the process of separation of a single piece of dead bone. Syphilitic caries is most common in the skull (Fig. 408), but it is met with also in other parts. The upper part of the sternum is not an uncommon situation. It is also met with in the extremities. I have twice seen a peculiar form of caries of the cancellous tissue of the head of the tibia in old syphilitic cases. In both cases, which were very similar, the patients had been affected for a length of time with nodes of the tibia, as a consequence of long antecedent syphilitic taint. A chronic abscess eventually developed over the head of the bone, leading to a carious cavity. I exposed this and gouged the diseased bone away ; it was peculiarly dry, light, and almost flocculent, if such a term can be

applied to bone. Both patients recovered well from the operation; but one of them, a female, died two years afterwards of epilepsy, consequent on syphilitic gummata of the dura mater.

Both in acquired and in hereditary syphilis the bones of the fingers and toes are sometimes attacked, giving rise to the condition known as *syphilitic dactylitis*. It most commonly assumes the form of gummatous periostitis, often followed by softening of the new tissue and necrosis of the phalanx. The affected bones are much enlarged.

From the foregoing description it will be seen that the diseases of bones due to syphilis are all modifications of the same process which characterizes the disease elsewhere in its tertiary stage, namely an overgrowth of the connective tissue. The new tissue accumulates in some places in such masses as to form a distinct tumour, the gumma, which being imperfectly supplied with blood tends to degenerate. The node and the uncomplicated sclerosis of bone form the simplest stage of the process; the formation of gummata is the next advance; necrosis is an accident due to exaggeration of the sclerosis, or to exposure of the bone from softening of the gummata, and caries results as from the latter condition. It is not surprising, therefore, that we meet with these various effects combined in every possible way; the gumma is always surrounded by periostitis with or without the formation of new bone, caries and necrosis occur mixed together, and new growth and destruction may go on side by side.

The *Constitutional Treatment* of syphilitic diseases of the bones is that already recommended for the tertiary stage of the disease. Mercury is admissible only if the patient is otherwise in good health. Usually the iodides of potassium or sodium give the desired relief when administered in sufficiently large doses. *Locally* the treatment varies with the form assumed by the disease. The simple node usually requires no local treatment. If it is very chronic and painful, blisters will almost always give relief. If this fail and the case proves very intractable, and especially if there is considerable formation of new bone, I have found the greatest advantage result from cutting down upon the enlarged, thickened, and tender bone, and by means of a Hey's saw making a deep cut into it about one and a half or two inches in length parallel to its axis, and down to the medullary canal. By this operation the tension is at once relieved, and the pain effectually and permanently removed. In syphilitic *necrosis* the necrosed bone should be separated as it becomes loose; the local irritation depending on its presence then subsides. When the bone has fallen into a *carious* state, the unhealthy surface should be thoroughly scraped with a sharp spoon, and the cavity dressed with iodoform or iodide of starch ointment.

Syphilitic disease of **Joints** is not of very frequent occurrence. Pains in the joints are not uncommon during the very earliest stages, before the appearance of the eruptions; and during the secondary stage some slight synovitis has occasionally been observed, apparently due to the disease, but these conditions are of no great importance. Jonathan Hutchinson, Jun., has paid much attention to this subject, and has collected many recorded cases of joint disease in tertiary syphilis.

Any of the larger joints may be affected, but the knees are most frequently diseased. Gummata may form in the synovial membrane, capsule, or surrounding structures, whilst in other cases the synovial membrane undergoes

uniform thickening. In either case there is likely to be considerable subacute or chronic effusion into the joint, and this may occur without any other signs of disease. Periosteal thickening of the articular ends of the bones may occur. These joint affections are usually accompanied by considerable nocturnal pain, but a painless chronic synovitis may be met with. Complete cure may follow suitable treatment, but a varying amount of stiffness of the joint often remains.

Gummatous infiltration of the **Bursæ** is an occasional symptom of tertiary syphilis. In a case recently in University College Hospital considerable solid enlargement of each bursa patellæ was present in a woman whose palate showed unmistakable evidence of old syphilitic ulceration. The swellings completely disappeared after a course of iodide of potassium.

7. Syphilitic disease of the **Muscles and Tendons** has been described by Bonisson and others. These structures are not unfrequently affected, but less often than the bones. In the muscles diffuse sclerosis has been described, but it is exceedingly rare. Gummata are much more common: they form ill-defined tumours in the substance of the muscle, growing slowly, with some aching pain and tenderness. They are less prone to soften than similar growths in more superficial structures. Elongated tumours resembling nodes have been described as affecting the tendons, and gummata are occasionally observed in their substance. They resemble similar growths elsewhere, and are best treated by iodide of potassium.

8. **Syphilitic disease of the Testicle.**—This assumes two forms—the diffuse overgrowth of the intertubular connective tissue, and the formation of gummata. These diseases affect the body of the gland, and are always met with as tertiary phenomena. The symptoms, pathological appearances, and treatment, are fully described with Diseases of the Testicle, Vol. II.

9. **Syphilitic Ovaritis** is a disease that I believe I have on several occasions met with. The history of the cases has been uniformly as follows: an attack of syphilis long before; various constitutional symptoms running through secondary and tertiary stages; inflammatory congestion of one ovary, as determined by vaginal and rectal exploration; eventual cure by means of leeching and the perchloride of mercury and bark or iodide of potassium—in fact, a condition of things closely resembling what occurs in syphilitic disease of the testicle.

10. **Visceral Syphilis.**—Our knowledge of the syphilitic diseases of internal organs is of modern origin. "Visceral Syphilis" was not only unknown to, but unsuspected by, so acute an observer as John Hunter, and the syphilographers of the early part of this century make no mention of it. To Dittrich, Lancereaux, Wilks, Bristowe, and Moxon we are indebted for the establishment of the fact that, after external manifestations of syphilis have in a great measure, if not entirely, disappeared, and the disease has entered its tertiary stage, gummata may form in most, if not in all, the internal organs, producing serious functional disturbance, and leading to organic changes of the most extensive and fatal character.

It may now be taken as a fact incontestably established by numerous pathological observations, that there are few, if any, organs that escape the ravages of syphilis; and although there may be a doubt whether some of the forms of disease met with in certain organs, as the liver, lungs, and spleen, and described as syphilitic, may not in reality be due to non-specific disease, to which, as well

as syphilis, they are common, there can be no doubt of the fact, that when gummata are met with in internal organs, the syphilitic nature of the disease is established.

The general pathological characters of the changes in the viscera and in the arteries have already been described (p. 1132). The complete description of the visceral affections belongs to Medicine rather than to Surgery, and it will be sufficient here briefly to indicate their nature.

In the *heart*, syphilitic growths have been found on the endocardium, less frequently in the valves: and two forms of myocarditis of syphilitic origin—one circumscribed, the other diffuse—have been described by Lancereaux.

The *lungs*, *liver*, and *spleen* are all liable to syphilitic growths. As a general rule, these may appear under two forms—either as gummata or as a diffuse interstitial growth, which in the liver may simulate cirrhosis, and in the lung some of the forms of “fibroid phthisis.” These syphilitic visceral diseases not unfrequently run a fatal course; rarely, however, destroying the patient before the age of 35 (Wilks). The diagnosis of the specific nature of the affection must always be open to doubt, except in those cases in which the history of the infection has been continuous, and some of the more superficial and easily recognizable syphilitic affections are associated with the visceral forms of the disease. So far as treatment is concerned, our chief reliance must be placed on iodide of potassium, or if that fail, on the careful administration of mercury.

11. Syphilitic disease of the **Mamma** is of extreme rarity, and little is definitely known about it. Gummata have been described by Henning as having been observed after death in one case.

12. There is no more distressing form of syphilitic disease than that which affects the **Nervous System**. The brain and spinal cord and their meninges, and the trunks of the nerves, are all liable to suffer.

Syphilitic affections of the nervous system have been described as occurring during the first year after infection, but such cases are of extreme rarity: as a rule they do not manifest themselves till after the end of the second year, and they may appear as late as the tenth, or, it is said, even the twentieth. They occur at all ages, and are not uncommon in young men. I have often seen syphilitic disease of the nervous system about the age of 25 or 30. It is the common cause of paralysis in early manhood. The development of the symptoms may follow some slight accident—a fall upon or a strain of the back, or over-exertion in walking, riding, or running. The primary disease has often been slight, the secondary symptoms trivial; and indeed so great importance may have been attached to the venereal infection until the manifestations of its destructive effects on the brain and cord. In other cases the patient may be suffering, at the time of the appearance of the nervous symptoms, from severe tertiary affections, such as *ecthyma*, *rupia*, *serpiginous* or *sloughing* ulceration of the throat, or painful nodes on the cranium, vertebral column, or long bones. Habitual excess in alcoholic stimulants forms a powerful predisposing cause of syphilitic disease of the nervous system.

The pathological changes in the nervous system are of the same character as those in other parts of the body. They consist of chronic inflammation, with thickening of the meninges; overgrowth and induration of the interstitial tissue of the nervous centres and nerves; the formation of gummata; and the obstructive changes in the arteries already described (p. 1132). Certain clinical

degenerative diseases of the cord, especially sclerosis of the posterior columns (locomotor ataxy), follow syphilis with sufficient frequency to justify the belief that the disease may stand in some causal relation to them.

Syphilitic disease of the brain declares itself by two chief symptoms, which may occur either separately or conjoined; viz., paralysis and epileptic convulsions. Before these definite signs manifest themselves, various premonitory symptoms may have existed. The most common is severe pain in the head, usually fixed in one spot, often worse at night; there may also be some mental disturbance and want of sleep.

Paralysis from syphilitic disease of the brain usually assumes the form of hemiplegia. It may be preceded by paresis of special parts, as of one limb or group of muscles, which may be temporary in its character. The nerves of sensation may also be affected. Special cranial nerves may suffer. The third, fourth, sixth, and seventh are often early attacked, giving rise to ptosis, strabismus, or facial palsy. I have never seen the fifth nerve paralysed in syphilis, but cases have been recorded in which it was affected. Oculo-motor paralysis in some form, on the other hand, is very frequently the result of syphilis, and when it occurs in young men it should, however passing and slight, always attract the most serious attention, as it is often the precursor of more general paralysis. The early affection of the nerves that lie in the wall of the cavernous sinus is probably due rather to syphilitic thickening of the dura mater, with which they are in such close relation, than to an affection of the substance of the brain.

If the patient be hemiplegic, he may be completely so, but very often the paralysis is limited to one limb, or may be irregular in its degree in different parts. It is often accompanied by rigidity. These differences are due to the situation of the disease in the brain. Gummata in the dura mater or bone in the region of the cortical motor centres may cause irregular paresis or complete paralysis of the parts corresponding to the affected centre. Syphilitic growths in the deeper parts of the brain may give rise to complete hemiplegia, coming on gradually, and occlusion of a cerebral artery affected with the changes already described as occurring in syphilis may lead to the same symptoms being developed suddenly. Aneurisms of the cerebral arteries, ending in rupture with the ordinary signs of apoplexy, may also occur as the consequence of syphilis.

Optic neuritis is very common in syphilitic disease of the brain, especially in cases of very chronic meningitis, or when gummata are present.

Epileptic seizures are common in syphilitic affections of the brain. They generally result from chronic thickening of the dura mater, or the development of gummata in the membranes or substance of the brain in the region of the cortical motor centres. Gowers states that they "differ from the ordinary convulsions of epilepsy, especially when the motor zone of the cortex is diseased, in the deliberate onset of at least some of the attacks; in consciousness being lost late, and in the patient being aware of the local onset of the convulsions in the face, hand, or foot. In other cases, probably when the sensory rather than the motor region is diseased, a sensory aura, often involving the special senses, may herald the fit." According to Gowers, syphilitic epilepsy is recognized by its appearing usually at an age when the idiopathic disease seldom commences, by the headache between the fits, by the coincidence of optic neuritis, and often of local paralytic symptoms, and by the early and

often progressive mental disturbance. The fits are often of a very violent character, and followed by coma. But dangerous as these attacks may become, there is always a prospect of cure by proper treatment, although in some cases the fits may persist even after there is every reason to believe that the syphilitic growth which originated them has been absorbed. In other cases again, the mental powers undergo gradual deterioration, delusions manifest themselves, and the patient falls into a state of semi-imbecility.

There is no more pitiable object to be seen than a man, young or in the prime of life, suffering from syphilitic disease of the nervous centres—affected by ptosis, with one eye staring and immovable or squinting, the face distorted, the lip dropped and saliva dribbling, defective in his articulation, straddling and insecure in his walk, dragging one leg behind him, at times the victim of the most severe epileptic paroxysms, often covered with rapid sores—he is truly a fit object for commiseration rather than reproach.

Syphilitic disease of the Spinal Cord.—The most common syphilitic lesions of the cord are chronic meningitis and the development of gummata, which arise most frequently in the membranes, but sometimes originate in the substance of the cord itself. The gummata are usually small, rarely exceeding half an inch in diameter, though Wilks has recorded a case in which the tumour reached the size of a large filbert. Most commonly only one gumma is met with, but cases have been described in which numerous small tumours—the size of millet-seeds were present. When the disease assumes the form of meningitis, there is usually considerable thickening of the dura mater, but the other membranes also may suffer, and the superficial parts of the cord be implicated. The roots of the nerves are compressed as they pass through the thickened membranes. The disease may be widely diffused, but is more commonly limited in extent, the region of the lumbar enlargement being especially prone to be affected.

Syphilis may also be the cause of disseminated chronic myelitis, leading to sclerosis, and Gowers has brought forward a large amount of evidence to show that locomotor ataxy (sclerosis of the posterior columns) may have its origin in this way; about one-half of the cases of this disease occur in patients who have suffered from constitutional syphilis.

The *Symptoms* of syphilitic disease of the cord come on gradually. There is pain either in the back opposite the seat of disease, or referred to the parts supplied by the nerves arising from the affected portion of the cord. Various affections of sensation are commonly met with; there may be numbness, tingling or "pins and needles," or localized spots of hyperæsthesia or anæsthesia. Paralysis of one limb or a part of a limb, or complete paraplegia, may form a prominent symptom. Wasting occurs only in those muscles which are paralysed in consequence of damage to the part of the cord from which their nervous supply is derived, or of pressure on the roots of the nerves. Thus, although there may be complete paraplegia, the wasting may affect only certain groups of muscles. The reflex function of the cord is abolished in the diseased part, but lower down it may be increased; thus in disease in the dorsal region there may be exaggerated reflex movements in the lower limbs. Rigidity of muscles is common, spasm comparatively rare. When the paralysis is unilateral, the modifications of sensation will be on the same side as those of motion when the roots of the nerves are affected, but on the opposite side when the condition is due to the growth of a localized tumour,

either in the substance of the cord or in its membranes. The symptoms may be rendered very irregular and complex by the co-existence of various lesions, such as irregular patches of chronic meningitis, or a gumma combined with meningitis, or more than one gumma in different parts of the cord; and this irregularity of the symptoms may be still further increased by simultaneous disease of the brain and its membranes. The age of the patient, the history of syphilis, and the irregularity of the symptoms often render the diagnosis comparatively easy.

The *Nerves* are comparatively seldom affected, though gummata have been met with growing from the connective tissue forming their sheaths. These have been observed almost exclusively in the cranial nerves.

In the *Treatment* of syphilitic disease of the central nervous system, if not too far advanced, there is fortunately much to be done for the patient's relief, if not complete cure. Mercury in some form, more especially the perchloride with decoction of cinchona, if not previously fully used, should have a fair trial. Iodide of potassium in gradually increasing doses—up to fifteen or twenty grains, three times a day, if the patient can stand it—should be given at once in those cases in which the patient has already had a full course of mercury, or in which the constitutional state does not justify the administration of mercury at the time the nervous symptoms set in. Counter-irritation by means of blisters will occasionally be found useful. The epileptic convulsions may be relieved by bromide of potassium or of ammonium, but these must not be given to the exclusion of the iodides. Under this treatment cases at first apparently hopeless may rapidly recover, but when the disease is far advanced, with the formation of gummata of large size, the prognosis becomes very bad.

INFANTILE, CONGENITAL, OR INHERITED SYPHILIS.

Chancres on the labia of the mother may possibly infect the child at birth, just as they may inoculate the hand of the accoucheur; but syphilis thus contracted by the infant is not the form of the disease that is described as **Infantile Syphilis**. This is a truly hereditary infection, transmitted to the infant at the time of its conception, or communicated to it through the medium of the mother during intra-uterine life, and existing as a constitutional affection at the time of its birth. Though we may believe that syphilis is not easily eradicated from a system into which it has once been received, and that under certain conditions it may readily be transmitted to the offspring, yet I think that we are still ignorant of the amount and nature of the constitutional affliction of the parents that are necessary for the development of syphilis in their children, and that we are certainly not warranted in concluding that a parent who has been, or even who is actually affected by constitutional syphilis, must necessarily have a syphilitic family; although the probability undoubtedly is that the offspring will be affected. I have had under my observation a gentleman whom I had attended for secondary syphilis, and who, contrary to my advice, married some years ago; and, though he has since then suffered from psoriasis of the hands, mucous tubercles, fissures on the lips and tongue, and syphilitic disease of the testicle, yet his wife has borne a perfectly healthy family, not only without any syphilitic taint, but without any apparent constitutional cachexy.

When the parents are syphilitic, the foetus frequently fails to arrive at maturity. This may be due to disease of the placenta, or of the umbilical cord, or to the direct action of the syphilitic virus on the foetus itself. In the placenta extravasations of blood, fatty degeneration, and the formation of caseous, and occasionally of calcareous masses, are the most common abnormal conditions observed. In the cord the vessels are occasionally found to have undergone changes identical in character with those already described as taking place in the arteries of the adult (p. 1132). The foetus itself also shows evidence of disease in the great majority of cases in which it perishes before arriving at maturity, or is born dead at the full time. Mewis states that an examination of ninety-two syphilitic foetuses showed the spleen to be diseased in seventy-two, the bones in sixty-four, the liver in fifty-six, the pancreas in fourteen, the suprarenal bodies in eleven, the lungs in three, and the skin in one only. In consequence of these diseases of the placenta and the foetus, it often happens that early abortion or miscarriage takes place. Many consecutive miscarriages may take place in consequence of the parents being affected with constitutional syphilis. It is a common history in these cases that the period at which miscarriage takes place becomes later in each succeeding pregnancy, until at last, perhaps after a dead foetus has been delivered at full term, a living child may be born bearing evidence of inherited syphilis. Such a history is very characteristic of syphilis, even if the parents have ceased to show any visible signs of the disease. When the parents are known to be syphilitic, if they be treated by a mercurial course, miscarriage can frequently be prevented, though the child may show some signs of the disease.

The offspring of syphilitic parents as a rule develop symptoms resembling in most points the acquired form of the disease. It is not impossible, however, that the taint may manifest itself by an impaired state of the constitution, and that syphilis may thus be a predisposing cause of scrofula or rickets. There is, however, no satisfactory evidence that this is the case.

The **Period at which the Symptoms manifest themselves** varies greatly. As a rule, a syphilitic child when born alive, though often small, badly developed, and cachectic in its appearance, shows no definite manifestations of the disease; but in the course of a few weeks, usually from two to eight, the symptoms declare themselves. Diday and De Meric collected a large number of cases, in most of which the signs of the disease developed in the fifth or sixth week. Many betrayed their disorder in the first month; and in some few it was delayed until the child had attained the age of three months. The earlier the disease shows itself, the more fatal are its effects. Children who manifest no symptoms till they are two or three months old usually recover their health in a short time.

The effects of inherited syphilis may also manifest themselves even in adult age. Hutchinson believes that this may take place without any signs of syphilis during infancy; this view, however, is not entertained by Berkeley Hall, and most other writers on the disease. They assert that though they may have been slight, some symptoms have in every case been present during the early months of life. These cases are rare, and the following which fell under my own observation is a good instance. The patient was a young woman, aged seventeen, who was covered with a marked squamous syphilis, with which she had been affected for several years. The mother told me

that, shortly after birth, evidences of infantile syphilis had appeared; that these had yielded to treatment, but that, as the period of puberty approached, the rash, which was undoubtedly syphilitic, had shown itself.

Symptoms.—The symptoms of inherited syphilis are sufficiently well marked in most cases, consisting principally of general constitutional disturbance, with affections of the skin, mucous membranes, bones, viscera, and eye, which more or less closely resemble the manifestations of acquired syphilis.

Constitutional Symptoms.—The first indication is often the atrophic and cachectic appearance of the child; this not unfrequently shows itself at birth, without any more definite signs of the disease. Such children are often small, shrivelled, wan and wasted when born; the face especially has an aged look, the features being pinched, the flesh soft and flabby, and the skin loose and wrinkled; the complexion has a yellowish or earthy tinge, which has been compared to that of *casse au lait*. These appearances are, however, by no means always present. Many syphilitic children are born apparently healthy and fat; but they soon emaciate when the cutaneous and other manifestations of the disease make their appearance a few weeks after birth. In slight cases, however, the child may remain fat and well-nourished, though anæmic, throughout the whole course of the symptoms.

Local Symptoms.—In the great majority of cases the most marked symptoms are due to the affections of the skin and mucous membranes. As in acquired syphilis the first appearance may be a roseolous eruption on the skin, but this is of short duration, and seldom clearly marked. The earliest marked feature is usually the appearance of *mucous tubercles*. These form at the angles of the lips, in the cavity of the mouth, in the pharynx, in the nose, at the anus, and wherever the skin is moist, as in the folds of the groin, and between the scrotum and thigh. They are of the same nature and appearance as those met with in acquired syphilis.

The affection of the **nose** is amongst the most constant and characteristic features of the disease, and is usually the earliest local sign that declares itself. There is much congestive swelling of the mucous membrane, with a secretion of thick yellow offensive mucus, causing the child to make a peculiar snuffling noise in breathing, as if it had a chronic catarrh. This symptom is so constant that it has given rise to the popular name of "the snuffles" which is applied to congenital syphilis. The degree to which the nose is affected varies considerably. In the mildest cases the symptoms merely resemble those of a slight cold; in the most extreme forms the discharge dries into scabs at the nostrils, beneath which ulcers may form; mucous tubercles develop on the membrane, and ulceration may follow, leading to disease of the bones, with flattening of the bridge of the nose. In all cases free breathing through the nose is interfered with, sucking consequently becomes difficult, and the trouble in feeding the child is correspondingly increased.

The **mouth** is similarly affected, but usually in a less degree. Radiating fissures, sometimes extending somewhat deeply, are common on the lips, especially at the angles of the mouth. The mucous membrane of the cheeks and tongue is covered with mucous patches, and sometimes with superficial ulcers.

The mucous membrane of the **larynx** is congested and swollen in most cases, and sometimes mucous tubercles may be formed at the opening of the glottis. The laryngeal affection is the cause of the hoarse cry which usually forms a marked feature in the disease.

The **Eruptions on the Skin** are usually most abundant on the nates, scrotum, and the soles of the feet; hence in examining a child supposed to be syphilitic these parts should always be looked at first. In moist situations the eruptions most frequently assume the form of smooth, flat mucous tubercles, varying in size from a pea to a threepenny-piece: they are slightly elevated, and covered with a slimy whitish secretion. Cracks or fissures are common at the anus as well as at the mouth. In the drier parts the eruption is often described as *squamous*, though it is not really scaly, but composed of smooth flat patches of a coppery red colour. These patches are often well-marked on the soles of the feet, and are followed by peeling of the cuticle.

A diffuse *erythematous* eruption is perhaps the most common, and may be difficult to distinguish from the simple intertrigo which is so common in infants about the nates as the result of irritation of urine, &c. The syphilitic eruption, however, often spreads to the calves and soles and upwards on to the back, and the rash is more uniform and confluent than is usually seen in the simple intertrigo.

Papular eruptions are not common. The *bullous* eruption, or so-called syphilitic pemphigus, is less common than those first mentioned, yet I have frequently seen it in syphilitic children. It appears in the form of vesicles which enlarge into bullæ about the size of a split pea, with a dusky coppery areola; they dry into brown scales or scabs, and commonly occur simultaneously with mucous tubercles in other parts of the body. The eruption is almost invariably present on the soles and palms: it appears early, and may be present at birth. The prognosis in all cases of bullous syphilide is very grave. The eruption has to be distinguished from the simple pemphigus which occurs in non-syphilitic children: this is probably a septic rash, and unlike the bullous syphilide, never appears on the soles of the feet.

A *pustular* eruption is also occasionally met with. The pustules dry early, leaving a black scab, beneath which ulceration may take place. It is met with only in very feeble children.

Subcutaneous gummata are met with occasionally in inherited syphilis, but seldom before the second year.

The *Hair* very commonly is thin, and is often lost from the posterior and lateral aspects of the head. The *Nails* are seldom affected, but may be brittle and grow irregularly.

When we consider the influence exercised by the syphilitic poison upon the skin and its appendages, the hair and nails, we should *a priori* have expected that the **teeth**, being developed from the same embryonic layer, would participate in the morbid processes induced by it in the allied structures. The fact of their doing so does not, however, appear to have attracted the notice of any observer, until Hutchinson directed the attention of the profession to this very interesting subject, and pointed out the destructive and space-effect produced upon the teeth by inherited syphilis. This injurious influence manifests itself both in the temporary and in the permanent teeth; but it is characteristic only in the permanent set. It must not, however, be supposed that in all cases of infantile syphilis the teeth are affected; indeed, in many instances they are not, and it has been particularly pointed out by Hutchinson that it is only when there have been attacks of syphilitic stomatitis, that we are to expect to meet with these abnormalities in the teeth.

The *temporary teeth* of syphilitic infants are cut early, are of bad colour,

and liable to a crumbling decay. The upper central incisors usually suffer early, and always first; then the lateral ones become carious and drop out; and lastly, in some cases, though rarely, the canines wear away so as to present a tusk-like appearance. In consequence of the early decay of the incisors, children are often edentulous, so far as these teeth are concerned, from an early age, until the permanent ones are cut.

The *permanent teeth* present the more marked characteristics of an inherited syphilitic taint; and in these, as in the temporary teeth, the disease declares itself chiefly in the central incisors of the upper jaw. These will be observed to be usually dwarfed, too short and too narrow, rounded at the angles, standing apart with interspaces or converging, and marked by a deep broad notch. They are of a bad colour, soft and crumbling, are slender, and readily wear down (Figs. 409—411). The characteristic features are the dwarfing and the central cleft in the free edge. In other cases the cutting edge of the incisor teeth is narrow, so that the teeth have a peculiar "pegged" shape.

Fig. 400.—Syphilitic Teeth (in a boy aged 12 years).

Fig. 410.—Two Central Syphilitic Incisors Deeply Notched (Hutchinson).

Fig. 411.—One Central Incisor Notched (Hutchinson).

The upper alveolar border is often narrow and the arch of the palate unduly high.

The **Bones** are very frequently affected in congenital syphilis, though until recently the changes that take place had been partly overlooked and partly confounded with rickets. The observations of Wegner, Parrot, Barlow, and others, have, however, clearly established the fact that the implication of the bones is second in frequency only to that of the skin.

Parrot states that the affections of the bones in hereditary syphilis assume two principal forms, one consisting in atrophy of the pre-existing structures, and the other in the development of new tissue. The Atrophic form he divides into two varieties. The first, to which he applies the term *Gelatiniform*, affects equally the cranium and the bones of the extremities. The bone is altered in colour, varying from a pale red or rose tint to different shades of yellow. The medulla becomes transparent, and is at last reduced to a network composed of vessels and delicate fibrillae, the meshes of which are filled with watery fluid. When the compact tissue is invaded it becomes rapidly

decalcified; the lamellae seem to melt away, and large spaces appear between them, filled with a gelatinous substance, like the altered medullary tissue. The second variety he terms *chondro-calcareous atrophy*. The most marked feature of this form is that the layer of calcified cartilage which naturally exists in the growing line between the shaft and the epiphysis assumes an abnormal thickness and loses all regularity in its outline. The calcified cartilage can be recognized by its density, brittleness, and chalky appearance. The formation of this brittle tissue renders the bone liable to fracture, and when the two forms of atrophy occur simultaneously this result is almost certain to take place. The fracture occurs always in close proximity to the epiphysis, and the accident is not unfrequently followed by suppuration, and from the close proximity to the joint suppurative arthritis may be set up. These fractures give rise to symptoms closely resembling paralysis of the affected limb, and Parrot has applied to the condition the name of *syphilitic pseudo-paralysis*. The limb hangs powerless, and, as a rule, there is singularly little pain, but the muscles respond readily to the faradic current. The looseness of the epiphysis can sometimes be readily recognized, and some fine grating crepitus may be present.

Fig. 412.—A tibia from a syphilitic child showing osteophytic growths.

The second form of disease of the bones in hereditary syphilis, to which Parrot applies the term *osteophytic*, is much more common. This also he divides into two varieties, according to the density of the new tissue. When this is hard and bony he terms it *osteoid*; when soft, *fibro-spongioid* or *rachitic*. The osteoid form of growth may be met with at any period of childhood, and possibly may commence before birth; the rachitic is never met with before the fifth or sixth month. The osteoid growth is composed of trabeculae, arranged more or less perpendicularly to the surface of the bone, separated from each other by medullary tissue; the new tissue contains large quantities of lime salts. It differs from normal bone in its brittleness and in its yellow or pink colour. In the rachitic form the new tissue is almost white, pearly, or yellowish in colour. It is fibroid in structure and very vascular. Various modifications between these two forms of tissue may be met with. Thus the osteoid tissue may be arranged in several layers, or spongy tissue may be found covering the harder tissue. The periosteum covering the new growth is always distinctly thickened, and adheres firmly to it. There is almost always a distinct line of demarcation between the new tissue and the healthy bone beneath. The thickness of the growth varies from one-tenth to three-eighths of an inch on the long bones, but it may exceed this on those of the skull. In extreme cases almost the whole skeleton may be affected, but more commonly the diseased condition is met with only in certain parts. The most common situations are the lower end of the humerus, the tibia, the femur, and the ulna, where, unless the child be very fat, it can often be recognized during life. In the rachitic form the long bones may undergo modifications in form from bending or fracture, as in rickets.

The bones of the **Skull** present changes of a very marked character. These most commonly consist of the formation of "bosses" of new bone, from the

outer table only, around the anterior fontanelle and along the line of the sagittal and interfrontal sutures. Between these bosses the sutures may at first form distinct sulci, but later on they are often bridged over, and premature union may take place. If the child dies the bosses will be found to be composed of soft bone, very red in tint, sometimes even of a dark maroon colour. If macerated the new bone is porous and granular in structure, and is often deeply grooved by vascular channels. There is little if any thickening of the periosteum. The anterior part of the skull may reach a third of an inch or more in thickness. The effect of these growths is to give the forehead the rounded prominent form which was pointed out by Hutchinson many years ago as being often associated with other signs of congenital syphilis in later life. Barlow and Lees have pointed out that the condition known as *cranio-tabes* is also met with in syphilitic infants, although it is by no means confined to them. In this the bones of the vault of the skull become extremely thin in circumscribed patches, so as to yield to gentle firm pressure, feeling like parchment beneath the finger. In some spots the bony material may entirely disappear, leaving only a thin membrane. These spots are most common in the occipital region, where the bone is exposed to direct pressure while the child is lying on its back, but they are also met with in the parietal bones. The bony growths are met with at any time during the first two years, but the irregularity they give rise to may be recognized at any age. *Cranio-tabes* occurs at an early period during the first year of life. Both conditions may occur in the same skull. In addition to the above diseases of the bones *gummata* are occasionally met with in the skull, and *dactylitis*, similar to that described as occurring in acquired syphilis, is not uncommon. Up to puberty chronic inflammation of various long bones, especially of the tibia, is occasionally met with in syphilitic subjects.

Attention was first especially drawn to an affection of the **Joints** in congenital syphilis by Clutton in 1846. It occurs usually between the ages of 8 and 15, and consists in a painless effusion into the knee-joints which is in some cases accompanied by thickening of the synovial membrane. It is not attended with any impairment of mobility. The synovitis is usually bilateral, although the affection rarely begins simultaneously in the two joints. It is interesting that the joint affection is frequently associated with the affection of the eyes to be next described: thus of 11 cases collected by Clutton, 10 were affected with active keratitis, and in 1 there was evidence of past mischief.

Under the name of **Chronic Interstitial Keratitis**, Hutchinson has described a disease which he believes to be uniformly due to hereditary syphilis. It occurs between the ages of 5 and 18, but may occur much earlier, even during the first year. It consists at first of a hazy condition of the cornea, giving it the appearance of ground glass, followed by vascularization, without any tendency to ulceration. The opacity commences in the centre, and both eyes are usually affected. The vascularity is not confined to the surface, but seems to pervade the whole thickness of the cornea. One eye is usually affected before the other. Under a carefully conducted course of mercurials and iodides, accompanied by tonics and good diet, the transparency of the cornea can usually be restored.

Chronic affections of the **Ear**, leading to deafness, are not uncommon in inherited syphilis. They occur sometimes in conjunction with interstitial keratitis in the eye. Their pathology is not yet certainly known.

The **lymphatic glands** show no special morbid conditions resulting from inherited syphilis. Affections of the **Viscera** in congenital syphilis are by no means uncommon. They assume the same forms as in the adult, namely, general fibroid induration of the affected organ and the formation of gummata, the former condition being the more common. The spleen in syphilitic children is in most cases somewhat enlarged and hard. The liver is affected next in order of frequency. Syphilitic disease of the lung is met with only in children born dead, or dying soon after birth.

The **testicles** occasionally present a uniform, smooth, hard, painless enlargement, affecting the body of the gland, and corresponding in every respect to the same disease in the adult.

The **nervous system** is less commonly affected, but gummata are occasionally met with in the brain.

Evidence of Congenital Syphilis in later childhood or adult life.—

The taint of congenital syphilis may manifest itself after the period of infancy by various chronic inflammations of bone, by diseases of the eye, and occasionally of the viscera; and as these present, as a rule, no very definite signs of their origin, it is important to remember the points by which the nature of the case may be established. In the history we must inquire for miscarriages before the birth of the patient, for signs of syphilis in previous children born alive, and for symptoms of the disease in the parents, such as prolonged sore throat, eruptions on the skin, loss of hair, and pains in the bones. With regard to the patient, we must ask the period at which birth took place: the appearance at birth, whether fat or thin; the occurrence of snuffles and sores on the bottom. In examining the patient, we must look for stunted growth; a flat or ill-developed bridge to the nose; and radiating scars at the angles of the mouth. The forehead must be examined for bosses in the region of the anterior fontanelle, and the humerus, femur, and tibia should be searched for thickenings or want of symmetry in the two sides. The eye also should be examined for interstitial keratitis, and the teeth for the appearances already described. All these signs are seldom present together, but enough to enable the Surgeon to come to a correct conclusion will always be found in any case in which the disease has been sufficiently severe to affect the patient after early childhood.

Prognosis.—If the child is born with signs of syphilis, it usually dies. Emaciation increases, and death takes place either directly from the disease or in consequence of some complication, as diarrhoea, bronchitis, or pneumonia. If the child is born apparently fat and well, the prognosis depends much on the period at which the symptoms appear; the later the appearance, the better the prognosis. Most cases recover in which the symptoms do not manifest themselves till after the end of the first month.

TREATMENT.—The occurrence of syphilis in the infant may be prevented by putting the infected mother on a mercurial course as soon as her pregnancy is ascertained; this indeed may be necessary in order to prevent miscarriage, but should be done cautiously, and by inunction rather than by mercury administered by the mouth. Should repeated miscarriages have occurred, as the consequence of constitutional syphilis, one or other, or both of the parents, if both are at fault, should be put upon a mercurial course; and thus the recurrence of this accident may be prevented.

The **Curative Treatment** as regards the child is extremely simple. It

should be nursed by its mother, if she has sufficient milk and is in good health. If this be impossible, it should be brought up by hand, and must not be given to a wet-nurse, lest it infect her. (See p. 1122.) The child must then be put under the influence of mercury, which in these cases produces the most unmistakeable effects: indeed, the ready manner in which all disease may be eradicated from the system of a syphilitic child by this mineral, is perhaps one of the strongest proofs that can be adduced of the specific character of its action on the venereal poison. The mercury may be given by the mouth in the form of small doses of grey powder; but, as it often purges the child when administered in this way, Brodie recommended its introduction into the system by inunction, which process I invariably employ, and have found it a most successful mode of treating the disease. The most convenient plan is, as recommended by Brodie, to spread a drachm of mercurial ointment on the under part of a flannel roller stitched round the thigh just above the knee, and to renew this every day after the child has been well washed in a hot bath. The treatment should be continued until all rash and snuffling have disappeared, when, the mercury having been discontinued, the cure may be perfected by the administration of small doses of iodide of potassium in milk or cod-liver oil. The skin must be kept in a healthy state by a hot bath every day. Occasionally the cutaneous manifestations of infantile syphilis are complicated with, and obscured by, some of the common diseases of the skin incident to early childhood; more particularly with pustular eczema of the head, face, and body. In these circumstances the diagnosis may not be easy, though the history of the case, the concomitant appearance of two forms of the disease, and the existence of snuffling and cachexy, tend to establish it. The eruption also, in these circumstances, is browner and more squamous than usual. In cases such as these, the best plan is to treat the syphilitic affection with the mercurial inunction, and then to prescribe a mild course of the *liq. arsenii et hydrargyri iodidi*, one to two minims for a dose, keeping the child at the same time on a good nourishing diet.

A LIST OF WORKS ON
MEDICINE, SURGERY
AND
GENERAL SCIENCE,
PUBLISHED BY
LONGMANS, GREEN & CO.,
LONDON, NEW YORK, AND BOMBAY.

Medical and Surgical Works.

ASHBY. NOTES ON PHYSIOLOGY FOR THE USE OF STUDENTS PREPARING FOR EXAMINATION. By HENRY ASHBY, M.D. Lond., F.R.C.P., Physician to the General Hospital for Sick Children, Manchester; formerly Demonstrator of Physiology, Liverpool School of Medicine. Sixth Edition, thoroughly revised. With 141 Illustrations. Fcap. 8vo, price 5s.

ASHBY AND WRIGHT. THE DISEASES OF CHILDREN, MEDICAL AND SURGICAL. By HENRY ASHBY, M.D. Lond., F.R.C.P., Physician to the General Hospital for Sick Children, Manchester; Lecturer and Examiner in Diseases of Children in the Victoria University; and G. A. WRIGHT, B.A., M.B. Oxon., F.R.C.S. Eng., Assistant Surgeon to the Manchester Royal Infirmary and Surgeon to the Children's Hospital; Examiner in Surgery in the University of Oxford. Enlarged and Improved Edition. With 192 Illustrations. 8vo, price 25s.

BENNETT.—*WORKS* by WILLIAM H. BENNETT, F.R.C.S., Surgeon to St. George's Hospital; Member of the Board of Examiners, Royal College of Surgeons of England.

CLINICAL LECTURES ON VARICOSE VEINS OF THE LOWER EXTREMITIES. With 3 Plates. 8vo. 6s.

ON VARICOCELE: A PRACTICAL TREATISE. With 4 Tables and a Diagram. 8vo. 5s.

CLINICAL LECTURES ON ABDOMINAL HERNIA: chiefly in relation to Treatment, including the Radical Cure. With 12 Diagrams in the Text. 8vo. 8s. 6d.

BENTLEY. A TEXT-BOOK OF ORGANIC MATERIA MEDICA.

Comprising a Description of the Vegetable and Animal Drugs of the British Pharmacopœia, with some others in common use. Arranged Systematically, and Especially Designed for Students. By ROBERT BENTLEY, M.R.C.S. Eng., F.L.S. With 62 Illustrations on Wood. Crown 8vo, price 7s. 6d.

COATS. A MANUAL OF PATHOLOGY. By JOSEPH COATS,

M.D., Professor of Pathology in the University of Glasgow. Third Edition. Revised throughout. With 507 Illustrations. 8vo, 31s. 6d.

COOKE.—WORKS by THOMAS COOKE, F.R.C.S. Eng., B.A., B.Sc., M.D. Paris, Senior Assistant Surgeon to the Westminster Hospital.

TABLETS OF ANATOMY. Being a Synopsis of Demonstrations given in the Westminster Hospital Medical School in the years 1871-75. Tenth Thousand, being a selection of the Tablets believed to be most useful to Students generally. Post 4to, price 10s. 6d.

APHORISMS IN APPLIED ANATOMY AND OPERATIVE SURGERY. Including 100 Typical *vivæ vocæ* Questions on Surface Marking, &c. Crown 8vo, 3s. 6d.

DISSECTION GUIDES. Aiming at Extending and Facilitating such Practical Work in Anatomy as will be specially useful in connection with an ordinary Hospital Curriculum. 8vo, 10s. 6d.

DICKINSON.—WORKS by W. HOWSHIP DICKINSON, M.D. Cantab., F.R.C.P., Physician to, and Lecturer on Medicine at, St. George's Hospital; Consulting Physician to the Hospital for Sick Children.

ON RENAL AND URINARY AFFECTIONS. Complete in Three Parts, 8vo, with 12 Plates and 122 Woodcuts. Price £3 4s. 6d. cloth.

. The Parts can also be had separately, each complete in itself, as follows :—

PART I.—*Diabetes*, price 10s. 6d. sewed, 12s. cloth.

„ II.—*Albuminuria*, price £1 sewed, £1 1s. cloth.

„ III.—*Miscellaneous Affections of the Kidneys and Urine*, price £1 10s. sewed, £1 11s. 6d. cloth.

THE TONGUE AS AN INDICATION OF DISEASE; being the Lumleian Lectures delivered at the Royal College of Physicians in March, 1888. 8vo, price 7s. 6d.

THE HARVEIAN ORATION ON HARVEY IN ANCIENT AND MODERN MEDICINE. Crown 8vo, 2s. 6d.

DUANE. THE STUDENT'S DICTIONARY OF MEDICINE AND THE ALLIED SCIENCES. Comprising the Pronunciation, Derivation, and Full Explanation of Medical Terms, together with much Collateral Descriptive Matter, numerous Tables, &c. By ALEXANDER DUANE, M.D., Assistant-Surgeon to the New York Ophthalmic and Aural Institute, Reviser of Medical Terms for "Webster's International Dictionary." 8vo, 21s.

ERICHSEN.—WORKS by Sir JOHN ERIC ERICHSEN, Bart., F.R.S., J.L.D. (Edin.), Hon. M. Ch. and F.R.C.S. (Ireland), Surgeon Extraordinary to H.M. the Queen; President of University College, London; Fellow and Ex-President of the Royal College of Surgeons of England; Emeritus Professor of Surgery in University College; Consulting-Surgeon to University College Hospital, and to many other Medical Charities.

THE SCIENCE AND ART OF SURGERY; A TREATISE ON SURGICAL INJURIES, DISEASES, AND OPERATIONS. Tenth Edition. Revised by the late MARCUS BECK, M.S. & M.B. (Lond.), F.R.C.S., Surgeon to University College Hospital, and Professor of Surgery in University College, London; and by RAYMOND JOHNSON, M.B. & B.S. (Lond.), F.R.C.S., Assistant Surgeon to University College Hospital, &c. Illustrated by nearly 1,000 Engravings on Wood. 2 Vols. royal 8vo, 48s.

FRANKLAND. MICRO-ORGANISMS IN WATER, THEIR SIGNIFICANCE, IDENTIFICATION, AND REMOVAL. Together with an Account of the Bacteriological Methods Involved in their Investigation. Specially Designed for the Use of those connected with the Sanitary Aspects of Water Supply. By Professor PERCY FRANKLAND, Ph.D., B.Sc. (Lond.), F.R.S., Fellow of the Chemical Society; and Mrs. PERCY FRANKLAND, Joint Author of "Studies on Some New Micro-Organisms Obtained from Air." With 2 Plates and numerous Diagrams. 8vo. 16s. net.

GAIRDNER AND COATS. ON THE DISEASES CLASSIFIED by the REGISTRAR-GENERAL as TABES MESENTERICA. LECTURES TO PRACTITIONERS. By W. T. GAIRDNER, M.D., LL.D. On the PATHOLOGY of PHTHISIS PULMONALIS. By JOSEPH COATS, M.D. With 28 Illustrations. 8vo, price 12s. 6d.

GARROD.—*WORKS* by Sir **ALFRED BARING GARROD, M.D., F.R.S., &c.; *Physician Extraordinary to H.M. the Queen; Consulting Physician to King's College Hospital; late Vice-President of the Royal College of Physicians.***

A TREATISE ON GOUT AND RHEUMATIC GOUT (RHEUMATOID ARTHRITIS). Third Edition, thoroughly revised and enlarged; with 6 Plates, comprising 21 Figures (14 Coloured), and 27 Illustrations engraved on Wood. 8vo, price 21s.

THE ESSENTIALS OF MATERIA MEDICA AND THERAPEUTICS. The Thirteenth Edition, revised and edited, under the supervision of the Author, by **NESTOR TIRARD, M.D. Lond., F.R.C.P.,** Professor of Materia Medica and Therapeutics in King's College, London, &c. Crown 8vo, price 12s. 6d.

GRAY. ANATOMY, DESCRIPTIVE AND SURGICAL. By **HENRY GRAY, F.R.S.,** late Lecturer on Anatomy at St. George's Hospital. The Thirteenth Edition, re-edited by **T. PICKERING PICK,** Surgeon to St. George's Hospital; Member of the Court of Examiners, Royal College of Surgeons of England. With 636 large Woodcut Illustrations, a large proportion of which are Coloured, the Arteries being coloured red, the Veins blue, and the Nerves yellow. The attachments of the muscles to the bones, in the section on Osteology, are also shown in coloured outline. Royal 8vo, price 36s.

HALLIBURTON.—*WORKS* by **W. D. HALLIBURTON, M.D., B.Sc., M.R.C.P.,** Professor of Physiology at King's College, London; Lecturer on Physiology at the London School of Medicine for Women; late Assistant Professor of Physiology at University College, London.

A TEXT-BOOK OF CHEMICAL PHYSIOLOGY AND PATHOLOGY. With 104 Illustrations. 8vo, 28s.

ESSENTIALS OF CHEMICAL PHYSIOLOGY. 8vo, 5s.

. This is a book suitable for medical students. It treats of the subject in the same way as Prof. SCHÄFER'S "Essentials" treats of Histology. It contains a number of elementary and advanced practical lessons, followed in each case by a brief descriptive account of the facts related to the exercises which are intended to be performed by each member of the class.

LANG.—**THE METHODICAL EXAMINATION OF THE EYE.** Being Part I. of a Guide to the Practice of Ophthalmology for Students and Practitioners. By **WILLIAM LANG, F.R.C.S. Eng.,** Surgeon to the Royal London Ophthalmic Hospital, Moorfields, &c. With 15 Illustrations. Crown 8vo, 3s. 6d.

LANGTON. ABDOMINAL HERNIA. By JOHN LANGTON, F.R.C.S., Surgeon to St. Bartholomew's Hospital, Senior Surgeon to the City of London Truss Society, Member of the Council and Court of Examiners of the Royal College of Surgeons of England. With numerous Illustrations. [*In the press.*]

LIVEING.—WORKS by ROBERT LIVEING, M.A. & M.D. Cantab., F.R.C.P. Lond., &c., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, &c.

HANDBOOK ON DISEASES OF THE SKIN. With especial reference to Diagnosis and Treatment. Fifth Edition, revised and enlarged. Fcap. 8vo, price 5s.

ELEPHANTIASIS GRÆCORUM, OR TRUE LEPROSY; Being the Goulstonian Lectures for 1873. Cr. 8vo, 4s. 6d.

LONGMORE.—WORKS by Surgeon-General Sir T. LONGMORE (Retired), C.B., F.R.C.S., late Professor of Military Surgery in the Army Medical School; Officer of the Legion of Honour.

THE ILLUSTRATED OPTICAL MANUAL; OR, HANDBOOK OF INSTRUCTIONS FOR THE GUIDANCE OF SURGEONS IN TESTING QUALITY AND RANGE OF VISION, AND IN DISTINGUISHING AND DEALING WITH OPTICAL DEFECTS IN GENERAL. Illustrated by 74 Drawings and Diagrams by Inspector-General Dr. MACDONALD, R.N., F.R.S., C.B. Fourth Edition. 8vo, price 14s.

GUNSHOT INJURIES. Their History, Characteristic Features, Complications, and General Treatment; with Statistics concerning them as they have been met with in Warfare. With 78 Illustrations. 8vo, price 31s. 6d.

LUFF. TEXT-BOOK OF FORENSIC MEDICINE AND TOXICOLOGY. By ARTHUR P. LUFF, M.D., B.Sc. (Lond.), Physician in Charge of Out-Patients and Lecturer on Medical Jurisprudence and Toxicology in St. Mary's Hospital; Examiner in Forensic Medicine in the University of London; External Examiner in Forensic Medicine in the Victoria University; Official Analyst to the Home Office. With numerous Illustrations. 2 vols., crown 8vo, 24s.

MUNK. THE LIFE OF SIR HENRY HALFORD, Bart., G.C.H., M.D., F.R.S., President of the Royal College of Physicians, Physician to George III., George IV., William IV., and to Her Majesty Queen Victoria. By William MUNK, M.D., F.S.A., Fellow and late Vice-President of the Royal College of Physicians of London. With 2 Portraits. 8vo, 12s. 6d.

NEWMAN. ON THE DISEASES OF THE KIDNEY AMENABLE TO SURGICAL TREATMENT. Lectures to Practitioners. By DAVID NEWMAN, M.D., Surgeon to the Western Infirmary Out-Door Department; Pathologist and Lecturer on Pathology at the Glasgow Royal Infirmary; Examiner in Pathology in the University of Glasgow; Vice-President Glasgow Pathological and Clinical Society. 8vo, price 16s.

OWEN. A MANUAL OF ANATOMY FOR SENIOR STUDENTS. By EDMUND OWEN, M.B., F.R.S.C., Senior Surgeon to the Hospital for Sick Children, Great Ormond Street, Surgeon to St. Mary's Hospital, London, and co-Lecturer on Surgery, late Lecturer on Anatomy in its Medical School. With 210 Illustrations. Crown 8vo, price 12s. 6d.

POOLE. COOKERY FOR THE DIABETIC. By W. H. and Mrs. POOLE. With Preface by Dr. PAVY. Fcap. 8vo. 2s. 6d.

POORE. ESSAYS ON RURAL HYGIENE. By GEORGE VIVIAN POORE, M.D., F.R.C.P. Crown 8vo, 6s. 6d.

QUAIN. A DICTIONARY OF MEDICINE; Including General Pathology, General Therapeutics, Hygiene, and the Diseases of Women and Children. By Various Writers. Edited by RICHARD QUAIN, Bart., M.D.Lond., LL.D.Edin. (Hon.) F.R.S., Physician Extraordinary to H.M. the Queen, President of the General Medical Council, Member of the Senate of the University of London, &c. Assisted by FREDERICK THOMAS ROBERTS, M.D.Lond., B.Sc., Fellow of the Royal College of Physicians, Fellow of University College, Professor of Materia Medica and Therapeutics, University College, &c.; and J. MITCHELL BRUCE, M.A.Abdn., M.D.Lond., Fellow of the Royal College of Physicians of London, Physician and Lecturer on the Principles and Practice of Medicine, Charing Cross Hospital, &c. New Edition, Revised throughout and Enlarged. In 2 Vols. medium 8vo. cloth, red edges, price 40s. net.

QUAIN. QUAIN'S (JONES) ELEMENTS OF ANATOMY.

The Tenth Edition. Edited by EDWARD ALBERT SCHÄFER, F.R.S., Professor of Physiology and Histology in University College, London; and GEORGE DANCER THANE, Professor of Anatomy in University College, London. In 3 Vols.

VOL. I., PART I. EMBRYOLOGY. By Professor SCHÄFER. Illustrated by 200 Engravings, many of which are coloured. Royal 8vo, 9s. [Ready.]

VOL. I., PART II. GENERAL ANATOMY OR HISTOLOGY. By Professor SCHÄFER. Illustrated by 491 Engravings, many of which are coloured. Royal 8vo, 12s. 6d. [Ready.]

VOL. II., PART I. OSTEOLOGY. By Professor THANE. Illustrated by 168 Engravings. Royal 8vo, 9s. [Ready.]

VOL. II., PART II. ARTHROLOGY, MYOLOGY, ANGIOLOGY. By Professor THANE. Illustrated by 255 Engravings, many of which are Coloured. Royal 8vo, 18s. [Ready.]

VOL. III., PART I. THE SPINAL CORD AND BRAIN. By Professor SCHÄFER. Illustrated by 139 Engravings. Royal 8vo, 12s. 6d. [Ready.]

VOL. III., PART II. THE NERVES. By Professor THANE. Illustrated by 102 Engravings, many of which are Coloured. Royal 8vo, 9s. [Ready.]

VOL. III., PART III. THE ORGANS OF THE SENSES. By Professor SCHÄFER. Illustrated by 178 Engravings. Royal 8vo, 9s. [Ready.]

VOL. III., PART IV. SPLANCHNOLOGY. By Professor SCHÄFER and Professor JOHNSON SYMINGTON, M.D. With 337 Illustrations.

SUPERFICIAL AND SURGICAL ANATOMY.

By Professor THANE and Professor RICKMAN J. GODLEE, M.S.

(To be shortly published as an Appendix to the whole work.)

RICHARDSON. THE ASCLEPIAD. A Book of Original Research in the Science, Art, and Literature of Medicine. By BENJAMIN WARD RICHARDSON, M.D., F.R.S. Published Quarterly, price 2s. 6d. Volumes for 1884, 1885, 1886, 1887, 1888, 1889, 1890, 1891, 1892, & 1893. 8vo, price 12s. 6d. each.

SCHÄFER. THE ESSENTIALS OF HISTOLOGY: Descriptive and Practical. For the Use of Students. By E. A. SCHÄFER, F.R.S., Jodrell Professor of Physiology in University College, London; Editor of the Histological Portion of Quain's "Anatomy." Illustrated by more than 300 Figures, many of which are new. Third Edition, Revised and Enlarged. 8vo, 7s. 6d. (Interleaved, 10s.)

SCHENK. MANUAL OF BACTERIOLOGY. For Practitioners and Students. With especial reference to Practical Methods. By Dr. S. L. SCHENK, Professor (Extraordinary) in the University of Vienna. Translated from the German, with an Appendix, by W. R. DAWSON, B.A., M.D., Univ. Dub.; late University Travelling Prizeman in Medicine. With 100 Illustrations, some of which are coloured. 8vo, 10s. net.

SMALE AND COLYER. DISEASES AND INJURIES OF THE TEETH, including Pathology and Treatment: a Manual of Practical Dentistry for Students and Practitioners. By MORTON SMALE, M.R.C.S., L.S.A., L.D.S., Dental Surgeon to St. Mary's Hospital, Dean of the School, Dental Hospital of London, &c.; and J. F. COLYER, L.R.C.P., M.R.C.S., L.D.S., Assistant Dental Surgeon to Charing Cross Hospital, and Assistant Dental Surgeon to the Dental Hospital of London. With 334 Illustrations. Large Crown 8vo, 15s.

SMITH (H. F.). THE HANDBOOK FOR MIDWIVES. By HENRY FLY SMITH, B.A., M.B. Oxon., M.R.C.S. Second Edition. With 41 Woodcuts. Crown 8vo, price 5s.

STEEL.—WORKS by JOHN HENRY STEEL, F.R.C.V.S., F.Z.S., A.V.D., late Professor of Veterinary Science and Principal of Bombay Veterinary College.

A TREATISE ON THE DISEASES OF THE DOG; being a Manual of Canine Pathology. Especially adapted for the use of Veterinary Practitioners and Students. 88 Illustrations. 8vo, 10s. 6d.

A TREATISE ON THE DISEASES OF THE OX; being a Manual of Bovine Pathology. Especially adapted for the use of Veterinary Practitioners and Students. 2 Plates and 117 Woodcuts. 8vo, 15s.

A TREATISE ON THE DISEASES OF THE SHEEP; being a Manual of Ovine Pathology for the use of Veterinary Practitioners and Students. With Coloured Plate, and 99 Woodcuts. 8vo, 12s.

OUTLINES OF EQUINE ANATOMY; a Manual for the use of Veterinary Students in the Dissecting Room. Crown 8vo, 7s. 6d.

"STONEHENGE." THE DOG IN HEALTH AND DISEASE. By "STONEHENGE." With 84 Wood Engravings. Square crown 8vo, 7s. 6d.

THORNTON. HUMAN PHYSIOLOGY. By JOHN THORNTON, M.A., Author of "Elementary Physiography," "Advanced Physiography," &c. With 267 Illustrations, some of which are Coloured. Crown 8vo, 6s.

WALLER. AN INTRODUCTION TO HUMAN PHYSIOLOGY. By AUGUSTUS D. WALLER, M.D., Lecturer on Physiology at St. Mary's Hospital Medical School, London; late External Examiner at the Victorian University. Second Edition, Revised. With 305 Illustrations. 8vo, 18s.

WEICHSELBAUM. THE ELEMENTS OF PATHOLOGICAL HISTOLOGY, With Special Reference to Practical Methods. By Dr. ANTON WEICHSELBAUM, Professor of Pathology in the University of Vienna. Translated by W. R. DAWSON, M.D. (Dub.), Demonstrator of Pathology in the Royal College of Surgeons, Ireland, late Medical Travelling Prizeman of Dublin University, &c. With 221 Figures, partly in Colours, a Chromo-lithographic Plate, and 7 Photographic Plates. Royal 8vo, 21s. net.

WILKS AND MOXON. LECTURES ON PATHOLOGICAL ANATOMY. By SAMUEL WILKS, M.D., F.R.S., Consulting Physician to, and formerly Lecturer on Medicine and Pathology at, Guy's Hospital, and the late WALTER MOXON, M.D., F.R.C.P., Physician to, and some time Lecturer on Pathology at, Guy's Hospital. Third Edition, thoroughly Revised. By SAMUEL WILKS, M.D., LL.D., F.R.S. 8vo, 18s.

YOUATT.—WORKS by WILLIAM YOUATT.

THE HORSE. Revised and Enlarged by W. WATSON, M.R.C.V.S. With 52 Woodcuts. 8vo, 7s. 6d.

THE DOG. Revised and Enlarged. With 33 Woodcuts. 8vo, 6s.

General Scientific Works.

BENNETT AND MURRAY. A HANDBOOK OF CRYPTOGAMIC BOTANY. By A. W. BENNETT, M.A., B.Sc., F.L.S., and GEORGE R. MILNE MURRAY, F.L.S. With 378 Illustrations. 8vo, 16s.

CARNEGIE. LAW AND THEORY IN CHEMISTRY: A COMPANION BOOK FOR STUDENTS. By DOUGLAS CARNEGIE, sometime Scholar and Demonstrator in Chemistry of Gonville and Caius, Cambridge. Crown 8vo, 6s.

CLERKE. THE SYSTEM OF THE STARS. By AGNES M. CLERKE, Author of "A History of Astronomy during the Nineteenth Century." With 6 Plates and Numerous Illustrations. 8vo, 21s.

CLODD.—WORKS by EDWARD CLODD, Author of "*The Childhood of the World*," &c.

THE STORY OF CREATION. A Plain Account of Evolution. With 77 Illustrations. Crown 8vo, 3s. 6d.

A PRIMER OF EVOLUTION: being a Popular Abridged Edition of "The Story of Creation." With Illustrations. Fcp. 8vo, 1s. 6d.

CROOKES. SELECT METHODS IN CHEMICAL ANALYSIS (chiefly Inorganic). By W. CROOKES, F.R.S., V.P.C.S., Editor of "The Chemical News." Third Edition, re-written and enlarged. Illustrated with 67 Woodcuts. 8vo, 21s. net.

CULLEY. A HANDBOOK OF PRACTICAL TELEGRAPHY. By R. S. CULLEY, M.I.C.E., late Engineer-in-Chief of Telegraphs to the Post Office. With 135 Woodcuts and 17 Plates, 8vo, 16s.

GANOT. ELEMENTARY TREATISE ON PHYSICS; Experimental and Applied, for the use of Colleges and Schools. Translated and edited from GANOT's *Éléments de Physique* (with the Author's sanction) by E. ATKINSON, Ph.D., F.C.S., formerly Professor of Experimental Science, Staff College, Sandhurst. Fourteenth Edition, revised and enlarged, with 9 Coloured Plates and 1,028 Woodcuts. Large crown 8vo, 15s.

NATURAL PHILOSOPHY FOR GENERAL READERS AND YOUNG PERSONS; Being a Course of Physics divested of Mathematical Formulæ, and expressed in the language of daily life. Translated from GANOT's *Cours de Physique* (with the Author's sanction) by E. ATKINSON, Ph.D., F.C.S. Seventh Edition, carefully revised; with 37 pages of New Matter, 7 Plates, 569 Woodcuts, and an Appendix of Questions. Crown 8vo, 7s. 6d.

GOODEVE.—*WORKS* by **T. M. GOODEVE, M.A., Barrister-at-Law; Professor of Mechanics at the Normal School of Science and the Royal School of Mines.**

PRINCIPLES OF MECHANICS. New Edition, re-written and enlarged. With 253 Woodcuts and numerous Examples. Crown 8vo, 6s.

THE ELEMENTS OF MECHANISM. New Edition, re-written and enlarged. With 342 Woodcuts. Crown 8vo, 6s.

A MANUAL OF MECHANICS: an Elementary Text-Book for Students of Applied Mechanics. With 138 Illustrations and Diagrams, and 141 Examples taken from the Science Department Examination Papers, with Answers. Fcp. 8vo, 2s. 6d.

HELMHOLTZ.—*WORKS* by **HERMANN L. F. HELMHOLTZ, M.D., Professor of Physics in the University of Berlin.**

ON THE SENSATIONS OF TONE AS A PHYSIOLOGICAL BASIS FOR THE THEORY OF MUSIC. Second English Edition; with numerous additional Notes, and a new Additional Appendix, bringing down information to 1885, and specially adapted to the use of Musical Students. By **ALEXANDER J. ELLIS, B.A., F.R.S., F.S.A., &c.,** formerly Scholar of Trinity College, Cambridge. With 68 Figures engraved on Wood, and 42 Passages in Musical Notes. Royal 8vo, 28s.

POPULAR LECTURES ON SCIENTIFIC SUBJECTS. With 68 Woodcuts. 2 Vols. crown 8vo, 3s. 6d. each.

HERSCHEL. **OUTLINES OF ASTRONOMY.** By **Sir JOHN F. W. HERSCHEL, Bart., K.H., &c.,** Member of the Institute of France. Twelfth Edition, with 9 Plates, and numerous Diagrams. 8vo, 12s.

HUDSON AND GOSSE. **THE ROTIFERA OR 'WHEEL ANIMALCULES.'** By **C. T. HUDSON, LL.D.,** and **P. H. GOSSE, F.R.S.** With 30 Coloured and 4 Uncoloured Plates. In 6 Parts. 4to, price 10s. 6d. each; Supplement, 12s. 6d. Complete in Two Volumes, with Supplement, 4to, £4 4s.

. The Plates in the Supplement contain figures of almost all the Foreign Species, as well as of the British Species, that have been discovered since the original publication of Vols. I. and II.

KOLBE. **A SHORT TEXT-BOOK OF INORGANIC CHEMISTRY.** By **Dr. HERMANN KOLBE,** late Professor of Chemistry in the University of Leipzig. Translated and Edited by **T. S. HUMPIDGE, Ph.D., B.Sc. (Lond.),** late Professor of Chemistry and Physics in the University College of Wales, Aberystwyth. New Edition. Revised by **H. LLOYD-SMITH, Ph.D., D.Sc. (Lond.),** Professor of Chemistry in the University College of Wales, Aberystwyth. With a Coloured Table of Spectra and 66 Woodcuts. Crown 8vo, 8s. 6d.

LADD.—*WORKS* by **GEORGE T. LADD**, *Professor of Philosophy in Yale University.*

ELEMENTS OF PHYSIOLOGICAL PSYCHOLOGY: A TREATISE OF THE ACTIVITIES AND NATURE OF THE MIND FROM THE PHYSICAL AND EXPERIMENTAL POINT OF VIEW. With 113 Illustrations. 8vo, price 21s.

PSYCHOLOGY, DESCRIPTIVE AND EXPLANATORY: A Treatise of the Phenomena, Laws, and Development of Human Mental Life. 8vo. 21s.

OUTLINES OF PHYSIOLOGICAL PSYCHOLOGY. With numerous Illustrations. 8vo. 12s.

PHILOSOPHY OF MIND: an Essay on the Metaphysics of Psychology. 8vo, 16s.

LARDEN. **ELECTRICITY FOR PUBLIC SCHOOLS AND COLLEGES.** With numerous Questions and Examples with Answers, and 214 Illustrations and Diagrams. By **W. LARDEN, M.A.** Crown 8vo, 6s.

LINDLEY AND MOORE. **THE TREASURY OF BOTANY, OR POPULAR DICTIONARY OF THE VEGETABLE KINGDOM:** with which is incorporated a Glossary of Botanical Terms Edited by **J. LINDLEY, M.D., F.R.S.,** and **T. MOORE, F.L.S.** With 20 Steel Plates, and numerous Woodcuts. 2 Parts, fcp. 8vo, price 12s.

MARTIN. **NAVIGATION AND NAUTICAL ASTRONOMY.** Compiled by Staff-Commander **W. R. MARTIN, R.N.,** Instructor in Surveying, Navigation, and Compass Adjustment; Lecturer on Meteorology at the Royal Naval College, Greenwich. Sanctioned for use in the Royal Navy by the Lords Commissioners of the Admiralty. Royal 8vo, 18s.

MENDELÉEFF. **THE PRINCIPLES OF CHEMISTRY.** By **D. MENDELÉEFF,** Professor of Chemistry in the University of St. Petersburg. Translated by **GEORGE KAMENSKY, A.R.S.M.** of the Imperial Mint, St. Petersburg, and Edited by **A. J. GREENAWAY, F.I.C.,** Sub-Editor of the Journal of the Chemical Society. With 97 Illustrations. 2 Vols. 8vo, 36s.

MEYER. **OUTLINES OF THEORETICAL CHEMISTRY.** By **LOTHAR MEYER,** Professor of Chemistry in the University of Tübingen. Translated by Professors **P. PHILLIPS BEDSON, D.Sc.,** and **W. CARLETON WILLIAMS, B.Sc.** 8vo, 9s.

MITCHELL. MANUAL OF PRACTICAL ASSAYING. By JOHN MITCHELL, F.C.S. Sixth Edition. Edited by W. CROOKES, F.R.S. With 201 Woodcuts. 8vo, 31s. 6d.

MORGAN. ANIMAL BIOLOGY. An Elementary Text Book. By C. LLOYD MORGAN, Principal of University College, Bristol. With numerous Illustrations. Crown 8vo, 8s. 6d.

MUIR. THE ALCHEMICAL ESSENCE AND THE CHEMICAL ELEMENT : an Episode in the Quest of the Unchanging. By M. M. PATTISON MUIR, Fellow of Gonville and Caius College, Cambridge. 8vo. 4s. 6d.

ODLING. A COURSE OF PRACTICAL CHEMISTRY, Arranged for the use of Medical Students, with express reference to the Three Months' Summer Practice. By WILLIAM ODLING, M.A., F.R.S. With 71 Woodcuts. Crown 8vo, 6s.

OSTWALD. SOLUTIONS. By W. OSTWALD, Professor of Chemistry in the University of Leipzig. Being the Fourth Book, with some additions, of the Second Edition of Ostwald's "Lehrbuch der Allgemeinen Chemie." Translated by M. M. PATTISON MUIR, Professor of Gonville and Caius College, Cambridge. 8vo, 10s. 6d.

PAYEN. INDUSTRIAL CHEMISTRY ; A Manual for use in Technical Colleges or Schools, also for Manufacturers and others, based on a Translation of Stohmann and Engler's German Edition of PAYEN's *Précis de Chimie Industrielle*. Edited and supplemented with Chapters on the Chemistry of the Metals, &c., by B. H. PAUL, Ph.D. With 698 Woodcuts. 8vo, 42s.

REYNOLDS. EXPERIMENTAL CHEMISTRY for Junior Students. By J. EMERSON REYNOLDS, M.D., F.R.S., Professor of Chemistry, Univ. of Dublin. Fcp. 8vo, with numerous Woodcuts.

PART I.—*Introductory*, 1s. 6d.

PART III.—*Metals and Allied Bodies*, 3s. 6d.

PART II.—*Non-Metals*, 2s. 6d.

PART IV.—*Chemistry of Carbon Compounds*, 4s.

PROCTOR.—WORKS by RICHARD A. PROCTOR.

OLD AND NEW ASTRONOMY. By RICHARD A. PROCTOR and A. COWPER RANYARD. With 31 Plates and 472 Illustrations. Text. 4to, 21s.

LIGHT SCIENCE FOR LEISURE HOURS; Familiar Essays on Scientific Subjects, Natural Phenomena, &c. 3 Vols. crown 8vo, 5s. each.

THE ORBS AROUND US; a Series of Essays on the Moon and Planets, Meteors, and Comets. With Chart and Diagrams, crown 8vo, 5s. Cheap Edition, crown 8vo, 3s. 6d.

OTHER WORLDS THAN OURS; The Plurality of Worlds Studied under the Light of Recent Scientific Researches. With 14 Illustrations, crown 8vo, 5s. Cheap Edition, crown 8vo, 3s. 6d.

THE MOON; her Motions, Aspects, Scenery, and Physical Condition. With Plates, Charts, Woodcuts, and Lunar Photographs, crown 8vo, 5s.

UNIVERSE OF STARS; Presenting Researches into and New Views respecting the Constitution of the Heavens. With 22 Charts and 22 Diagrams, 8vo. 10s. 6d.

LARGER STAR ATLAS for the Library, in 12 Circular Maps, with Introduction and 2 Index Pages. Folio, 15s., or Maps only, 12s. 6d.

NEW STAR ATLAS for the Library, the School, and the Observatory, in 12 Circular Maps (with 2 Index Plates). Crown 8vo, 5s.

THE STUDENT'S ATLAS. In 12 Circular Maps on a Uniform Projection and 1 Scale, with 2 Index Maps. Intended as a *vade-mecum* for the Student of History, Travel, Geography, Geology, and Political Economy. With a letter-press Introduction illustrated by several cuts. 5s.

ELEMENTARY PHYSICAL GEOGRAPHY. With 33 Maps and Woodcuts. Fcp. 8vo, 1s. 6d.

LESSONS IN ELEMENTARY ASTRONOMY; with Hints for Young Telescopists. With 47 Woodcuts. Fcp. 8vo, 1s. 6d.

EASY LESSONS IN THE DIFFERENTIAL CALCULUS: indicating from the Outset the Utility of the Processes called Differentiation and Integration. Fcp. 8vo, 2s. 6d.

THE STARS IN THEIR SEASONS. An Easy Guide to a Knowledge of the Star Groups, in 12 Large Maps. Imperial 8vo, 5s.

STAR PRIMER. Showing the Starry Sky Week by Week, in 24 Hourly Maps. Crown 4to, 2s. 6d.

ROUGH WAYS MADE SMOOTH. Familiar Essays on Scientific Subjects. Crown, 3s. 6d.

HOW TO PLAY WHIST: WITH THE LAWS AND ETIQUETTE OF WHIST. Crown 8vo, 3s. 6d.

HOME WHIST: an Easy Guide to Correct Play. 16mo, 1s.

OUR PLACE AMONG INFINITIES. A Series of Essays contrasting our Little Abode in Space and Time with the Infinities around us. Crown 8vo, 5s.

STRENGTH AND HAPPINESS. Crown 8vo, 5s.

STRENGTH: How to get Strong and keep Strong, with Chapters on Rowing and Swimming, Fat, Age, and the Waist. With 9 illustrations. Crown 8vo, 2s.

[Continued.]

PROCTOR.—WORKS by **RICHARD A. PROCTOR**—*continued.***THE EXPANSE OF HEAVEN.**

Essays on the Wonders of the Firmament. Crown 8vo, 5s.
Cheap Edition, crown 8vo, 3s. 6d.

THE GREAT PYRAMID, OBSERVATORY, TOMB, AND TEMPLE. With Illustrations. Crown 8vo, 5s.**PLEASANT WAYS IN SCIENCE.** Crown 8vo, 5s.
Cheap Edition, crown 8vo, 3s. 6d.**MYTHS AND MARVELS OF ASTRONOMY.** Crown 8vo, 5s.
Cheap Edition, crown 8vo, 3s. 6d.

CHANCE AND LUCK ; a Discussion of the Laws of Luck, Coincidences, Wagers, Lotteries, and the Fallacies of Gambling, &c. Crown 8vo, 2s. boards, 2s. 6d. cloth.

NATURE STUDIES. By GRANT ALLEN, A. WILSON, T. FOSTER, E. CLODD, and R. A. PROCTOR. Crown 8vo, 5s.
Cheap Edition, crown 8vo, 3s. 6d.

LEISURE READINGS. By E. CLODD, A. WILSON, T. FOSTER, A. C. RUNYARD, and R. A. PROCTOR. Crown 8vo, 5s.

SLINGO AND BROOKER. ELECTRICAL ENGINEERING FOR ELECTRIC-LIGHT ARTISANS AND STUDENTS.

(Embracing those branches prescribed in the Syllabus issued by the City and Guilds Technical Institute.) By W. SLINGO and A. BROOKER. With 346 Illustrations. Crown 8vo, 12s.

SMITH. GRAPHICS; OR, THE ART OF CALCULATION BY DRAWING LINES, applied to Mathematics, Theoretical Mechanics and Engineering, including the Kinetics and Dynamics of Machinery, and the Statics of Machines, Bridges, Roofs, and other Engineering Structures. By ROBERT H. SMITH, Professor of Civil and Mechanical Engineering, Mason Science College, Birmingham.

PART I. Text, with separate Atlas of Plates—Arithmetic, Algebra, Trigonometry, Vector, and Locor Addition, Machine Kinematics, and Statics of Flat and Solid Structures. 8vo, 15s.

SORAUER. A POPULAR TREATISE ON THE PHYSIOLOGY

OF PLANTS. For the Use of Gardeners, or for Students of Horticulture and of Agriculture. By Dr. PAUL SORAUER, Director of the Experimental Station at the Royal Pomological Institute in Proskau (Silesia). Translated by F. E. WEISS, B.Sc., F.L.S., Professor of Botany at the Owens College, Manchester. With 33 Illustrations. 8vo, 9s. net.

THORPE. A DICTIONARY OF APPLIED CHEMISTRY.

By T. E. THORPE, B.Sc. (Vict.), Ph.D., F.R.S., Treas. C.S., Professor of Chemistry in the Royal College of Science, London. Assisted by Eminent Contributors. To be published in 3 vols. 8vo. Vols. I. and II. £2 2s. each, Vol. III. £3 3s.

TYNDALL.—*WORKS by JOHN TYNDALL, F.R.S., &c.*

FRAGMENTS OF SCIENCE. 2 Vols. Crown 8vo, 16s.

NEW FRAGMENTS. Crown 8vo, 10s. 6d.

HEAT A MODE OF MOTION. Crown 8vo, 12s.

SOUND. With 204 Woodcuts. Crown 8vo, 10s. 6d.

RESEARCHES ON DIAMAGNETISM AND MAGNE-CRYSTALLIC ACTION, including the question of Diamagnetic Polarity. Crown 8vo, 12s.

ESSAYS ON THE FLOATING-MATTER OF THE AIR in relation to Putrefaction and Infection. With 24 Woodcuts. Crown 8vo, 7s. 6d.

LECTURES ON LIGHT, delivered in America in 1872 and 1873. With 57 Diagrams. Crown 8vo, 5s.

LESSONS IN ELECTRICITY AT THE ROYAL INSTITUTION, 1875-76. With 58 Woodcuts. Crown 8vo, 2s. 6d.

NOTES OF A COURSE OF SEVEN LECTURES ON ELECTRICAL PHENOMENA AND THEORIES, delivered at the Royal Institution. Crown 8vo, 1s. 6d.

NOTES OF A COURSE OF NINE LECTURES ON LIGHT, delivered at the Royal Institution. Crown 8vo, 1s. 6d.

FARADAY AS A DISCOVERER. Crown 8vo, 3s. 6d.

WATTS' DICTIONARY OF CHEMISTRY. Revised and entirely

Re-written by H. FORSTER MORLEY, M.A., D.Sc., Fellow of, and lately Assistant-Professor of Chemistry in, University College, London; and M. M. PATTISON MUIR, M.A., F.R.S.E., Fellow, and Prælector in Chemistry, of Gonville and Caius College, Cambridge. Assisted by Eminent Contributors. To be Published in 4 Vols. 8vo. Vols. I. II. 42s. each. Vol. III. 50s. Vol. IV. 63s.

WEBB. CELESTIAL OBJECTS FOR COMMON TELESCOPES.

By the Rev. T. W. WEBB, M.A., F.R.A.S., Vicar of Hardwick, Herefordshire. Fifth Edition, Revised and greatly Enlarged by the Rev. T. E. ESPIN, M.A., F.R.A.S. (Two Volumes.)

VOL. I. With Portrait and a Reminiscence of the Author, 2 Plates, and numerous Illustrations. Crown 8vo, 6s.

VOL. II. With Illustrations and Map of Star Spectra. Crown 8vo, 6s. 6d.

WRIGHT. OPTICAL PROJECTION: A Treatise on the Use of the Lantern in Exhibition and Scientific Demonstration. By LEWIS WRIGHT, Author of "Light: a Course of Experimental Optics." With 232 Illustrations. Crown 8vo, 6s.

M31 Erichsen, Sir J.E.
